Measurements of the case depths of carbonitrided parts may refer to effective case depth or total case depth, as with reporting case depths for carburized parts. For very thin cases, usually only the total case depth is specified. In general, it is easy to distinguish case and core microstructures in a carbonitrided piece, particularly when the case is thin and is produced at a low carbonitriding temperature; more difficulty is encountered in distinguishing case and core when high temperatures, deep cases, and medium-carbon or high-carbon steels are involved. Whether or not the core has a martensitic structure is also a contributing factor in case-depth measurements.

Effect of Time and Temperature. Based on a survey of industrial practice, Fig. 4 shows case depths for different combinations of total furnace treating time and temperature. (Note that all values given for case depth are for effective case depth unless otherwise stated.)

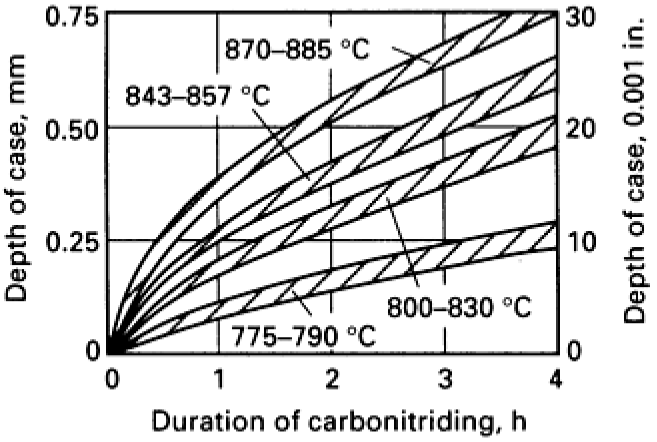

Fig. 4 Results of a survey of industrial practice regarding effects of time and temperature on effective case depth of carbonitrided cases

Figure 5(a) shows the effects of total furnace time on case depth for 1020 steel. Specimens were heated to 705, 760, 815, and 870 °C (1300, 1400, 1500, and 1600 °F) for periods of 15, 30, and 45 min. Figure 5(b) indicates the total case depths that can be obtained on a 1112 steel held for 15 min at various temperatures between about 750 and 900 °C (1380 and 1650 °F) All data in Fig. 5 were obtained in a single plant.

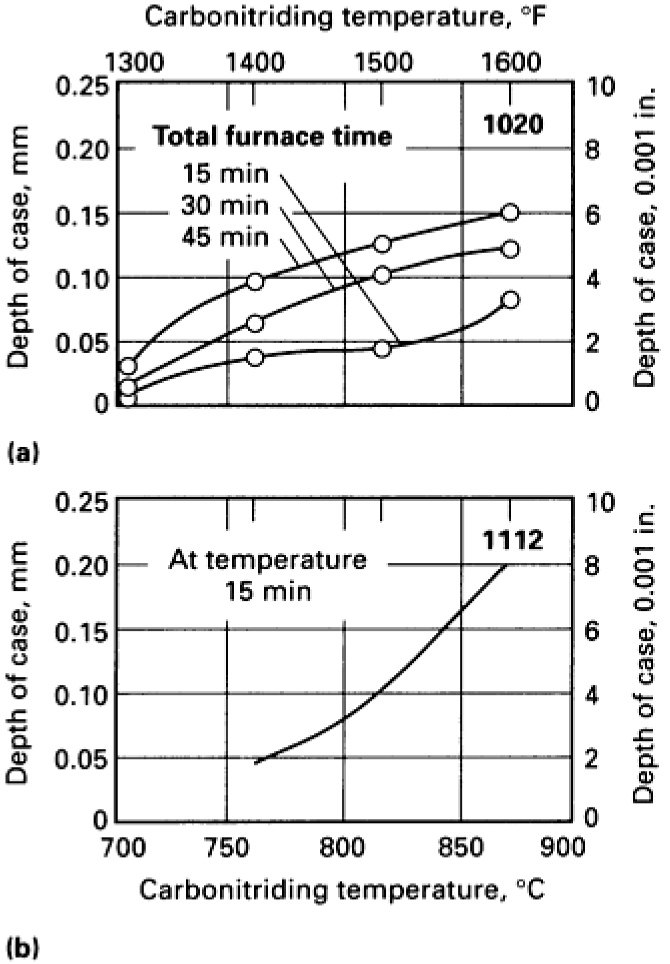

Fig. 5 Effects of temperature and of duration of carbonitriding on effective case depth. Both sets of data were obtained in the same plant. Note that upper graph (for 1020 steel) is in terms of total furnace time, whereas bottom graph (for 1112 steel) is for 15 min at temperature.

Case-depth uniformity in carbonitriding depends on temperature uniformity within the furnace chamber, adequate circulation and replenishment of atmosphere, and distribution of the furnace charge so that it is uniformly exposed to the atmosphere.

Accurate control of treatment time is also a factor in controlling case-depth uniformity. All parts in a load should be at a uniform temperature prior to exposure to the carbonitriding atmosphere in order to achieve uniform results when the processing times are short.

Example 2: Variations in Case Depth of Carbonitrided 1010 Steel.

Case-depth variations typical of carbonitriding at 775 to 800 °C (1425 to 1475 °F) are shown in Fig. 6. The data were obtained on two parts that were carbonitrided along with large production lots. One of these parts, a rack made of 1010 steel, was carbonitrided at 790 to 800 °C (1450 to 1475 °F) in a horizontal batch furnace equipped with an enclosed quench tank. Acceptable limits of case depth for these racks were 0.05 to 0.13 mm (0.002 to 0.005 in.).

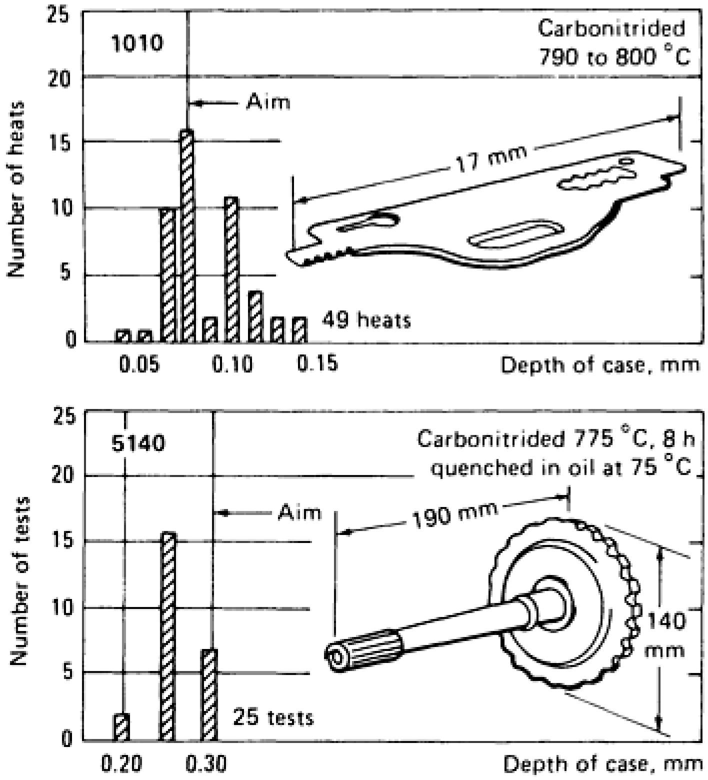

Fig. 6 Distribution of effective case depth of 1010 steel racks and 5140 steel pinion shafts

The other part, a pinion shaft of 5140 steel, was carbonitrided at 775 °C (1425 °F) for 8 h and then quenched in oil at about 75 °C (170 °F) Attainment of acceptable case depth of 0.2 to 0.3 mm (0.008 to 0.012 in.) was 100% in 25 tests.

Although the data in this example and Fig. 6 may be considered typical, they do not fully reflect the high degree of uniformity of case depth that can be achieved. For example, one plant reports total case-depth uniformity of ±0.025 mm (±0.001 in.) within a load and between loads in more than 25,000 cycles for case depths as low as 0.125 mm (0.005 in.) on small parts carbonitrided in large batch furnaces. Time, temperature, and processing variables were automatically controlled. The parts were also preheated to a uniform temperature in a neutral atmosphere prior to starting the carbonitriding process.

Hardenability of Case

One major advantage of carbonitriding is that the nitrogen absorbed during processing lowers the critical cooling rate of the steel. That is, the hardenability of the case is significantly greater when nitrogen is added by carbonitriding than when the same steel is only carburized (Fig. 7). This permits the use of steels on which uniform case hardness ordinarily could not be obtained if they were only carburized and quenched. Where core properties are not important, carbonitriding permits the use of low-carbon steels, which cost less and may have better machinability or formability.

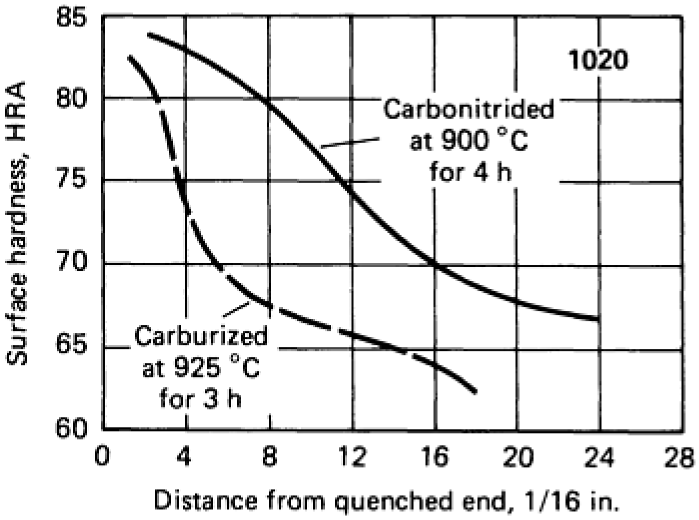

Fig. 7 End-quench hardenability curve for 1020 steel carbonitrided at 900 °C (1650 °F) compared with curve for the same steel carburized at 925 °C (1700 °F). Hardness was measured along the surface of the as-quenched hardenability specimen. Ammonia and methane contents of the inlet carbonitriding atmosphere were 5%; balance, carrier gas. Source: Ref 5

Because of the hardenability effect of nitrogen, carbonitriding makes it possible to oil quench steels such as 1010, 1020, and 1113 to obtain martensitic case structures. Because of lower processing temperatures and/or the use of less severe quenches, carbonitriding may produce less part distortion and better control of dimensions than carburizing, and thus may eliminate the need for straightening or final grinding operations.

Hardness Gradients

Hardness at various levels in the case depends on the microstructure. Hardness gradients associated with the microstructures of 1117 steel are presented in Fig. 8. When the carbonitriding atmosphere was relatively high in ammonia (11% NH_3), the nitrogen content of the case was high, and enough austenite was retained after quenching to lower the hardness to 48 HRC, 500 g (1.1 lbf) load, at a depth of 0.025 mm (0.001 in.) below the surface. The amount of retained austenite was decreased, and hardness consequently was increased, either by lowering the ammonia flow rate from 0.57 to 0.14 m^3/h (20 to 5 ft^3/h), which reduced the ammonia content of the furnace atmosphere from 11 to 3%, or by introducing a 15-min diffusion period at the end of the carbonitriding operation. Either treatment increased the hardness to meet or exceed a specified minimum value of 55 HRC, 500 g (1.1 lbf) load at 0.025 mm below the surface.

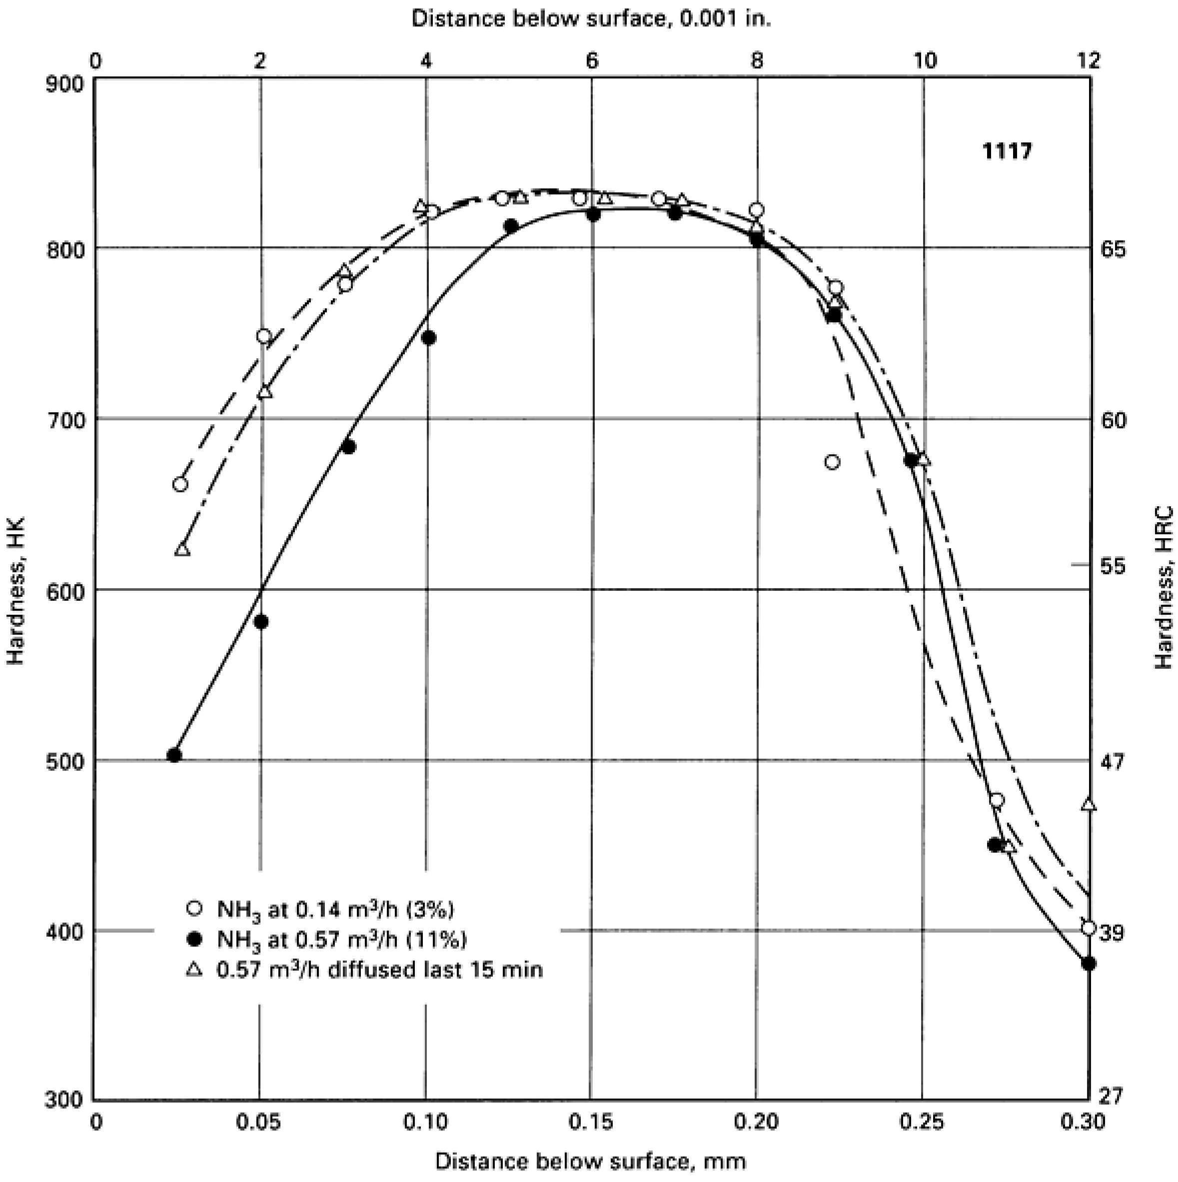

Fig. 8 Hardness gradients in 1117 steel carbonitrided at 815 °C (1500 °F) for 1 $\frac{1}{2}$ h and quenched in oil. Required minimum hardness of 630 HK (55 HRC) at 0.025 mm below the surface was met by reducing the percentage and flow rate of ammonia or by adding a diffusion period after carbonitriding, as indicated. Atmosphere consisted of endothermic carrier gas (dew point, -1 °C) at 4.25 m^3/h (150 ft^3/h), natural gas at 0.17 m^3/h (6 ft^3/h), and ammonia in the amounts indicated.

Similar data relating ammonia content to hardness for 1018 steel carbonitrided at 790 °C (1455 °F) for 2 $\frac{1}{2}$ h and at 845 °C (1550 °F) for 2 $\frac{1}{2}$ h are shown in Fig. 9.

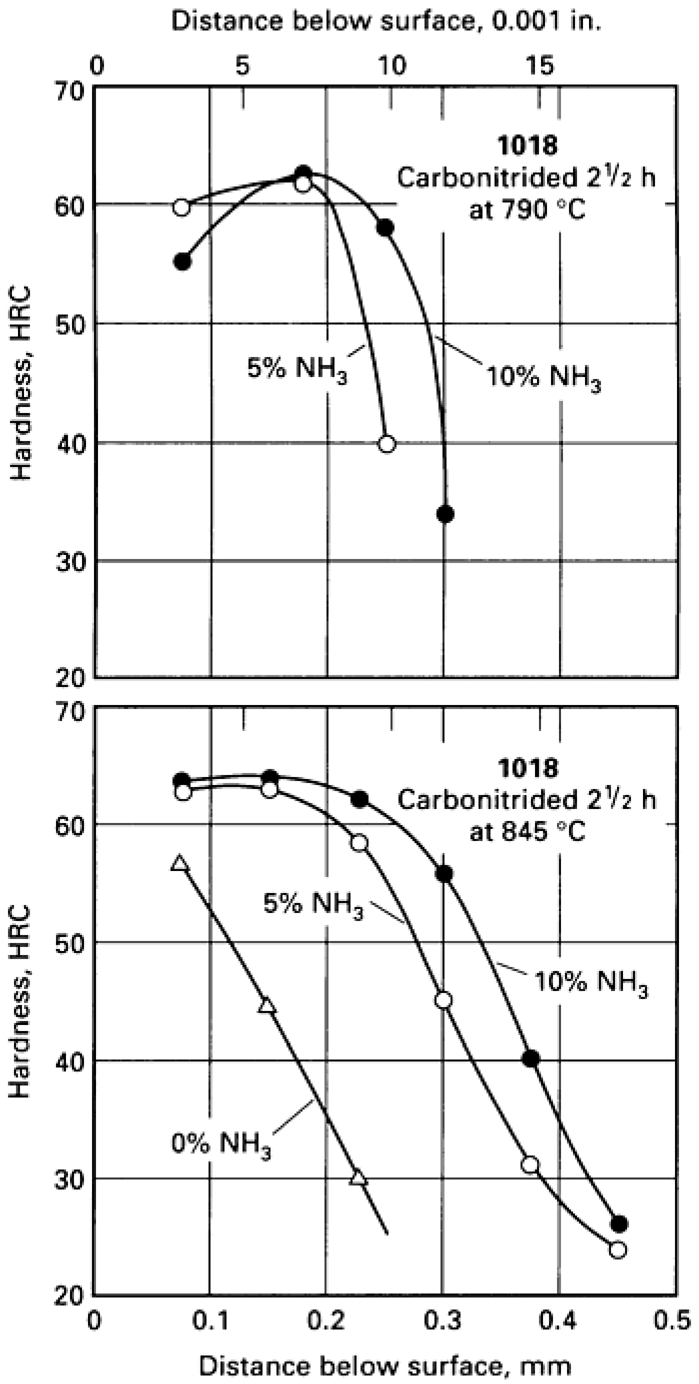

Fig. 9 Fffect of ammonia content of carbonitriding gas on hardness gradient

Void Formation

Subsurface voids or porosity in the case structure (Fig. 10) may occur in carbonitrided parts if the processing conditions are not adjusted properly. Although details of the mechanism of void formation are not completely understood, this problem has been related to excessive ammonia additions. Table 1 summarizes the factors that have been shown singly or in combination to contribute to void formation. No attempt has been made to quantify the interaction of the material and process variables presented in Table 1. Rather, this information should be used as a guide for avoiding or eliminating porosity problems. It should also be noted that the reprocessing of parts previously carbonitrided can in many instances also lead to void formation.

Table 1 Effect of material/variables on the possibility of void formation in carbonitrided cases

Material/processing variables[(a)]	Possibility of void formation

Temperature increase	Increased
Longer cycles	Increased
Higher case nitrogen levels	Increased
Higher case carbon levels	Increased
Aluminum-killed steel	Increased
Increased alloy content of steel	Decreased
Severe prior cold working of material	Increased
Ammonia addition during heat-up cycle	Increased

(a) All other variables held constant. Sources: Based on data in Fig. 10 and Ref 4 and 5

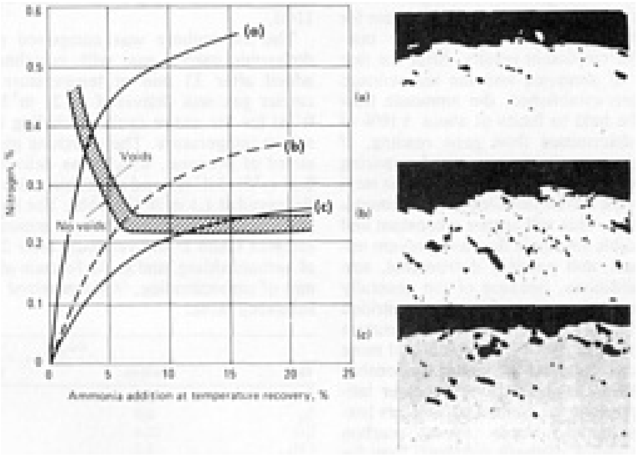

Fig. 10 Effect of ammonia additions on nitrogen content and formation of subsurface voids in foils. (a) 850 °C (1560 °F) 0.29% CO_2. (b) 925 °C (1695 °F) 0.13% CO_2. (c) 950 °C (1740 °F) 0.10% CO_2. Source: Ref 6

None of the data included in this article were obtained from parts or test pieces containing case porosity.

Applications

Although carbonitriding is a modified carburizing process, its applications are more restricted than those of carburizing. As has been stated previously, carbonitriding is largely limited to case depths of about 0.75 mm (0.03 in.) or less, while no such limitation applies to carburizing. Two reasons for this are: carbonitriding is generally done at temperatures of 870 °C (1600 °F) and below, whereas, because of the time factor involved, deeper cases are produced by processing at higher temperatures; and the nitrogen addition is less readily controlled than is the carbon addition, a condition that can lead to an excess of nitrogen, and, consequently, to high levels of retained austenite and case porosity when processing times are too long.

The resistance of a carbonitrided surface to softening during tempering is markedly superior to that of a carburized surface. Other notable differences exist in terms of residual-stress pattern, metallurgical structure, fatigue and impact strength at specific hardness levels, and effects of alloy composition on case and core characteristics.

Various production parts that have been successfully carbonitrided are listed in Table 2. A review of this list suggests the range of applications for which carbonitriding has been found to be an advantage.

Table 2 Typical applications and production cycles for carbonitriding

For many applications, carbonitriding the less expensive steels will provide properties equivalent to those obtained in gas carburized alloy steels. The following example illustrates choices of carbonitrided carbon steels for applications ordinarily requiring alloy steels.

Example 3:

Camshaft eccentrics stamped from 1010 aluminum-killed steel 4 mm (0.16 in.) thick were carbonitrided to a depth of 0.25 to 0.50 mm (0.01 to 0.02 in.) and a minimum surface hardness equivalent to 58 HRC. The required metallurgical properties for this application could have been attained also with carbonitrided or gas-carburized 1011 or 1016 steel. However, the 1010 steel had the advantage of facilitating the stamping operation because of its lower carbon and manganese contents and fine grain size.

Furnaces

Almost any furnace suitable for gas carburizing can be adapted to carbonitriding. Whether dense or shallow (openly spaced) work loads are to be processed, the furnace must be equipped with a fan to circulate the atmosphere. For work that is to be clean and bright after quenching, the furnace must be equipped with protective-atmosphere vestibules to the quench area.

Atmosphere Constituents

The atmospheres used in carbonitriding generally comprise a mixture of carrier gas, enriching gas, and ammonia. Basically, the atmospheres used in carbonitriding are produced by adding from about 2 to 12% ammonia to a standard gas-carburizing atmosphere.

Ammonia used for carbonitriding is anhydrous ammonia of 99.9+% purity. Grade designations such as Premium, Refrigeration, and Metallurgical are used to specify suitable materials. Grades known as Commercial and Agricultural contain appreciable amounts of carbon dioxide, water, and oils, which prohibit their use in furnace atmospheres.

Most ammonia is produced from natural gas, so costs and availability are related to natural gas supplies.

Control of Atmospheres

The three types of gases that comprise carbonitriding atmospheres usually are measured through flowmeters and may be premixed just before they enter the furnace. Large continuous furnaces require addition of the gas mixture at several points to provide the desired composition within the chamber. Control of the atmosphere usually is obtained by producing a carrier gas that is as constant in chemical composition and dew point as practical, and by varying the enriching gas and ammonia either manually or automatically to give the desired carbon and nitrogen composition in the carbonitrided case. In varying the enriching gas, care must be taken not to introduce excessive amounts of high hydrocarbons into the furnace because this will cause sooting. Heavy deposits of soot, in addition to making the work difficult to clean, have a detrimental effect on alloy furnace parts and may impede the rate of carbonitriding.

Ammonia Content. Among factors to be considered in establishing ammonia content for the influent gas are:

- *Atmosphere Turnover.* Frequently, lower ammonia percentages must be used with high rates of furnace gas change (that is, total gas flow divided by furnace chamber volume) to produce a specific microstructure for a specific furnace and load
- *Recirculation Rate.* Generally, increases in recirculation rate, and hence in atmosphere uniformity, permit the use of lower ammonia concentrations
- *Furnace-Cycle Time.* The rate of absorption of nitrogen in austenite decreases with time; hence, short furnace cycles and low case depths require higher ammonia percentages
- *Furnace Temperature.* Higher ammonia percentages often must be used with higher furnace temperatures
- *Load Size, Density, and Surface Area.* As size, density, and surface area of load increase, a higher rate of flow of ammonia is required to match the increase in nitrogen demand
- *Carbon Potential/Hydrocarbon Addition.* Lower ammonia percentages can normally be used with higher carbon potentials. However, as the load size or surface area of the load increases, hydrocarbon additions of up to 25% by volume may be necessary to adequately control the carbon potential early in the cycle or for shallow case depths
- *Type of Steel.* The minimum percentage of ammonia required for hardenability depends largely on steel composition. Austenite retention increases with an increase in ammonia content. Therefore, lower ammonia contents should be used with alloy steels, particularly those containing nickel or high manganese, and with higher-manganese carbon steels such as 1117, 1118, and 1024

Only enough ammonia should be added to sustain the carbonitriding reactions in the atmosphere; excess ammonia does not contribute to the nitrogen content of the case and can lead to void formation, as discussed above. Usually, 2.5 to 5% ammonia is sufficient to produce a satisfactory nitrogen content in the case. Ammonia contents as high as 10% or more, although relatively common, are often unnecessarily high.

Contaminants must be avoided in order to maintain an effective atmosphere in the furnace chamber. Infiltration of air and leaks in radiant tubes cause products of combustion, which are detrimental to the atmosphere, to enter the work chamber. Even the work load itself can provide a source of contamination. When significant amounts of grease, oil, cleaning agents, moisture, or quenching salts are present on surfaces of the work load, these materials can seriously contaminate the atmosphere. This source of contamination can be avoided by cleaning the work with a suitable agent before charging and by the use of purging cycles.

Influence of Furnace Type. Different types of furnaces require different percentages of entering component gases and different volumes of gases, depending on turnover (the number of gas changes per hour). Major variables include: the reactions of the gas with furnace brickwork and alloy; tightness of the furnace and number of door openings (shaker-hearth and belt furnaces will have an opening between the door and hearth at all times); and degree of circulation of gases, as related to load density and surface area of work. Data on the interrelationship of rate of gas flow, furnace volume, and number of gas changes per hour, as a function of type of furnace, are given in Table 3. From these data it is evident that:

- For brick-lined batch furnaces, fewer gas changes per hour are required as the furnace volume increases (ostensibly because relatively less gas leakage through furnace-door openings occurs as furnace volume increases)
- Shaker-hearth (or belt-type) furnaces require much higher gas flows per unit volume because of large losses of atmosphere through the fixed door opening at the charge end of the furnace

Table 3 Influence of type of furnace on mixture and flow rate of carbonitriding gases

Type of furnace	Constituents of gas, % by volume			Total gas flow,		Furnace volume,		Gas changes per hour
	Ammonia	Natural gas	Carrier gas	m^3/h	ft^3/h	m^3	ft^3	
Batch, brick-lined	10.4	20.8	68.8	6.8	240	0.29	10	23.5

Batch Furnace Atmospheres

For maximum uniformity of case composition and case depth, the load must be heated uniformly to the carbonitriding temperature, and an adequate supply of atmosphere maintained at constant composition must be circulated throughout the load. Processing uniformity may be significantly improved by preheating parts in an atmosphere of endothermic gas for 15 to 60 min to ensure temperature uniformity within the load before adding enriching gas and ammonia for the actual carbonitriding portion of the cycle. This is a practicable procedure for batch furnaces that have sufficient heating capacity as well as an efficient work-loading pattern, good atmosphere-circulating fans, and dependable devices for mixing and controlling the addition of gases.

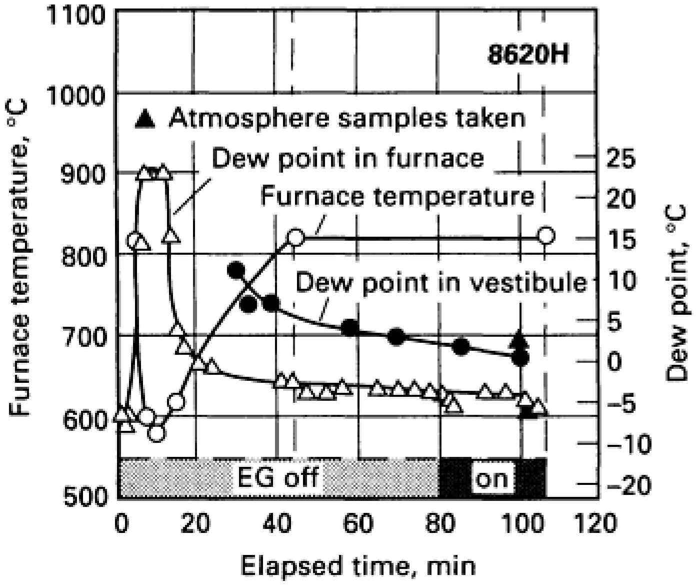
Control of Composition. As in gas carburizing, the composition of the atmosphere for carbonitriding should be carefully controlled for consistent results. After the rate of flow of ammonia and the temperature have been established, the ammonia flow should be held to limits of about ±10% of the predetermined flow gage reading. If similar parts are to be processed requiring the same ammonia addition, a stainless steel orifice plate can be installed in the ammonia supply line. This will ensure a constant and reproducible ammonia flow and prevent unintentional, and possibly detrimental, ammonia additions. Because of the generally lower carbon content of the carbonitrided case, the lower operating temperature (which permits higher dew points and more carbon dioxide), and the higher hardenability of the carbonitrided case, greater latitude is possible for control parameters (oxygen potential, water vapor, carbon dioxide, and/or methane contents) than for the same steel composition using the carburizing process.

For example, when carburizing at 925 °C (1700 °F) to obtain a case carbon content of 0.90 ± 0.05% or 0.80 ± 0.05%, it is desirable to hold the dew point within ±0.5 °C (±1 °F), and the carbon dioxide content within ±0.005%, of the control values; when carbonitriding at 815 °C (1500 °F) to obtain a case carbon content of 0.80 ± 0.05%, it is desirable to hold the dew point within ±1.5 °C (±3 °F), and the carbon dioxide content within ±0.03%, of the control values. The carbon dioxide levels corresponding to a certain carbon potential will not be the same for carbonitriding and carburizing, as discussed above.

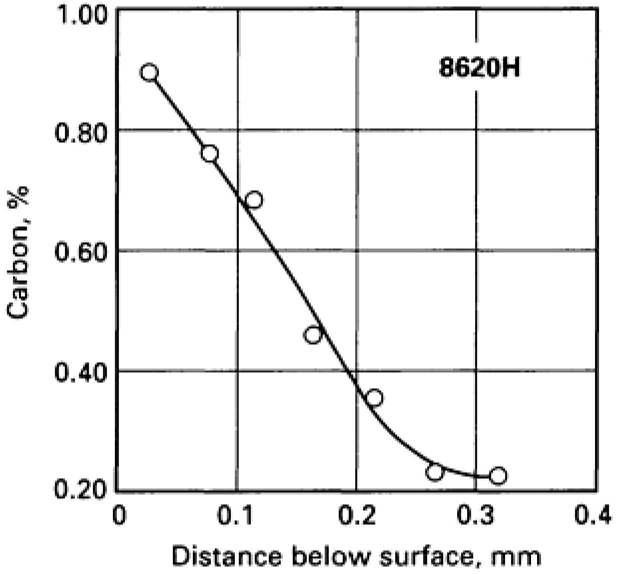
Data reported for atmospheres consisting of endothermic generator gas with additions of 5% ammonia and less than 1% propane indicate dew points in the furnace chamber of -7 °C at 845 °C (20 °F at 1550 °F) and of -4 °C at 815 °C (25 °F at 1500 °F) for a surface carbon content of 0.80 to 0.90% with 1018 and 8620 steels. Dew points ranging from -7 to 4 °C (20 to 40 °F) will cover most commercial carbonitriding applications at approximately 845 °C (1550 °F) with surface carbon content of about 0.80%.

Example 4:

Gears (Fig. 11) made of 8620H steel were carbonitrided in batches, each of which had a net weight of 340 kg (750 lb) and a gross weight of 460 kg (1010 lb). Typically, carbonitriding was done at 815 °C (1500 °F) for 30 min, after which the gears were quenched directly from the carbonitriding temperature.



(a)



(b)

Fig. 11 Effect on gears carbonitrided in a batch-type furnace. (a) Temperature and dew-point variations during carbonitriding cycle. (b) Carbon gradient produced by the cycle shown in (a). EG, enriching gas

The furnace was a batch-type furnace with a brick-lined heating chamber. It was heated by radiant tubes and had a vestibule-enclosed quench. Dimensions of the furnace chamber were 1.4 m wide by 1.7 m long by 1.1 m high (56 by 66 by 43 in.) from brick floor to center of arch. The variation of furnace temperature with time during a typical carbonitriding cycle is shown in Fig. 11(a).

The atmosphere was composed of endothermic carrier gas, with enriching gas added after 33 min at temperature. The carrier gas was delivered at 21 m^3/h (750 ft^3/h) for the entire cycle, including the 63 min at temperature. The enriching gas consisted of propane, which was delivered at 0.14 m^3/h (5 ft^3/h), and ammonia, which was delivered at 1.1 m^3/h (38 ft^3/h). The furnace-gas analysis, determined from atmosphere samples taken in the vestibule after 23 min of carbonitriding, and in the furnace after 26 min of carbonitriding, is summarized in the following table:

Gas	Gas, %	
	Vestibule	Furnace
CO_2	0.8	0.4

O_2	0.0	. . .
CO	22.4	20.4
CH_4	1.2	1.2
H_2	34.2	34.2
N_2	bal	bal

The carrier-gas dew point, measured at the generator, was maintained at -15 to -14 °C (5 to 7 °F) throughout the cycle. Figure 11(a) indicates the dew points in the furnace and in the vestibule at various elapsed times during the carbonitriding cycle.

Figure 11(b) shows a typical carbon gradient in a gear resulting from the processing described.

Control of atmosphere composition begins by accurately controlling the carrier gas. With endothermic gas generators, the air-gas ratio is usually adjusted to produce a dew point of 2 to 4 °C (35 to 40 °F), which is equivalent to about 0.25 to 0.32% carbon dioxide content. Automatic, closed-loop control based on oxygen potential, carbon dioxide, or dew point is preferred for ensuring the uniformity of endothermic generator gas output.

Dew-point instruments that contain a lithium chloride cell are not recommended for use with carbonitriding atmospheres because ammonia will cause deterioration of the lithium chloride. If an infrared instrument for CO_2 is used, it is recommended that stainless steel tubing be used instead of copper to avoid the corrosive action of the ammonia. Aluminum tubing can be used successfully if care is taken to avoid any possibility of producing water condensate in the sample lines. In general, the advice of the instrument manufacturer should be obtained before using these devices with carbonitriding atmospheres.

Because of the relatively light carbonitrided case, turnings from test bars are not frequently employed for determining carbon content. Metallographic examination and the control of case microhardness gradient are common process control methods. However, the most commonly used process control setups incorporate a regulator to control ammonia flow.

Better control of furnace atmospheres can be obtained when the parts to be carbonitrided and the work baskets are free of dirt and oil. Sintered powder metallurgy parts containing oil must be "burned out" in a tempering furnace before they are carbonitrided.

Continuous Furnace Atmospheres

Setting up a program for efficient and dependable control of a carbonitriding atmosphere in a continuous furnace is similar to that for a batch furnace. Good circulation of atmosphere and good control of temperature are of prime importance. It is advantageous to introduce ammonia only to those areas in which the temperature of the work is equal to the operating temperature for carbonitriding. If the furnace is of appreciable internal length, about $3\frac{1}{2}$ m ($11\frac{1}{2}$ ft) or more, it is important to introduce the mixture of carburizing gas and ammonia at frequent intervals over the length of the furnace where the work is at temperature and in regions where the temperatures may be decreased for metallurgical reasons near the end of the cycle.

Safety

Caution: Gaseous carbonitriding media are highly toxic, flammable, and explosive. The safety precautions that must be taken to protect equipment and personnel are essentially the same as those used in gas carburizing.

Ammonia cylinders should not be located near the furnaces, in direct sunlight, or near flammable gases or other combustibles. It is recommended that the ammonia supply be placed in a room that is well ventilated at the ceiling and separated from the work area by a fire-resistant wall.

Because ammonia is lighter than air, as well as a moderate fire hazard and a toxic material, an automatic sprinkling system is recommended. *Caution: Gas masks should be readily available, but should not be stored in the same area as the ammonia.* A sulfur stick can be used to check for ammonia leaks. Additional recommendations pertaining to safety in ammonia systems can be obtained from fire insurance companies.

Caution: Under no circumstances should combustible gas be introduced into the furnace when the furnace temperature is less than 760 °C (1400 °F). When a lower operating temperature is required, the furnace should be heated to 760 °C and purged with generator gas before the temperature is decreased. This type of operation can be very dangerous and should be done only by qualified personnel.

Temperature Selection

Choice of carbonitriding temperature is based on a number of considerations, including steel composition, dimensional control, fatigue and wear properties, hardness, microstructural constituents, cost, and equipment.

Steel Composition. Although higher temperatures permit the use of higher concentrations of ammonia, ammonia content must be decreased as the alloy content of the steel increases to minimize austenite retention. To this extent, temperature, atmosphere, and alloy content are closely interrelated.

Dimensional control is often the most important consideration in the selection of carbonitriding temperature. The following two examples illustrate the relation between carbonitriding temperature and dimensional stability.

Example 5:

A 1010 steel rack 11.75 cm long by 1 mm thick (4.63 in. long by 0.040 in. thick) could not be kept within limits of straightness tolerance (and, because of brittleness, it could not be straightened) after it was quenched from a carbonitriding temperature of 845 °C (1550 °F) into warm oil at about 65 to 70 °C (150 to 160 °F) The part had a case-depth requirement of 0.075 mm (0.003 in.) and a flatness requirement of 0.05 mm (0.002 in.) over its entire length. Lowering the temperature to the range of 790 to 800 °C (1450 to 1475 °F) significantly reduced distortion and increased ductility to within acceptable limits. Although temperatures below 790 °C (1450 °F) might have resulted in even less distortion and more ductility, they were not used because of the increase in time required to produce the desired case depth.

Example 6:

Figure 12 presents data pertaining to the effect of carbonitriding temperature on the dimensional stability of three production parts. All three parts of 1010 commercial-quality steel sheet were processed in batch-type equipment at temperatures ranging from 790 to 845 °C (1450 to 1550 °F) The atmospheres consisted of endothermic gas at 7 m^3/h (250 ft^3/h), enriching gas at 0.8 m^3/h (30 ft^3/h), and ammonia at 0.14 m^3/h (5 ft^3/h). Dew points were maintained at -1 to -4 °C (25 to 30 °F). Depending on temperature, furnace times were varied to produce specified case depths of 0.13 to 0.20 mm (0.005 to 0.008 in.).

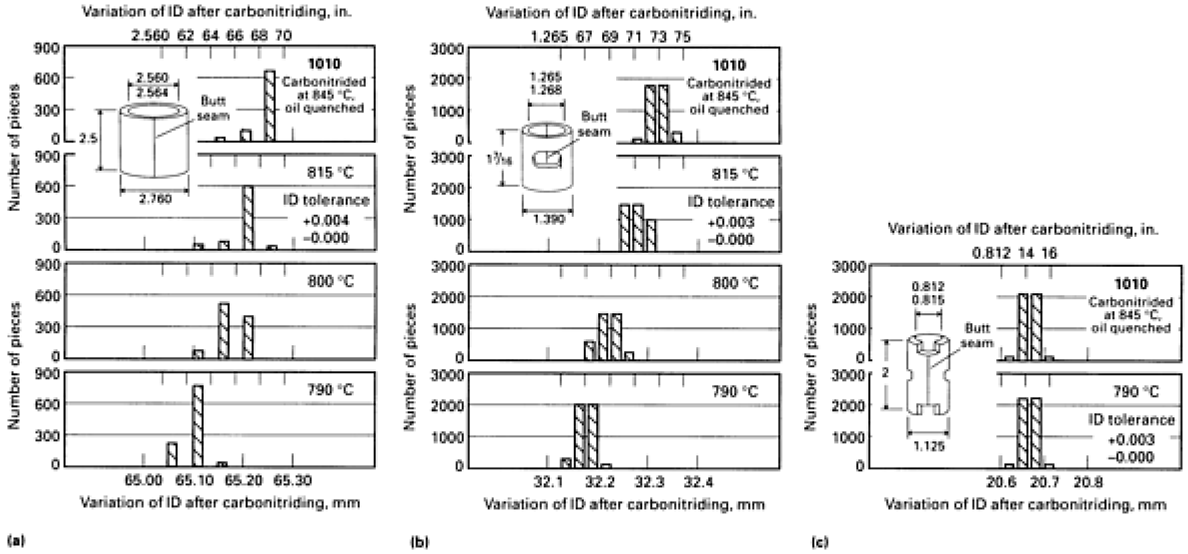


Fig. 12 Effect of carbonitriding temperature on dimensional stability of three 1010 steel production parts. Parts were carbonitrided to produce a case depth of 0.13 to 0.20 mm (0.005 to 0.008 in.) with minimum surface hardness of 89 HR15N. Gas ratios and dew points were essentially the same for all temperatures. Time at temperature was 15 to 45 min, depending on temperature. ID, inside diameter. Part dimensions and tolerances

given in inches

Equal numbers of parts were hand loaded in baskets and processed in a batch furnace. The parts shown in Fig. 12(a) and 12(b) were loaded with their axes in the vertical position; parts like those in Fig. 12(c) were randomly loaded. Baskets and parts were quenched in slightly agitated oil at 60 to 70 °C (140 to 160 °F).

Data in Fig. 12 represent eight heats for the part in Fig. 12(a) and three heats for each of the two other parts. All parts were within inside-diameter tolerance before carbonitriding.

For the parts carbonitrided at four temperatures, the least distortion resulted at the lowest temperature. Distortion is lower at lower temperatures because there is more ferrite in the structure at the lower temperature and consequently less volume expansion on quenching. However, for the part with the smallest inside diameter (Fig. 12c), dimensional variation was not affected by a reduction in temperature.

Temperature also has a direct bearing on core hardness. Steels treated at the higher carbonitriding temperatures and quenched from above the upper critical temperature of the core will produce higher core hardnesses. These high core hardnesses are usually desirable in applications involving high surface loads because a strong core is needed to support the hardened case.

Special fabrication and service requirements of a particular part may restrict the choice of carbonitriding temperature. For instance, in one application, cold headed pins used in door-catch mechanisms required both riveting quality and wear resistance. A carbonitriding temperature of 790 °C (1450 °F) satisfied both requirements by producing a soft center for riveting and a thin, file-hard case for wear resistance.

Control of Retained Austenite

Nitrogen lowers the transformation temperature of austenite. Therefore, a carbonitrided case usually contains more retained austenite than a carburized case of the same carbon content. The low indentation hardness resulting from retained austenite is undesirable in many applications. It can be extremely detrimental in components of close fitting assemblies--for example, shaft and sleeve assemblies wherein the shaft is intended to rotate or reciprocate in the sleeve. The delayed transformation of austenite to martensite at ambient temperature results in a volume increase that may cause moving parts to bind or "freeze" in service.

The amount of retained austenite can be significantly decreased by cooling the quenched parts to -40 to -100 °C (-40 to -150 °F). When close-tolerance ground parts are involved, this treatment should precede finish grinding. Subzero treatment of parts that are to be tempered should precede final tempering. Subzero treatment may cause microcracks in the case, particularly in coarse-grain steels. Because the amount of retained austenite is normally at a maximum near the steel surface, it can be removed from symmetrical contours by grinding. However, care must be exercised in grinding high retained austenite surfaces because of the increased possibility of grinding burn or checking. If grinding is not required for any reason other than to remove retained austenite, it also may be considered an expensive operation. The most economical way to minimize retained austenite is by selection of preferred steels and control of the carbonitriding process.

Minimizing retained austenite in the carbonitrided case is assisted by modification of several processing factors:

- *Furnace Temperature.* An increase in furnace temperature will reduce the nitrogen content of the outer portions of the case, thus minimizing the amount of retained austenite. It is far better to reduce ammonia flow, rather than depend upon increased temperature to lower the nitrogen content
- *Carbon Potential.* Lowering the carbon potential will also help reduce retained austenite
- *Ammonia content* of the carbonitriding atmosphere should be restricted to the minimum required to obtain the desired hardenability. A 1 to 5% ammonia content in the inlet gas is usually a satisfactory starting point; a lower content decreases the rate of penetration, but may be desirable to minimize retained austenite and to avoid case porosity

Quenching Media and Practices

Whether carbonitrided parts are quenched in water, oil, or gas depends on the allowable distortion, metallurgical requirements (such as case and core hardness), and type of furnace equipment employed.

Water Quenching. If the accompanying distortion is tolerable, parts made of low-carbon steel may be quenched in water. For example, shift-lever pins made of B1212 steel are water quenched.

Water quenching usually is restricted to those furnaces in which the work is transferred from the furnace into the air prior to quenching, thus avoiding possible contamination of the furnace atmosphere by water vapor. However, water quenching from a rotary retort furnace is feasible, provided the quench chute is equipped with gas ejectors and a water-distribution system for condensing water vapor.

It should be noted that ammonia is very soluble in water and forms a product (NH_4OH) that is extremely corrosive to copper-base materials. In continuous operations where water is exposed to an ammonia-bearing atmosphere, brass agitators, copper tube bundles in heat exchangers, and similar copper-alloy components should be avoided.

Gas Quenching. Parts that have small mass (such as thin stampings) may be quenched in a stream of cooled atmosphere gas or nitrogen. Gas or atmosphere quenching serves principally to reduce distortion, thus eliminating the high costs of straightening.

In gas quenching, parts must be loaded into furnace trays carefully so that the surfaces of the parts can be cooled rapidly enough to produce the desired hardness. Trays should be loaded and stacked so that the total mass of the load does not exceed that which can be satisfactorily quenched.

Tempering

Many shallow-case carbonitrided parts are used without tempering. The presence of nitrogen in the carbonitrided case increases its resistance to softening, and the increase varies with the amount of nitrogen in the case. Resistance to tempering may be desirable where service operating temperatures are abnormally high, or where hot straightening is employed.

Tempering data obtained on carbonitrided cases of 1018 steel are given in Fig. 13. The data relate temper-resistance to both carbonitriding temperature and the ammonia content of the atmosphere. Figure 14 presents a summary of the effects of carbonitriding temperature and ammonia content on temper-resistance, derived from the same specimens referred to in Fig. 13.

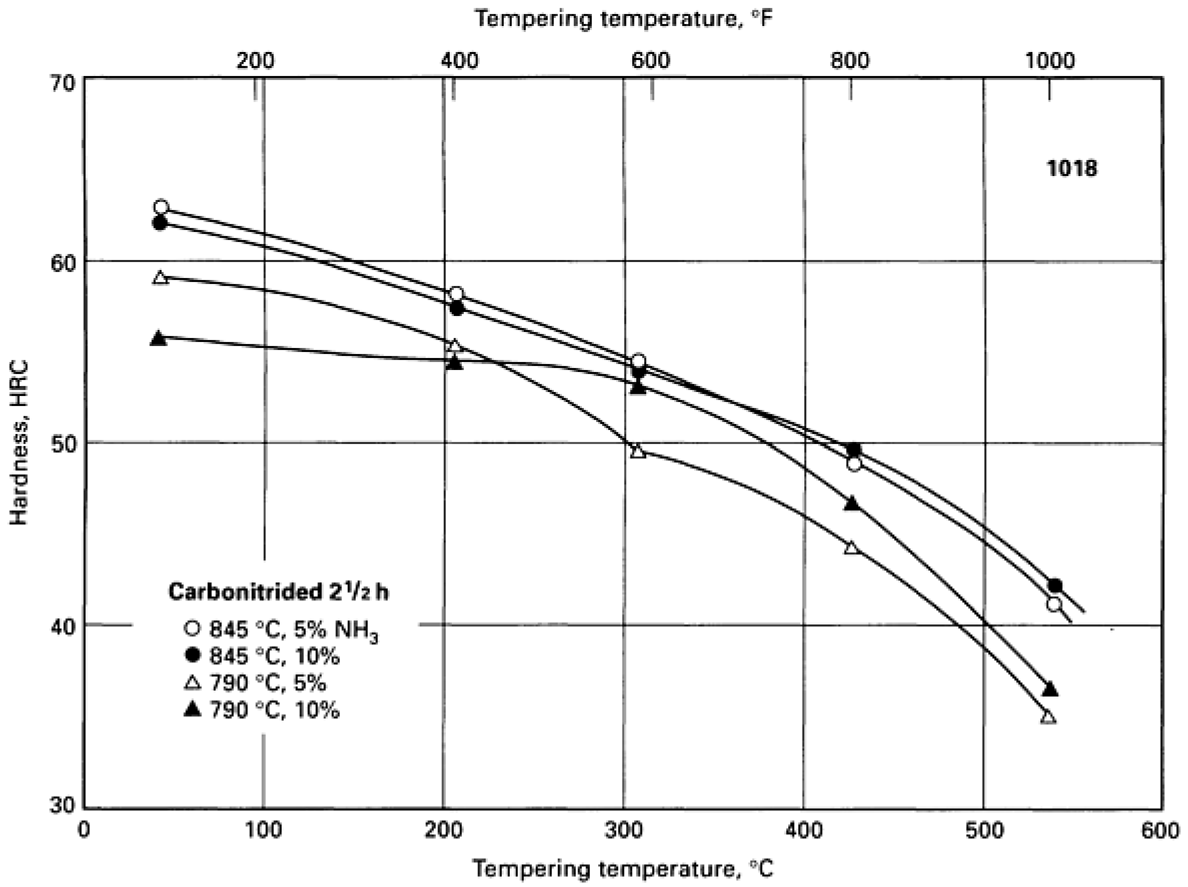

Fig. 13 Decrease of surface hardness with increasing temperature for specimens of 1018 steel carbonitrided under the conditions indicated. Rockwell C hardness converted from Rockwell 30-N. See also Fig. 14.

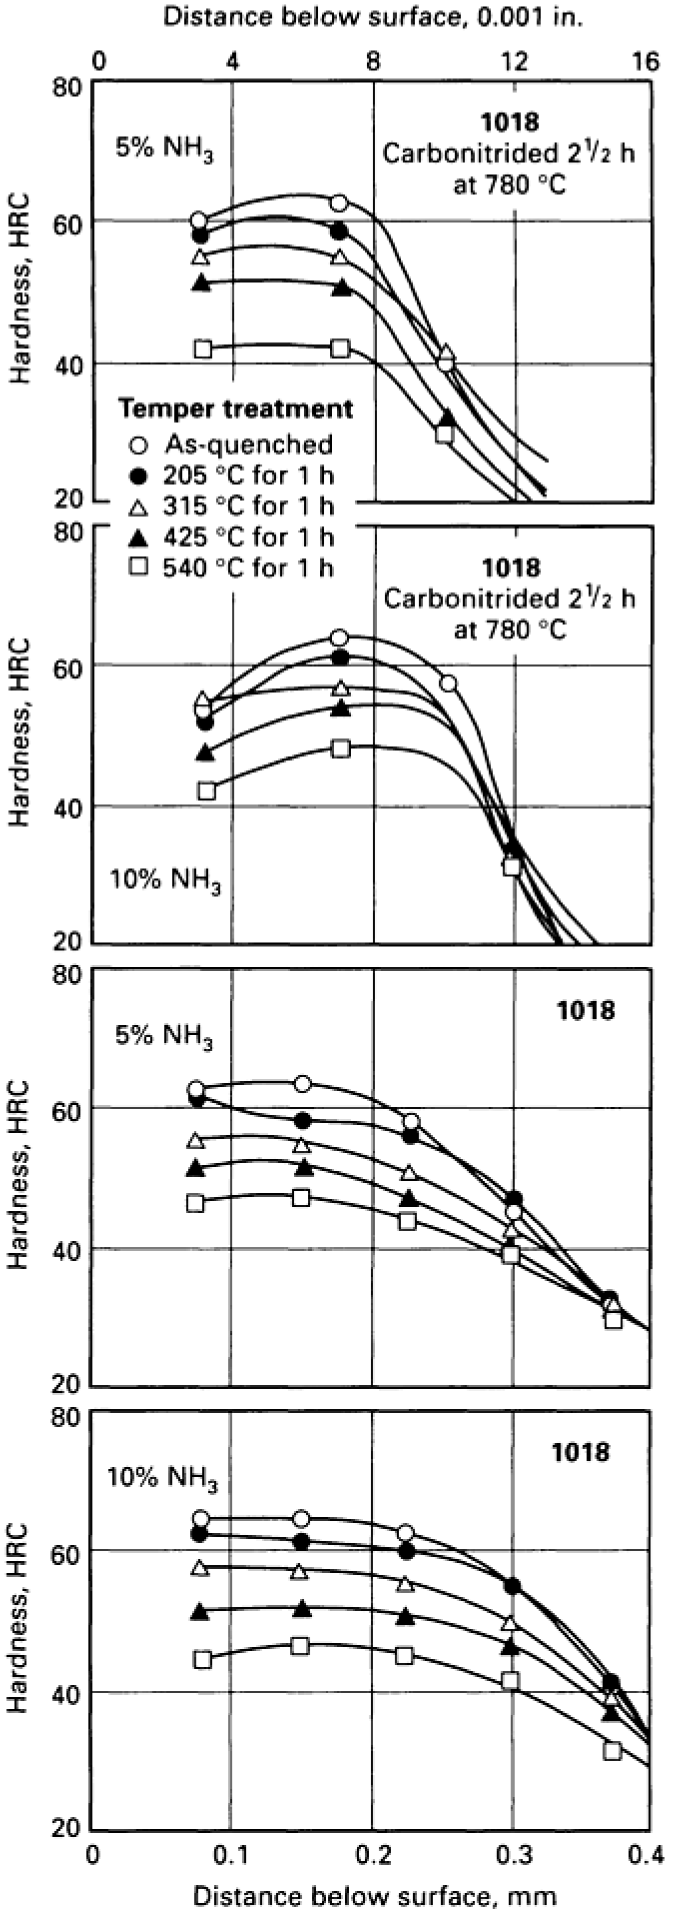

Fig. 14 Effect of tempering temperature on hardness gradients in carbonitrided cases. Rockwell C hardness

converted from Vickers. Specimens were the same as Fig. 13 and were tempered as indicated.

Because tempering a carbonitrided case at 425 °C (795 °F) and above results in a marked increase in notch toughness (see Table 4), parts that are to be subjected to repeated shock loading are invariably tempered to avoid impact and impact fatigue failures. Most carbonitrided gears are tempered at 190 to 205 °C (375 to 400 °F) to reduce surface brittleness and yet maintain a minimum case hardness of 58 HRC. Alloy steel parts that are to be surface ground are tempered to minimize grinding cracks. Low-carbon steel parts are frequently tempered at 135 to 175 °C (275 to 350 °F) to stabilize austenite and minimize dimensional variations. Tapping screws made of 1020 steel are tempered at 260 to 425 °C (500 to 795 °F) to reduce breakage in tapping holes in sheet metal. In contrast, parts that are case hardened primarily for wear resistance, such as dowel pins, brackets, and washers, need not be tempered.

Table 4 Effect of tempering on Charpy V-notch impact strength of carbonitrided 1041 steel

Specimens were carbonitrided at 845 °C (1550 °F) for 3 h in an atmosphere containing 7% ammonia, and were oil quenched from the carbonitriding temperature. Specimens were copper plated before machining of V-notch to permit exposure of the notch to the carbonitriding atmosphere.

Test	Tempering temperature		Impact strength		Hardness, HRC[(a)] Distance below surface, mm (in.)								
	°C	°F	J	ft · lb	Surface[(b)]	Core	0.075 (0.003)	0.15 (0.006)	0.25 (0.01)	0.38 (0.015)	0.64 (0.025)	1.0 (0.04)	1.4 (0.055)
1	As-quenched	As-quenched	1.4	1	60	53	63	64	64	63	61	61	58
2	370	700	2, 2	1.5, 1.5	47	46	57	57	55	54	49	50	50

(a) Converted from Vickers hardness.

(b) Surface hardness is less than hardness at 0.075 mm below the surface because of retained austenite.

(c) Tested at -18 °C (0 °F); all other tests at room temperature

Hardness Testing

The selection of a method of testing the surface hardness of carbonitrided steels depends primarily on the effective case depth on the parts to be tested. For effective case depths of 0.65 mm (0.025 in.) and above, accurate surface Rockwell C readings can be obtained. As the effective case depth decreases, lighter hardness testing loads must be used to obtain accurate surface hardness values. The Rockwell 15-N scale can be used in most instances for case depths of 0.25 to 0.40 mm (0.009 to 0.015 in.). On case depths of less than 0.25 mm, none of the Rockwell scales are reliable; testing may be done with files or a microhardness tester.

In file-hardness testing, parts with surface hardnesses that are less than full file hardness (64 to 68 HRC) can be tested with files that have been tempered to the desired hardness range. Surface hardness for such parts may be specified as Mfh 60, indicating that the part must be hardened to a mill file tempered to 60 HRC. However, a sample with high austenite content may indicate an indentation hardness of only 52 HRC and still resist a file hardened to 66 HRC.

Carbonitriding of Powder Metallurgy Parts

Carbonitriding is widely used as a process for case hardening parts made by powder metallurgy techniques from ferrous powders. Densities of the sintered compacts vary from approximately 6.5 g/cm^3 (0.23 lb/in.^{3}) up to those approaching that of wrought steel . Parts may or may not be copper infiltrated prior to carbonitriding.

Carbonitriding is effective in case hardening iron compacts made from electrolytic iron powders. Four characteristics of these compacts make case hardening by carburizing difficult: high martensite transformation temperature (M_s), very low hardenability, less surface oxidation, and inherent porosity, resulting in high rates of carbon penetration.

Carbonitriding at 790 to 815 °C (1450 to 1500 °F) solves these problems; lower rates of diffusion at these temperatures permit control of case depth and allow buildup of adequate carbon in the case. The effects of nitrogen in retarding the pearlite transformation result in sufficient hardenability to allow oil quenching.

File-hard cases (with microhardnesses equivalent to 60 HRC) and normal, predominantly martensitic structures can be consistently obtained. Shallow cases are obtainable, although the allowable range of case depth must be increased over that used for wrought steels. Typical ranges of case depth are 0.08 to 0.20 mm (0.003 to 0.008 in.) and 0.15 to 0.30 mm (0.006 to 0.012 in.).

The high rate of carbon and nitrogen penetration that occurs as the result of porosity is demonstrated in Fig. 15 for parts made of iron powder conforming to ASTM B 310, class A. Although the rate of penetration decreases with increasing density, case depths for the higher densities (7.20 to 7.30 g/cm^3, or 0.260 to 0.264 lb/in.^{3}) are much deeper than those obtained with a wrought steel (7.87 g/cm^3, or 0.284 lb/in.^{3}). Most commercial iron-powder compositions exhibit this type of response to carbonitriding; however, copper-infiltrated compacts are considerably more resistant to the penetration of carbon and nitrogen.

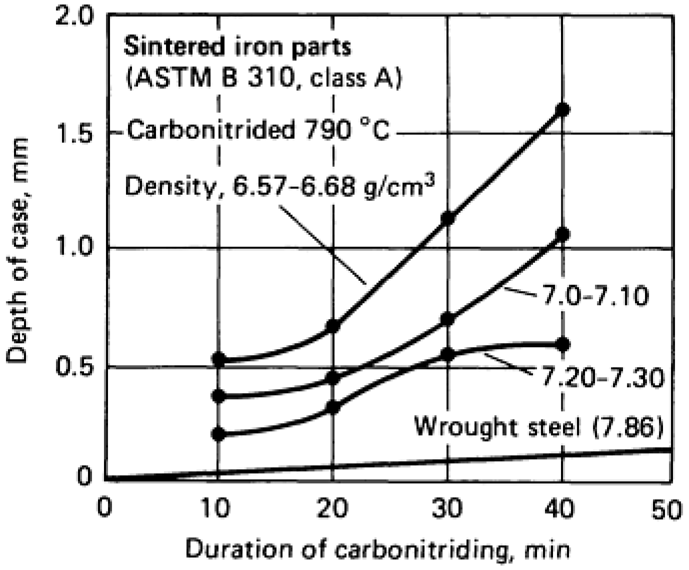

Fig. 15 Increase of case depth with decrease in density of iron powder metallurgy parts carbonitrided for various periods of time at 790 °C (1455 °F). Curve for steel is based on total furnace time and represents the average of the 775 to 790 °C (1425 to 1455 °F) band shown in Fig. 6.

Tempering. Carbonitrided iron powder metallurgy parts are usually tempered, despite the fact that there is little danger of cracking untempered pieces. Tempering accomplishes the incidental result of facilitating tumbling and deburring operations. Although tempering is potentially capable of removing oil picked up and held in the pores in the part, air tempering of oil-quenched powder metallurgy parts is normally limited to temperatures not exceeding 205 °C (400 °F) because of the fire hazard at higher temperatures. Carbonitrided iron powder metallurgy parts are usually tempered at temperatures slightly higher than the temperatures used for carbonitrided wrought steel parts. Special cleaning procedures to remove oil, thus eliminating fire hazards, are incorporated in the processing steps when the tempering temperature exceeds 205 °C.

Gas Nitriding of Steels

Revised by Conrad H. Knerr, Metlab; Thomas C. Rose, Alloy Hard Surfacing Inc.; and James H. Filkowski, Litton Precision Gear

---

Introduction

GAS NITRIDING is a case-hardening process whereby nitrogen is introduced into the surface of a solid ferrous alloy by holding the metal at a suitable temperature (below Ac_1, for ferritic steels) in contact with a nitrogenous gas, usually ammonia. Quenching is not required for the production of a hard case. The nitriding temperature for all steels is between 495 and 565 °C (925 and 1050 °F).

Application Factors

Principal reasons for nitriding are:

- To obtain high surface hardness
- To increase wear resistance and antigalling properties
- To improve fatigue life
- To improve corrosion resistance (except for stainless steels)
- To obtain a surface that is resistant to the softening effect of heat at temperatures up to the nitriding temperature

Because of the absence of a quenching requirement, with attendant volume changes, and the comparatively low temperatures employed in this process, nitriding of steels produces less distortion and deformation than either carburizing or conventional hardening. Some growth occurs as a result of nitriding, but volumetric changes are relatively small.

Nitridable Steels. Of the alloying elements commonly used in commercial steels, aluminum, chromium, vanadium, tungsten, and molybdenum are beneficial in nitriding because they form nitrides that are stable at nitriding temperatures. Molybdenum, in addition to its contribution as a nitride former, also reduces the risk of embrittlement at nitriding temperatures. Other alloying elements, such as nickel, copper, silicon, and manganese, have little, if any, effect on nitriding characteristics.

Although at suitable temperatures all steels are capable of forming iron nitrides in the presence of nascent nitrogen, the nitriding results are more favorable in those steels that contain one or more of the major nitride-forming alloying elements. Because aluminum is the strongest nitride former of the common alloying elements, aluminum-containing steels (0.85 to 1.50% Al) yield the best nitriding results in terms of total alloy content. Chromium-containing steels can approximate these results if their chromium content is high enough. Unalloyed carbon steels are not well suited to gas nitriding because they form an extremely brittle case that spalls readily, and the hardness increase in the diffusion zone is small.

The following steels can be gas nitrided for specific applications:

- Aluminum-containing low-alloy steels (Table 1)
- Medium-carbon, chromium-containing low-alloy steels of the 4100, 4300, 5100, 6100, 8600, 8700, and 9800 series
- Hot-work die steels containing 5% chromium such as H11, H12, and H13
- Low-carbon, chromium-containing low-alloy steels of the 3300, 8600, and 9300 series
- Air-hardening tool steels such as A-2, A-6, D-2, D-3, and S-7
- High-speed tool steels such as M-2 and M-4
- Nitronic stainless steels such as 30, 40, 50, and 60
- Ferritic and martensitic stainless steels of the 400 and 500 series
- Austenitic stainless steels of the 200 and 300 series
- Precipitation-hardening stainless steels such as 13-8 PH, 15-5 PH, 17-4 PH, 17-7 PH, A-286, AM350, and AM355

Table 1 Nominal composition and preliminary heat-treating cycles for aluminum-containing low-alloy steels commonly gas nitrided

(a) Sections up to 50 mm (2 in.) in diameter, quenched is oil; larger sections may be water quenched.

Aluminum-containing steels produce a nitrided case of very high hardness and excellent wear resistance. However, the nitrided case also has low ductility, and this limitation should be carefully considered in the selection of aluminum-containing steels. In contrast, low-alloy chromium-containing steels provide a nitrided case with considerably more ductility but with lower hardness. Nevertheless, these steels offer substantial wear resistance and good antigalling properties. Tool steels, such as H11 and D2, yield consistently high case hardness with exceptionally high core strength.

Prior Heat Treatment. All hardenable steels *must* be hardened and tempered before being nitrided. The tempering temperature must be high enough to guarantee structural stability at the nitriding temperature; the minimum tempering temperature is usually at least 30 °C (50 °F) higher than the maximum temperature to be used in nitriding.

In certain alloys, such as series 4100 and 4300 steels, hardness of the nitrided case is modified appreciably by core hardness; that is, a decrease in core hardness results in a decrease in case hardness. Consequently, in order to obtain maximum case hardness, these steels are usually provided with maximum core hardness by being tempered at the minimum allowable tempering temperature.

Applications. Examples of typical gas nitriding applications and procedures are presented in Table 2. Table 3 lists examples of parts for which nitriding eliminated production or service problems that arose when the parts were case hardened by other methods.

Table 2 Nitriding applications and procedures

Part	Dimensions or weight of part	Steel	Nitriding time, h
Single-stage nitriding			
Hydraulic barrel	50 mm (2 in.) OD, 19 mm ($\frac{3}{4}$ in.) ID, 150 mm (6 in.) long	AMS 6470	48

Table 3 Examples of parts for which nitriding proved superior to other case-hardening processes for meeting requirements

Part	Requirement	Material and process originally used	Resultant problem	Solution
Gear	Good wear surface and fatigue properties	Carburized 3310 steel 0.4 to 0.6 mm (0.017 to 0.025 in.) case	Difficulty in obtaining satisfactory case to meet a reliability requirement	AMS 6470 substituted for 3310 and double-stage nitrided for 25 h
High-speed pinion (on gear motor)	Provide teeth with minimum (equivalent) hardness of 50 HRC	8620 steel gas carburized at 900 °C (1650 °F) to 0.5 mm (0.02 in.) case, direct quenched from 845 °C (1550 °F) and tempered at 205 °C (400 °F)	Distortion in teeth and bore caused high rejection rate	4140 steel, substituted for 8620, was heat treated to 255 HB; parts were rough machined, finish machined, nitrided[(a)]
Bushings (for conveyor rollers handling abrasive alkaline material)	High surface hardness for abrasion resistance; resistance to alkaline corrosion	Carburized bushings	Service life of bushings was short because of scoring	Substitution of Nitralloy 135 type G (resulfurized) heat treated to 269 HB and nitrided[(b)]
Spur gears (in train of power gears; 10-pitch, tip modified)	Sustain continuous Hertz stress of 1035 MPa (150 ksi) (overload of 1550 MPa, or 225 ksi), continuous Lewis stress of 275 MPa (40 ksi) (overload of 725 MPa, or 105 ksi)[(c)]	Carburized AMS 6260	Gears failed because of inadequate scuff resistance, also suffered property losses at high operating temperatures	Substitution of material of H11 type, hardened and multiple tempered (3 h + 3 h) to 48 to 52 HRC, then double-stage nitrided[(d)]

(a) Single-stage nitrided at 510 °C (950 °F) for 38 h. Cost increased 5%, but rejection rate dropped to zero.

(b) Single-stage nitrided at 510 °C (950 °F) for 38 h. Case depth was 0.46 mm (0.018 in.), and hardness was 94 HR15-N; parts had three times the service life of carburized parts.

(c) Must withstand operating temperatures to 290 °C (550 °F).

(d) 15 h at 515 °C (960 °F) (15 to 25% dissociation); then 525 °C (980 °F) (80 to 83% dissociation). Effective case depth (to 60 HRC), 0.25 to 0.4 mm (0.010 to 0.015 in.); case hardness, 67 to 72 HRC (converted from Rockwell 15-N scale)

Single-Stage and Double-Stage Nitriding

Either a single- or a double-stage process may be employed when nitriding with anhydrous ammonia. In the single-stage process, a temperature in the range of about 495 to 525 °C (925 to 975 °F) is used, and the dissociation rate ranges from 15 to 30%. This process produces a brittle, nitrogen-rich layer known as the white nitride layer at the surface of the nitrided case.

The double-stage process, known also as the Floe process (U.S. Patent 2,437,249), has the advantage of reducing the thickness of the white nitrided layer.

The first stage of the double-stage process is, except for time, a duplication of the single-stage process. The second stage may proceed at the nitriding temperature employed for the first stage, or the temperature may be increased to from 550 to 565 °C (1025 to 1050 °F); however, at either temperature, the rate of dissociation in the second stage is increased to 65 to

80% (preferably, 75 to 80%). Generally, an external ammonia dissociator is necessary for obtaining the required higher second-stage dissociation.

The principal purpose of double-stage nitriding is to reduce the depth of the white layer produced on the surface of the case. Except for a reduction in the amount of ammonia consumed per hour, there is no advantage in using the double-stage process, unless the amount of white layer produced in single-stage nitriding cannot be tolerated on the finished part or unless the amount of finishing required after nitriding is substantially reduced. In Fig. 1, the amount of white layer formed during a 25-h double-stage nitriding treatment is compared to that formed during a 24-h single-stage nitriding of the same material.

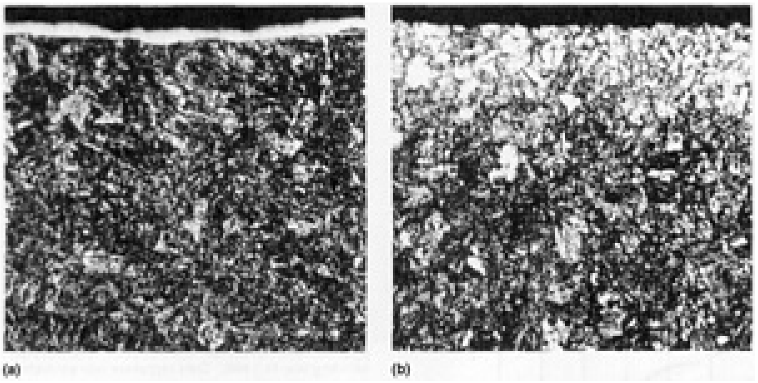

Fig. 1 Microstructure of quenched and tempered 4140 steel after (a) gas nitriding for 24 h at 525 °C (975 °F) with 20 to 30% dissociation and (b) gas nitriding for 5 h at 525 °C (975 °F) with 20 to 30% dissociation followed by a second stage of 20 h at 565 °C (1050 °F) with 75 to 80% dissociation. Both specimens were oil quenched from 845 °C (1550 °F) tempered for 2 h at 620 °C (1150 °F), and surface activated with manganese phosphate before nitriding. (a) Structure after single-stage nitriding 0.005 to 0.0075 mm (0.0002 to 0.0003 in.) white surface layer (Fe_2N), iron nitride, and tempered martensite. (b) The high second-stage dissociation caused absence of white layer, and the final structure had a diffused nitride layer on a matrix of tempered martensite. Both 2% nital. 400×

Figure 2 shows the effect of nitriding time on the depth of case developed on 4140 steel during double-stage nitriding at 525 °C (975 °F) for both stages. Use of a higher temperature during the second stage would have produced a deeper case of slightly lower hardness.

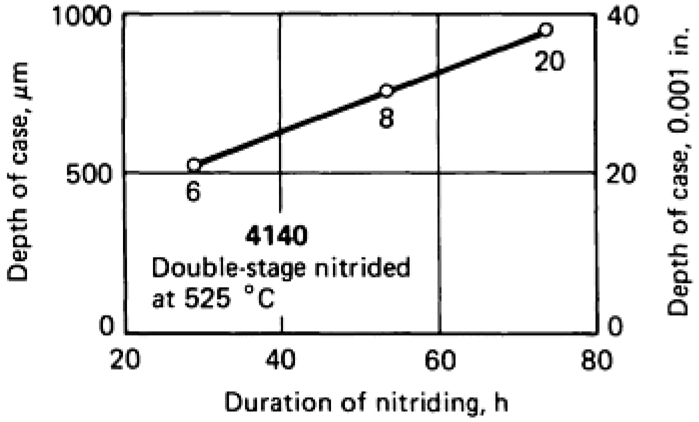

Fig. 2 Depth of case developed on 4140 steel during double-stage nitriding. Numbers indicate hours of nitriding at 15 to 25% dissociation. Remainder of cycle at 83 to 85% dissociation

Hardness gradients obtained in double-stage nitriding of SAE 7140 (AMS 6470) are shown in Fig. 3. The hardness results shown in Fig. 3(a), 3(b), and 3(c) were obtained by grinding off progressively increasing amounts of case to form steps on which HR-15N readings were made. Data for Fig. 3(d), 3(e), and 3(f) were obtained from microhardness measurements, converted to HRC equivalents. Similar data, for double-stage nitriding of AMS 6475, are shown in Fig. 4.

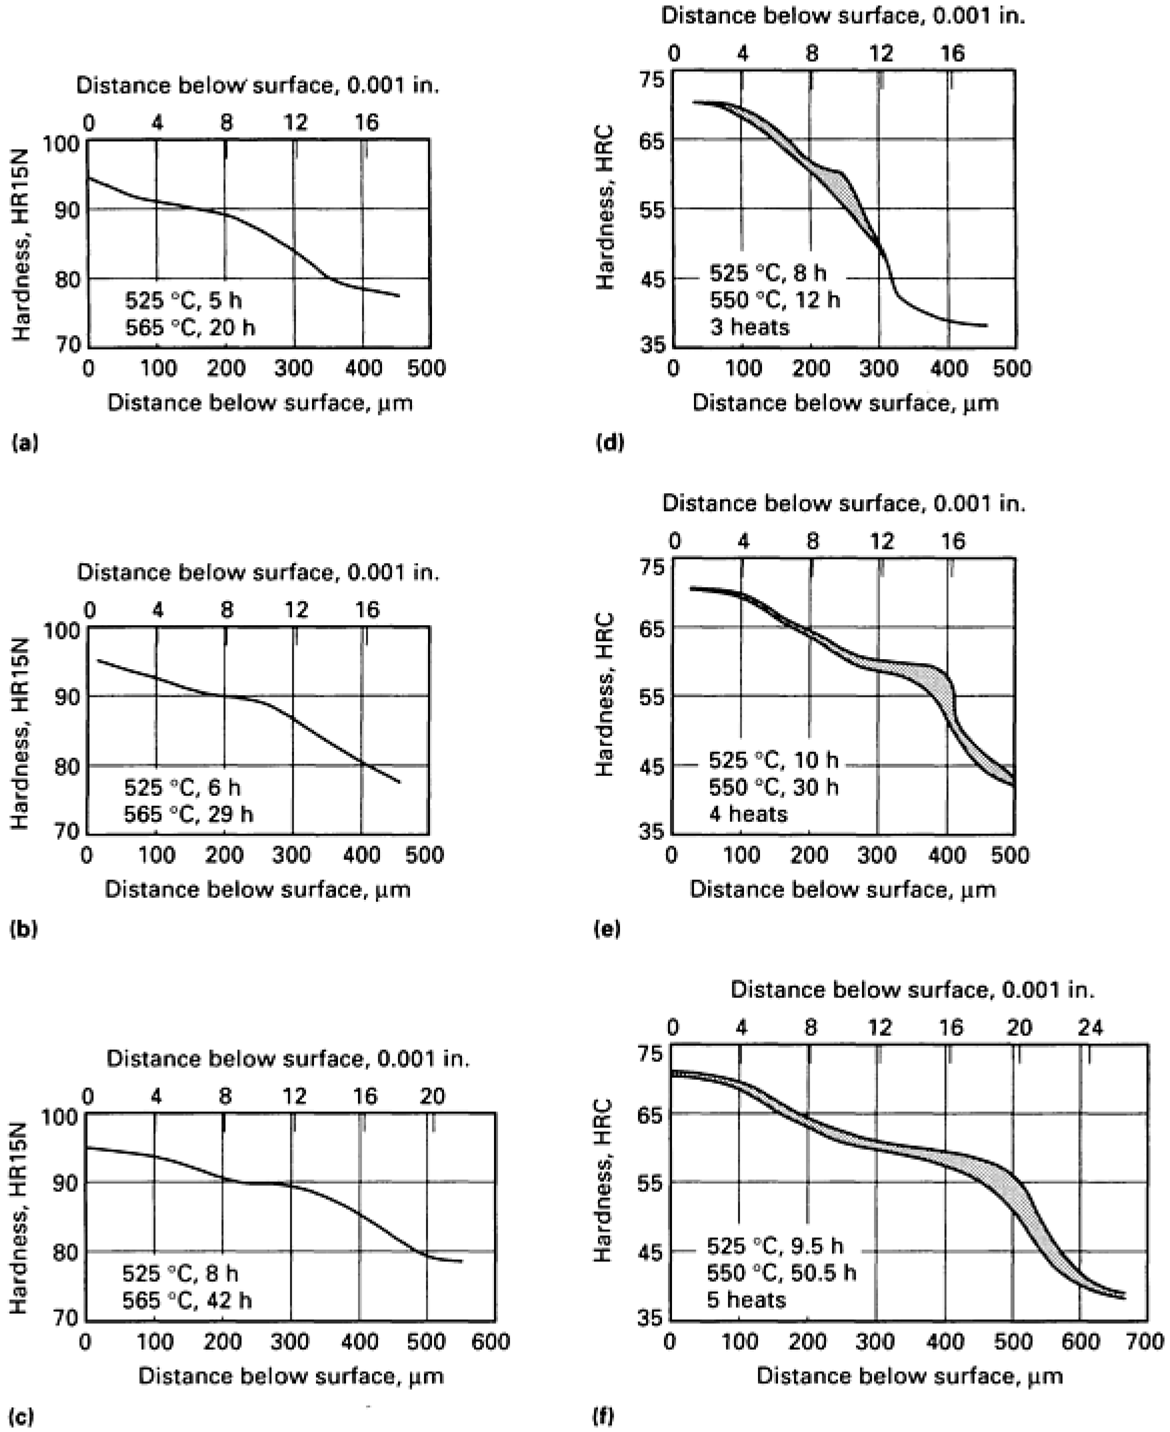

Fig. 3 Hardness gradients for double-stage nitrided SAE 7140 (AMS 6470) steel. (a)-(c) Material nitrided with dissociation rates of 15 to 20% during first stage and 60 to 70% during second stage. (d)-(f) Material nitrided with dissociation rates of 25 to 28% during first stage and 75 to 80% in second stage. Material produced by consumable-electrode vacuum-arc-remelting method

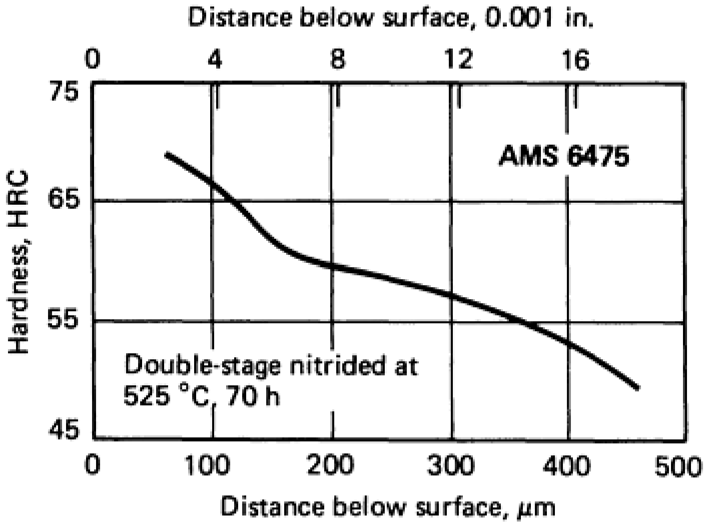

Fig. 4 Hardness gradient obtained for double-stage nitrided AMS 6475 steel. HRC hardness numbers were obtained by conversion from diamond pyramid hardness measurements. Core hardness after nitriding was 41.5 HRC. Data represent one air-melted heat of AMS 6475.

To summarize, the use of a higher temperature during the second stage:

- Lowers the case hardness
- Increases the case depth
- May lower the core hardness depending on the prior tempering temperature and the total nitriding cycle time
- May lower the apparent effective case depth because of the loss of core hardness, depending on how effective case depth is defined

Operating Procedures

After hardening and tempering, and before nitriding, parts should be thoroughly cleaned. Most parts can be successfully nitrided immediately after vapor degreasing. However, some machine-finishing processes such as buffing, finish grinding, lapping, and burnishing may produce surfaces that retard nitriding and result in uneven case depth and distortion. There are several methods by which the surfaces of parts finished by such methods may be successfully conditioned before nitriding.

One method consists of vapor degreasing parts and then abrasive cleaning them with aluminum oxide grit or other abrasives such as garnet, or silicon carbide, immediately prior to nitriding. Any residual grit must be brushed off before parts are loaded into the furnace. Parts should be handled with clean gloves.

A second method consists of preoxidizing the parts in an air atmosphere at approximately 330 °C (625 °F). This may be done as a separate operation, or it may be incorporated as part of the heating portion of the nitriding cycle if suitable precautions are taken.

Furnace Purging

After loading and sealing the furnace at the start of the nitriding cycle, it is necessary to purge the air from the retort before the furnace is heated to a temperature above 150 °C (300 °F). This prevents oxidation of parts and furnace components, and, when ammonia is used as the purging atmosphere, avoids production of a potentially explosive mixture. Nitrogen is preferred in place of ammonia for purging, but the same precautions should be taken to avoid oxidation of parts, except when preoxidation is intentionally included as part of the cycle.

A typical purging cycle using anhydrous ammonia follows:

- Close furnace and start flow of anhydrous ammonia gas at as fast a flow rate as is practical with first

step

- Set furnace temperature control at 150 °C (300 °F) simultaneously. Heat furnace to this temperature but do not exceed
- When the furnace has been purged to the degree that 10% or less air and 90% or more ammonia are present in the retort, the furnace may be heated to the nitriding temperature

It is not feasible to incorporate preoxidation as part of the cycle unless nitrogen is available as a purging medium at the end of the 320 °C (625 °F) oxidizing stage. *Caution: Under no circumstances should ammonia be introduced into a furnace containing air at 330 °C (625 °F) because of the explosion hazard.*

Purging is employed also at the conclusion of the nitriding cycle when the furnace is cooled from the nitriding temperature. It is common practice to remove the ammonia remaining in the retort with nitrogen to reduce the amount of ammonia that would otherwise be released into the immediate area when the load is removed. Dilution of the ammonia lessens the discomfort to employees working near the furnace. The introduction of nitrogen into the retort can be delayed until the nitrided parts have cooled to below 150 °C (300 °F).

Emergency Purging. If the supply of ammonia is cut off during the nitriding cycle, or if a break occurs in the supply line, there is great danger that air will be sucked into the furnace by the contraction of gases within the furnace. This danger is greatest during the cooling cycle. To guarantee a positive pressure within the furnace, it is general practice to provide an emergency purging system that will pump dry nitrogen or an oxygen-free generated gas into the furnace and maintain a safe pressure. If a generated gas is used, it should be as moisture-free as possible. These purge gases are released directly into the ammonia line by a special system of valves.

If emergency purging facilities are not available, further cooling of the furnace should be prevented. Exhaust and inlet lines should be closed, and if no air has entered the retort, the temperature of the furnace and load should be increased slightly to maintain a positive pressure within the retort. Temperature should be maintained until the break is repaired and the flow of ammonia is restored.

Nitrogen versus Ammonia for Purging. Advantages of nitrogen as a purging gas include its safety, ease of handling, and ease of control. The use of nitrogen, however, requires additional equipment, including piping.

Ammonia requires no additional equipment and is relatively safe when properly handled; *Caution: mixtures of 15 to 25% ammonia in air, however, are explosive if ignited by a spark.*

Dissociation Rates. The nitriding process is based on the affinity of nascent nitrogen for iron and certain other metallic elements. Nascent nitrogen is produced by the dissociation of gaseous ammonia when it contacts hot steel parts. Although various rates of dissociation can be used successfully in nitriding, it is important that the nitriding cycle begin with a dissociation rate of about 15 to 35% and that this rate be maintained for 4 to 10 h, depending on the duration of the total cycle; temperature should be maintained at about 525 °C (975 °F). Typically ammonia is supplied at a flow rate to achieve a minimum of four (4) atmosphere changes in the retort per hour. This initial cycle develops a shallow white layer from which diffusion of nitrogen into the main case structure proceeds.

In most nitriding cycles, dissociation rates vary somewhat, even though the controlling factors--ammonia flow rate, surface area, and nitriding temperature--remain constant. Characteristically, the dissociation rate gradually increases as the cycle proceeds at a constant ammonia flow rate. This increase, however, usually is not enough to affect nitrided case characteristics significantly.

When nitriding with a dissociation rate of 15 to 35%, it is normal to control this rate entirely by the flow rate of ammonia. At a dissociation rate of 75 to 80%, however, it is necessary to introduce completely dissociated ammonia from an external dissociator or nitrogen to ensure adequate positive flow within the furnace.

Furnace Heating and Cooling

For reasons of economy, it is generally desirable to keep the total cycle time as short as possible by heating and cooling as rapidly as the equipment will permit and allowing for the following considerations. It may be an advantage to:

- Limit the heating rate, for example to 55 °C/h (100 °F/h) or slower, to allow time for any residual contaminants on the work and from stop-off paint to be completely expelled before reaching the nitriding temperature
- Both heat and cool at limited rates to minimize temperature gradients throughout large loads or in large and complex parts, and thus to minimize distortion

Many pit-type nitriding furnaces are equipped with a heat exchanger that will accelerate cooling of the furnace and work load at the conclusion of the nitriding cycle. When an external water-cooled heat exchanger is used, the furnace heating elements are turned off when the nitriding cycle is completed, and the furnace temperature is allowed to drop approximately 55 °C (100 °F). At this point, the ammonia flow is approximately doubled, and the cooling water is turned on in the heat exchanger. The circulating blower of the heat exchanger also is turned on, and a gate valve is opened to permit circulation of the furnace atmosphere through the heat exchanger. Extreme care must be exercised to ensure a positive gas flow through the furnace as evidenced by the exit gas bubbles. When gas flow through the furnace has been stabilized, the flow may be reduced to the minimum required for positive pressure. After cooling to 150 °C (300 °F) or below, the furnace may be opened.

Bell-type furnaces may be cooled with a cooling bell that is placed over the sealed nitriding retort after the heating bell has been removed. The following is a typical procedure for cooling a bell-type furnace with either raw ammonia or dissociated ammonia:

- Place cooling bell in position on base
- Insert plug of cooling bell into receptacle
- Turn on bell cooling fan
- Cool furnace and load to not less than 315 °C (600 °F), as indicated on base recorder. Turn off flow of dissociated ammonia, and increase flow of raw ammonia to approximately 1.4 m^3/h (50 ft^3/h)
- When burette reading indicates a dissociation rate of 5% or less and temperature is 120 °C (250 °F) or below, shut off flow of ammonia to furnace and open air valve to furnace. If dissociation rate is 5% or less before temperature falls to 120 °C (250 °F), flow of raw ammonia can be reduced to 1.1 m^3/h (40 ft^3/h) for remainder of cooling time
- Remove cooling bell
- Open air valve to meter; allow 4.2 m^3/h (150 ft^3/h) of air into furnace, and open exhaust valve wide. (Level on manometer will drop nearly to zero)
- Turn off base fan when burette reading increases to 65% dissociation. (*Caution: A mixture of 16 to 25% ammonia in air is explosive. Therefore, fan must be shut off when ammonia level reaches 35%, or 65% burette reading.*) This eliminates hazard from sparks that may be generated by a moving fan
- Continue to purge furnace until burette reading is 95% or higher. (This is not a safety precaution but is done to minimize discomfort to personnel nearby when furnace is opened)
- Close air valve
- Drain oil seal
- Raise retort about 0.3 m (1 ft) and wipe off seal from retort lip before removing retort completely
- Remove the charge from the furnace

Control of Case Depth

Case depth and case hardness, the two criteria most commonly referred to in the control of case properties, vary not only with the duration and other conditions of nitriding, but also with steel composition, prior structure, and core hardness.

Aluminum-Containing Steels. Of the aluminum-containing nitriding steels, the most widely used is SAE 7140 (AMS 6470). Figure 5 indicates the hardness gradients and case depths obtained with this steel, as a function of cycle time and nitriding conditions. Results were obtained in single-stage nitriding for various lengths of time up to 800 h and at temperatures ranging from 510 to 540 °C (950 to 1000 °F); several different dissociation rates are represented. The 800-h specimens were nitrided in 11 consecutive 72-h periods. It is apparent that the rate of nitriding decreases over extended periods of time; the case depth obtained after 800 h is only about three times that obtained in 100 h.

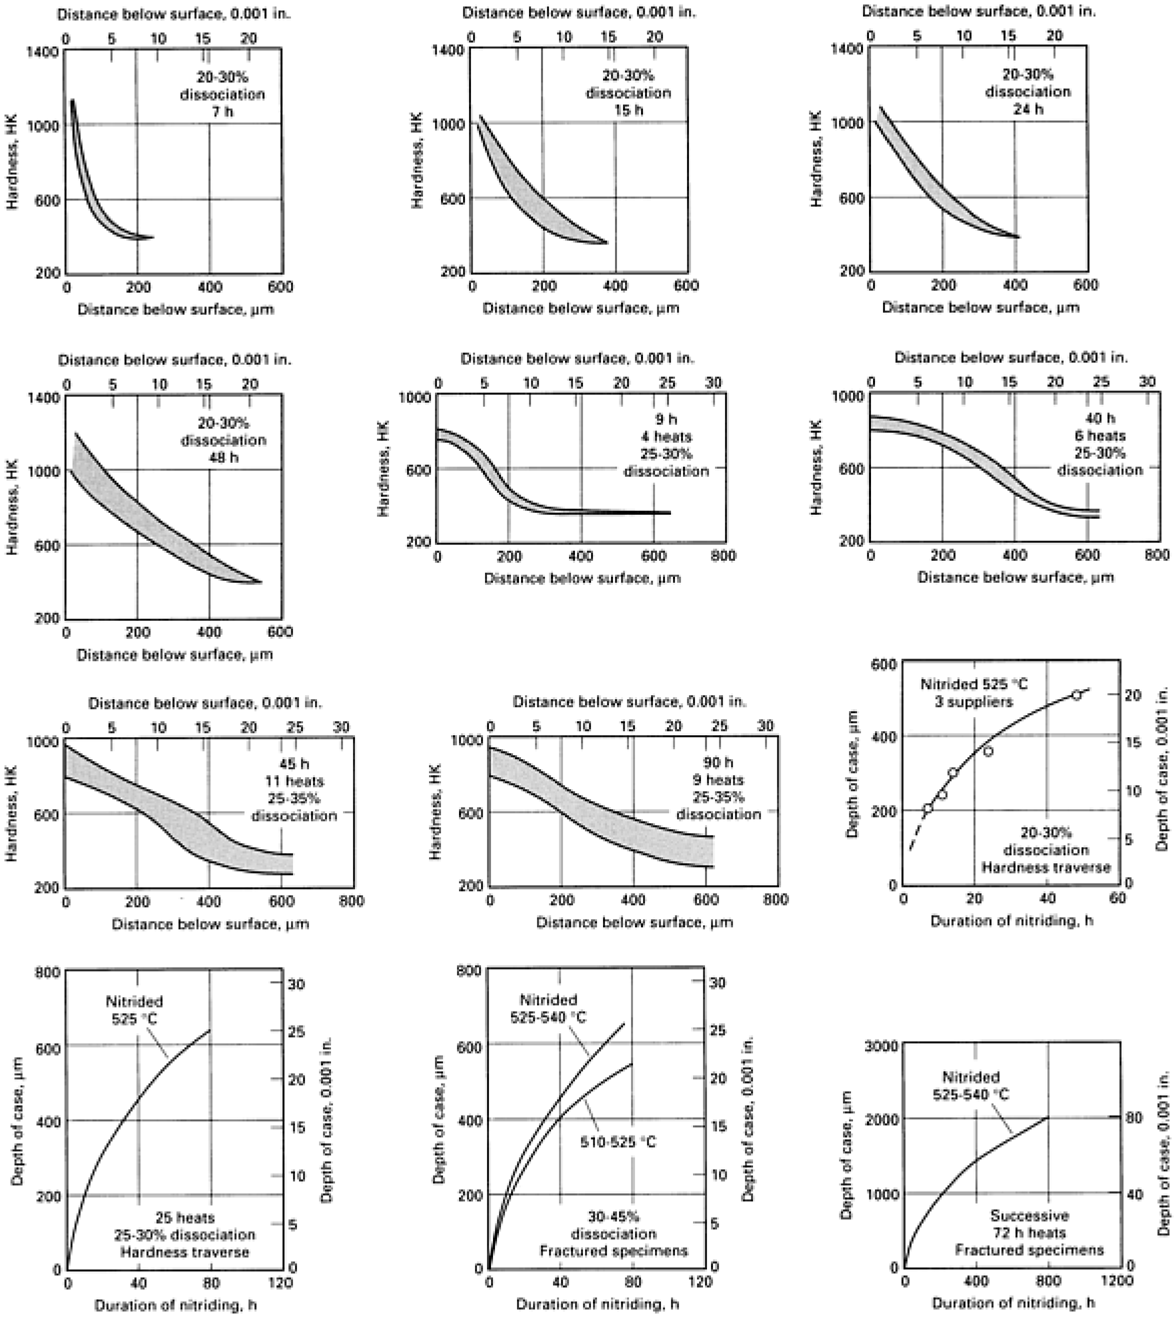

Fig. 5 Hardness gradients and case depth relations for single-stage nitrided aluminum-containing SAE 7140 steel

Chromium-Containing Low-Alloy Steels. Data relating case depth to nitriding time and conditions for chromium-containing low-alloy steels (principally 4140, 4337, 4340, and 8640) are given in Fig. 6 and 7. Of these steels, 4140 exhibits the best nitriding characteristics because of its higher chromium content and nickel-free composition. Although 4340 develops a heavier case than 8640 in the first 24 h of nitriding, this difference begins to decrease at the end of a 48-h cycle (Fig. 7).

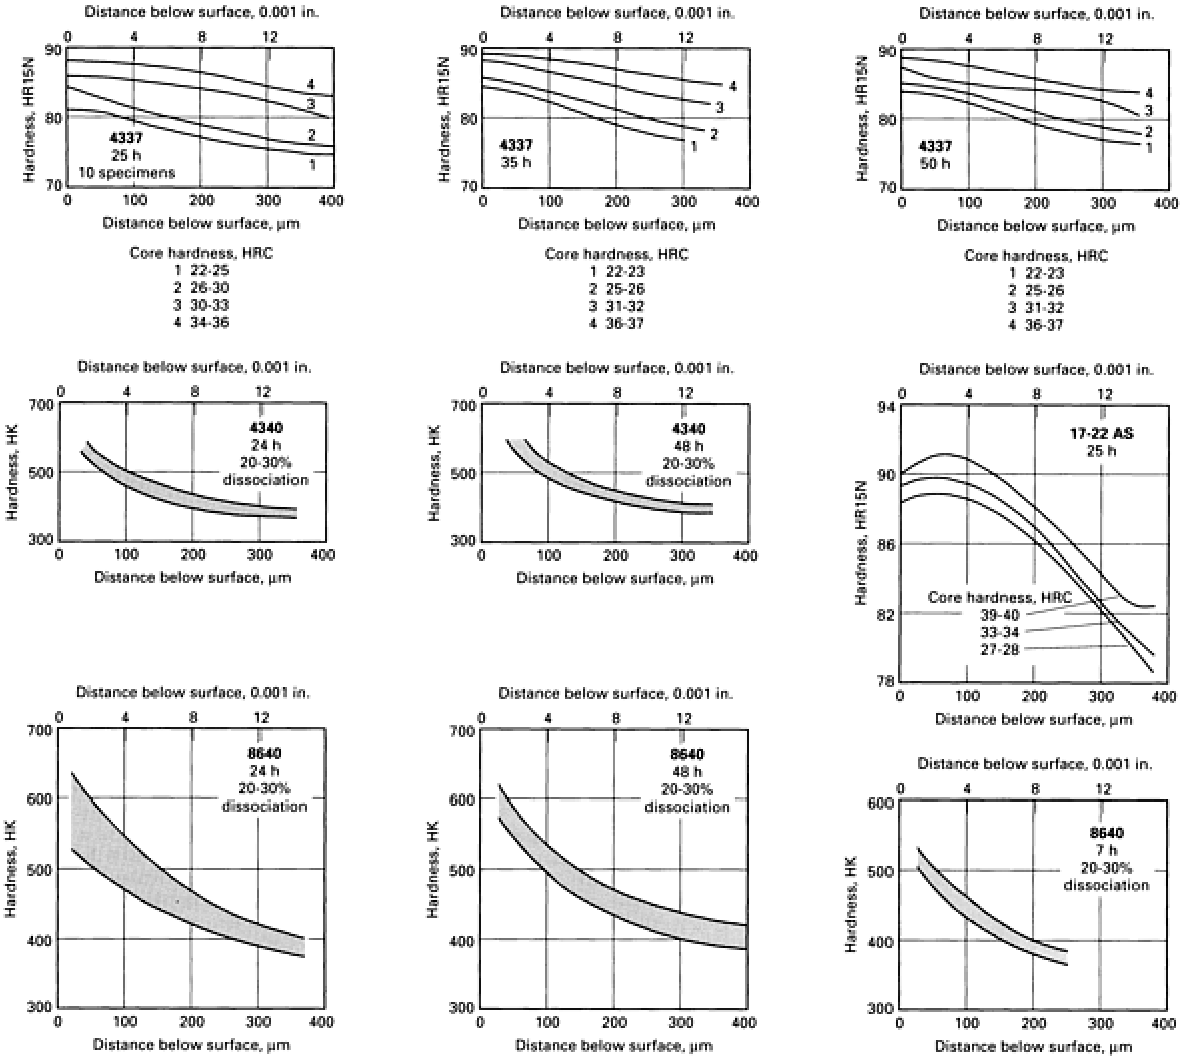

Fig. 6 Hardness gradients for nitrided chromium-containing low-alloy steels

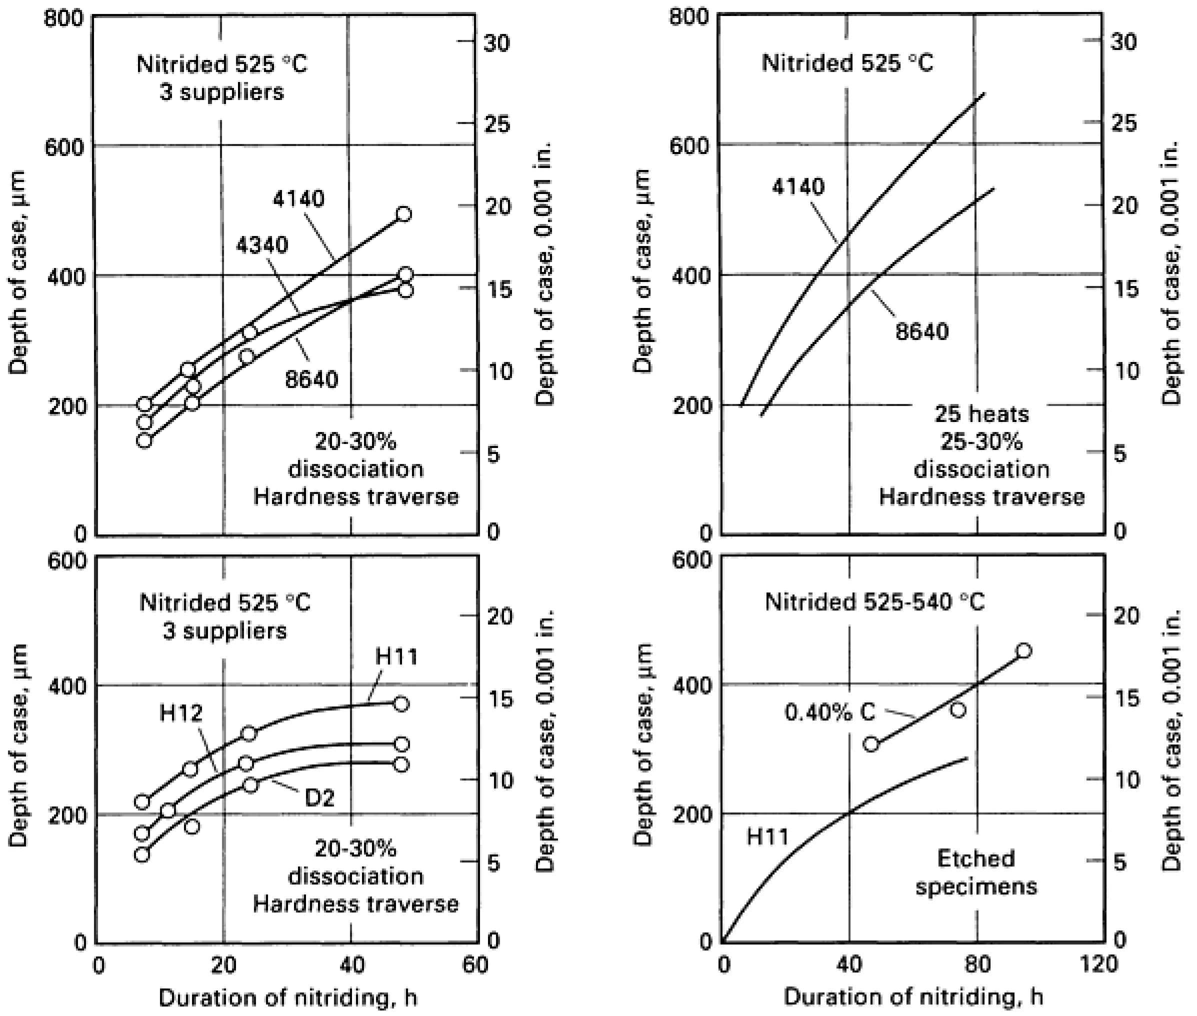

Fig. 7 Depth of case as a function of duration of nitriding for chromium-containing low-alloy and tool steels

Data for the AMS equivalents of 4337 and 4140 (AMS 6412 and 6382, respectively) in Fig. 6 are of particular interest because they demonstrate the effect of core hardness on the hardness of the nitrided case. Core hardnesses as low as 21 to 23 HRC, and as high as 36 to 37 HRC, are considered.

Chromium-containing tool steels such as H11, H12, H13, and D2 provide high core strength with high case hardness, an excellent combination for applications involving severe impact or very high unit loading. Use of these steels is limited primarily by high cost and fabricating difficulties. Case depth results for these steels in single-stage nitriding at 525 °C (975 °F) and at 525 to 540 °C (975 to 1000 °F) are given in Fig. 7. The relatively shallow case depths obtained reflect the retarding effect of increased chromium content on the penetration of nitrogen. Hardness gradients for the same steels are shown in Fig. 8.

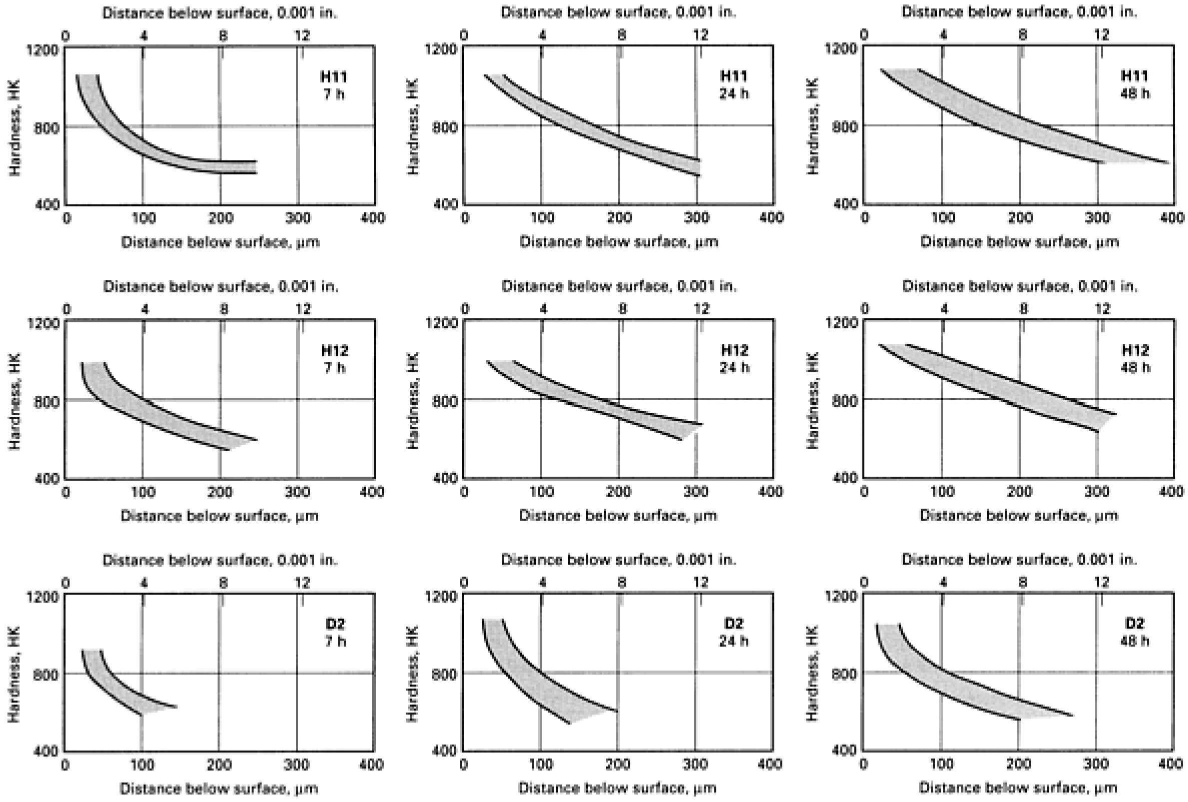

Fig. 8 Hardness gradients for chromium-containing tool steels

Distortion and Dimensional Changes

Distortion in nitriding may result from:

- Relief of residual stresses from prior operations such as welding, hardening, machining, and so forth
- Stress introduced during nitriding due to inadequate support in the furnace, or too rapid or nonuniform heating or cooling
- Stress introduced by the increase in volume that occurs in the case. This change causes a stretching of the core, which results in tensile stresses that are balanced by compressive stresses in the case after the parts have cooled to room temperature. The magnitude of the permanent set in the core and case is affected by yield strength of the material, thickness of the case, and by the amount and nature of the nitrides formed

When the prior manufacturing practice and the mechanics of the nitriding cycle are properly controlled, growth becomes the primary cause of distortion. This is governed largely by composition, tempering temperature, time and temperature of nitriding, relative thickness of case and core, and shape of the part. Growth also is affected when some areas of the part are masked to prevent nitriding.

The amount of growth is usually constant for identical parts nitrided in different batches by a fixed processing cycle. Thus, after the amount of growth for a particular part has been determined experimentally, allowance for it can be made during final machining prior to nitriding. Before experiments are conducted to determine growth, parts must be thoroughly stress relieved.

An example of growth as a function of the wall thickness of hollow cylinders made of Nitralloy 135 is shown in Fig. 9. These data may be used as an approximation in estimating growth when nitriding by the double-stage process. They should be used as a guide for determining size changes only with respect to parts of this design, however; the growth that occurs in solid rounds of bars is of the order of a 0.4 mm (0.0015 in.) increase in diameter.

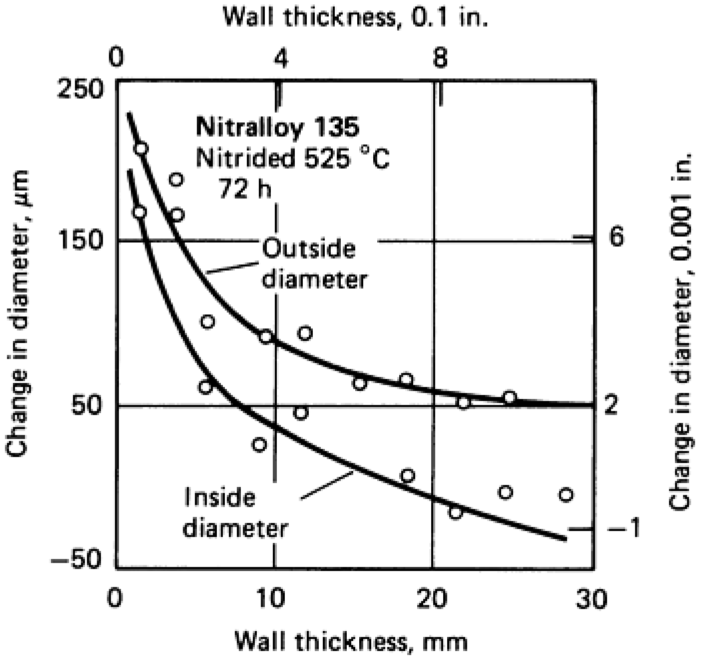

Fig. 9 Growth as a function of the wall thickness of 70 mm (2 $\frac{3}{4}$ in.) diam hollow cylinders double-stage nitrided for 72 h

In some parts, the dimensional changes during nitriding involve both internal and external surfaces. For example, the bore diameter of a 300 mm (12 in.) diam spur gear decreased as much as 0.025 mm (0.001 in.), whereas the overall gear dimension increased up to 0.1 mm (0.004 in.).

Sharp corners or edges should be avoided on parts to be nitrided because the projections formed at sharp corners, as a result of the growth that takes place, are high in nitrogen content and susceptible to chipping. Similarly, sharp edges nitride throughout the section and have no supporting core. When sharp corners are unavoidable, brittleness may be reduced by nitriding one side only, if the other side is not a wearing surface. Frequently, the problems of growth are eliminated by nitriding only those surfaces that will be subject to wear in service.

Stabilizing Treatment. In nitrided parts, there is a balance between compressive stresses in the case and tensile stresses in the core. If this balance is upset by grinding off a part of the case, slow dimensional changes may occur as the stresses approach equilibrium. (In some instances, slow dimensional changes resulting from stress redistribution during grinding have been erroneously attributed to wear.) To prevent these changes, nitrided parts are first ground almost to the final dimensions, then heated to 565 °C (1050 °F) for 1 h, and finally finish ground or lapped. Parts nitrided and not ground after nitriding have excellent dimensional stability.

Changes in Helix Angle. A sensitive indicator of dimensional changes resulting from heat treating helical gears is the change in helix angle. Accurate and reproducible measurement of helix angle can be made with electronic measuring instruments.

In general, the change in helix angle is greatest on gears with few teeth and negligible on gears with many teeth. For example, the lead of a 13-tooth 5-pitch pinion gear might change as much as 0.0005 mm/mm (0.0005 in./in.) of face in nitriding whereas the lead of the mating 67-tooth gear would not change. Consequently, when gears with few teeth are to be nitrided, the amount of helix angle change should be compensated for in machining the gear teeth.

Example 1: Lead Changes of Helical Gear after Nitriding.

The amount of lead change encountered with a nitrided 13-tooth 5-pitch helical pinion gear made of 4142 steel varied from batch to batch; the depth of case also varied. It was determined that these variations resulted from the use of different nitriding time cycles from batch to batch in an attempt to accommodate different nitriding specifications in the same furnace load. These variations were sufficient to throw the lead dimension of the gears out of tolerance and necessitated reworking of the gears by a costly lapping operation.

Subsequently, when the nitriding cycle was held constant, the gears were produced regularly within the required tolerance. Figure 10 shows the effect of case depth on the lead change of these gears.

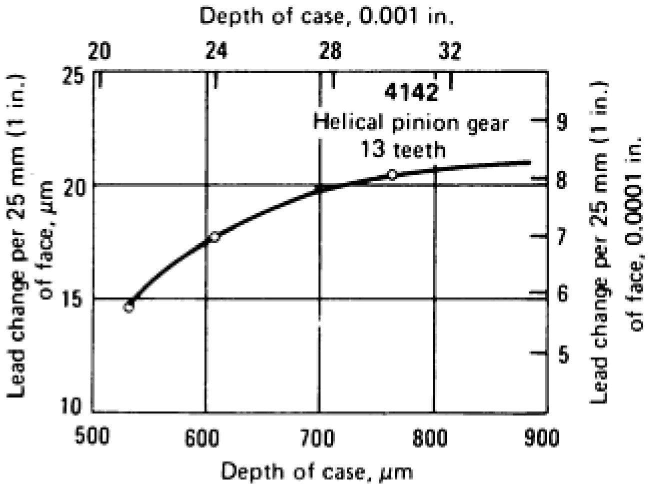

Fig. 10 Increase in lead change with depth of nitrided case for 13-tooth, 5-pitch helical pinion gear. Gears were hardened, tempered at 565 °C (1050 °F), and nitrided in two stages at 525 °C (975 °F) using ammonia dissociation rates of 15 to 25% for the first stage and 83 to 85% for the second stage.

Lead measurements also can be used to determine whether distortion in nitrided gears has been caused by residual stress in the raw material. When there is a sharp increase in the standard deviation, or scatter, of lead measurements after nitriding, the difficulty usually can be attributed to stress relief during the nitriding cycle.

Example 2: Effect of Previous Heat Treatments on Lead Changes after Nitriding.

Shaft pinions made of mill-heat-treated 4150 bar stock were scrapped because of a pronounced increase in deviation of lead measurements after nitriding. An investigation of this problem consisted of machining gears from one third of a lot of material in the as-received condition, stress relieving another third of the material at a temperature 30 °C (50 °F) higher than the nitriding temperature before machining it into gears, and oil quenching from 845 °C (1550 °F), and tempering the last portion before machining; gears of all three prior conditions were then nitrided. Figure 11(a) shows the improvement obtained by proper heat treatment prior to machining and nitriding.

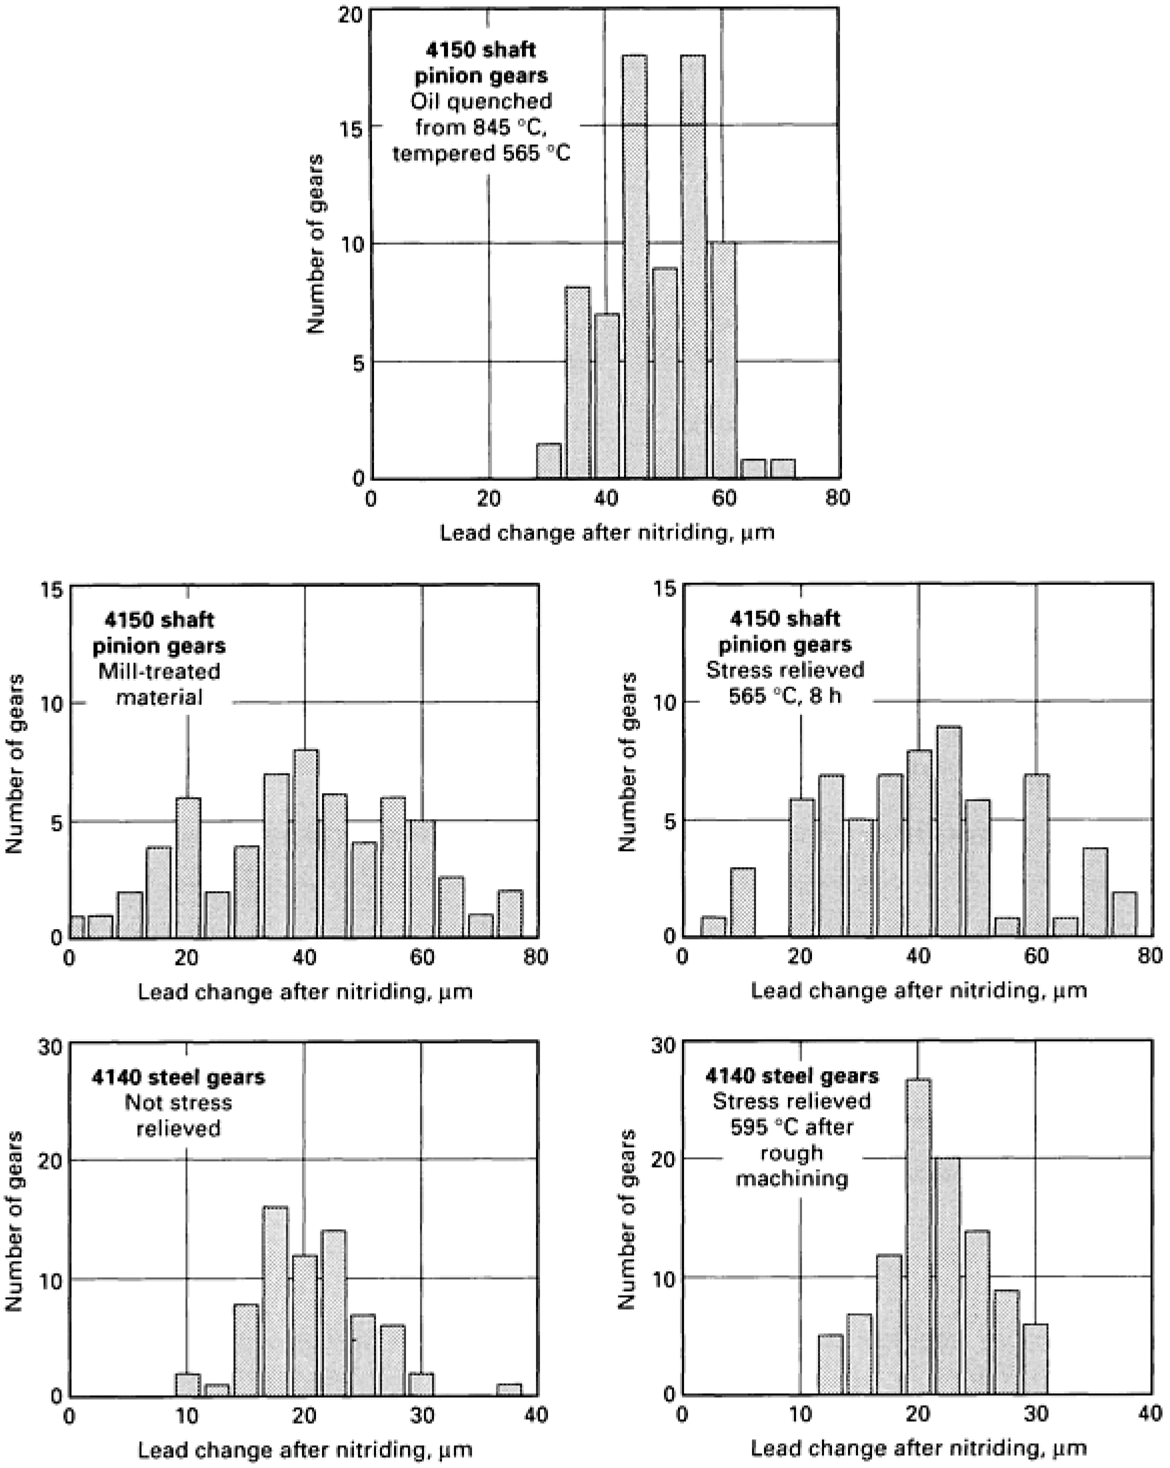

Fig. 11 Effect of stress-relieving treatments on lead change of nitrided gears

Stress Relieving. Many standard procedures require that parts be rough machined, stress relieved, and finish machined before being nitrided. For many parts, this lengthy procedure may not be required.

Figure 11(b), which presents data relating to the lead change in 4140 steel gears after nitriding, illustrates one instance in which little benefit was obtained by the stress relief of rough-machining stresses before nitriding. In general, it has been found that stress relieving after rough machining is required only for slender parts or parts with thin wall sections or large or complex sections, such as large welded gear assemblies. When distortion is caused by the removal of induced machining stresses during nitriding, stress relieving at 620 °C (1150 °F) for 4 h prior to nitriding will lessen or eliminate this problem.

Design Changes. Sometimes components that have been fully stress relieved distort during nitriding. This is usually the result of the high compressive stresses induced by the volume change occurring from the nitriding action itself. Minor

design changes or modification of the production planning of the part to improve the stress balance may prove helpful, as indicated for the parts illustrated in Fig. 12.

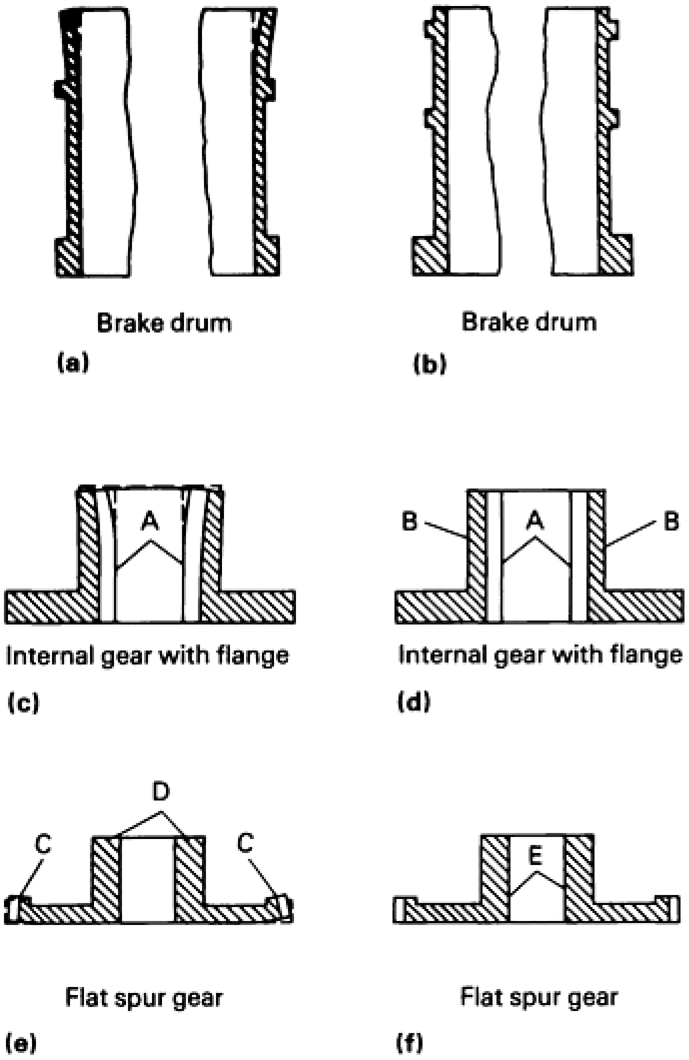

Fig. 12 Minor design changes and modifications of production planning to eliminate distortion during nitriding. (a) Nitriding of ID caused excessive taper past shoulder. (b) Location of original shoulder was changed, and second shoulder was added. (c) Compressive stresses caused gear teeth A to taper during nitriding. (d) Gear teeth A and external surface B were nitrided. (e) Nitriding of gear teeth C and surface D caused warpage. (f) Entire part was nitrided except surface E, which was finished after nitriding.

Finishing Costs. The amount of distortion resulting from nitriding is small compared to that resulting from other case-hardening processes, which involve quenching to form martensite. Consequently, the increased cost of the nitriding operation and of steels suitable for nitriding often can be offset by the savings resulting from finishing to size prior to nitriding.

Example 3: Reduction of Gear Finishing Costs with Nitriding.

One manufacturer realized considerable savings in the cost of producing gears by changing from 4130 steel to AMS 6475 (Nitralloy N). Gears made of 4130 steel were carburized in salt and marquenched in salt at 260 °C (500 °F), and had to be lapped after being treated to eliminate distortion; the Nitralloy gears were nitrided, and lapping was not required. Although the 4130 steel cost less than the Nitralloy, the cost of lapping required for the 4130 gears substantially offset the lower cost of this material. See Table 4 for distortion data for carburized and for nitrided gears of five sizes.

Equipment

Furnaces of several designs are in common use in gas-nitriding installations. Most of these are batch furnaces, which incorporate certain essential features:

- A means of sealing the charge to exclude air and other contaminants while containing the controlled atmosphere
- An inlet line for introducing atmosphere and an outlet line for exhausting used atmosphere
- A means of heating and appropriate temperature controls
- A means, such as a fan, for circulating atmosphere and equalizing temperature throughout the work load

The vertical retort furnace (Fig. 13) is stationary; parts to be nitrided are loaded into a work basket, which is lowered into the heating chamber. The lid rests on an asbestos gasket and dips into an oil-filled trough, thus effecting the seal. Atmosphere enters at the top and leaves at the bottom of the furnace. Cooling is achieved by starting a fan and opening a valve in a water-jacketed cooling manifold. Furnaces of similar design, but without the water-jacketed manifold, are used when rapid cooling as a means of increasing furnace output is not required; the quality of nitriding achieved is equivalent to that of manifolded furnaces.

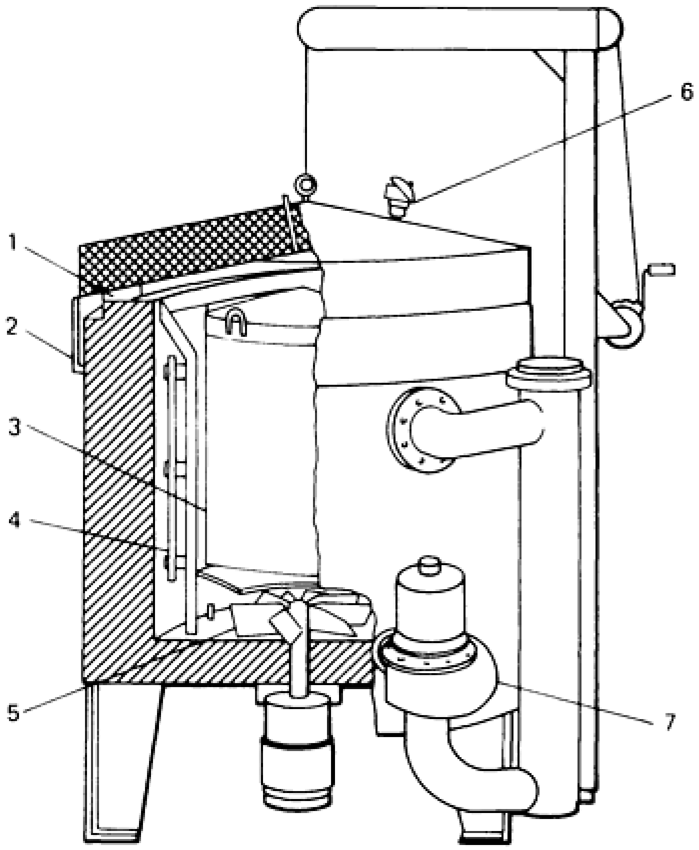

Fig. 13 Vertical retort nitriding furnace. 1, gasket; 2, oil seal; 3, work basket; 4, heating elements; 5, circulating fan; 6, thermocouple; and 7, cooling assembly. At end of cycle, a valve is opened and fan (not shown) incorporated in the external cooler circulates atmosphere through the water-jacketed cooling manifold.

Nitriding has also been successful in sealed vertical retorts without fans. Proper flows and exhaust line pressures are critical to provide sufficient ammonia. Not using the retort fan eliminates a common area of gas leakage and/or air entry.

The bell-type movable furnace (Fig. 14) has a stationary base and is equipped with atmosphere inlet and outlet, control thermocouple, circulating fan, and outlets for electric power and controls. Parts to be nitrided are loaded into work baskets, which are placed on a work support at the furnace base. A retort is lowered over the base and dips into an oil-filled trough, effecting the seal. Heat is provided by a heating bell, which is lowered over the retort and rests at the bottom on a flat portion of the retort. Heat passes through the retort walls and is transferred to the work load by radiation and convection as the atmosphere is circulated. Cooling is achieved by replacing the heating bell with a cooling bell, which draws air up around the retort walls and out at the top of the bell. This air movement is accomplished by a fan in the top of the cooling bell.

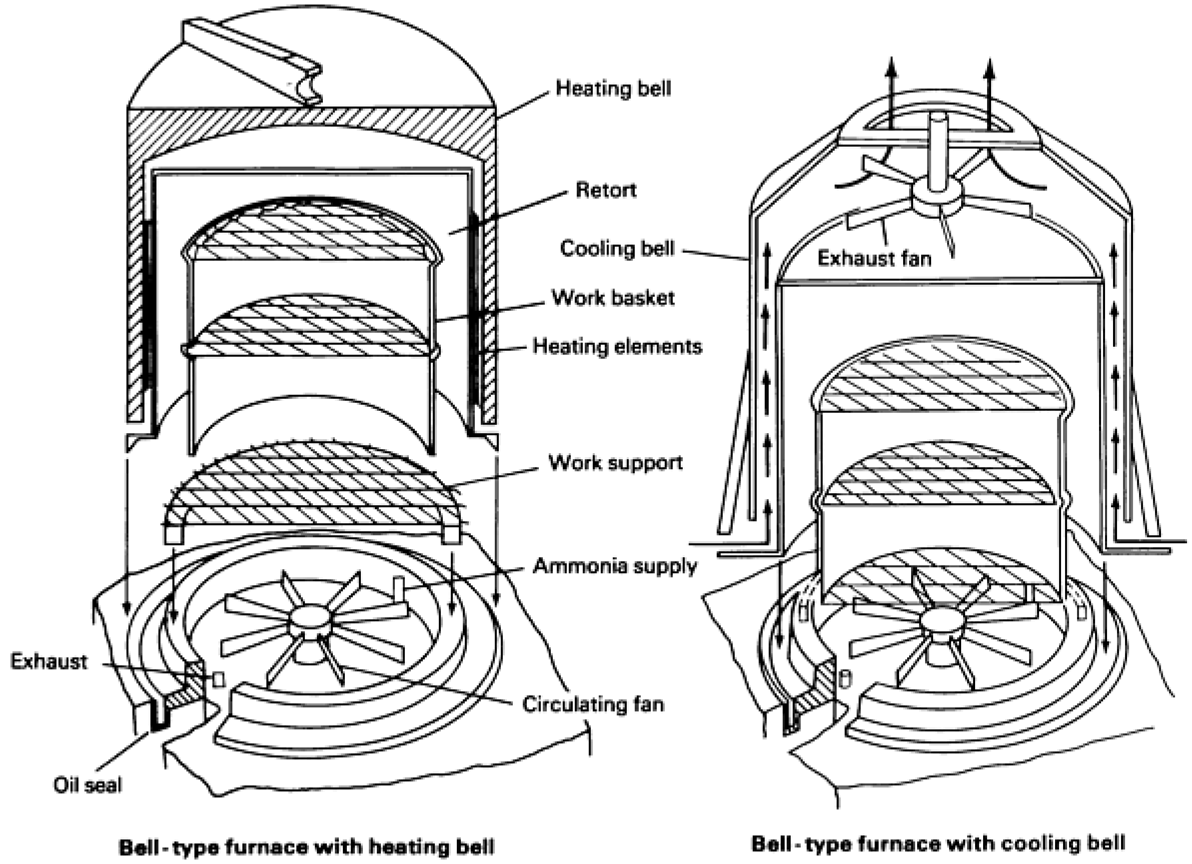

Fig. 14 Schematic of bell-type furnace showing stationary base surmounted by bell

It is customary to provide more bases than heating and cooling bells. This permits more efficient utilization of the bells. A cooling bell is not essential where there is no demand for rapid cooling as a means of increasing output of the base; the quality of nitriding achieved is equivalent to that achieved using a cooling bell, but the heat radiated from the retort can be a source of discomfort to persons working in the immediate area.

Box Furnaces. A box-type movable furnace with two stationary locations for work baskets also has been used for nitriding. Each location is equipped with atmosphere inlet and outlet, control thermocouple, circulating fan, and separate controls. Parts to be nitrided are loaded into baskets, which are placed on a heavy metal plate at each location. A cover is placed over the charge and settles into a groove in the plate that is filled with fine chrome ore, thus effecting the seal. Lugs on the cover fit into a U-shaped holder through which pins are driven to secure the cover to the plate.

The furnace then is moved into position over the charge on rails, after which sliding doors at each end of the furnace are lowered. Heat passes through the walls of the cover and is transferred to the load by radiation and convection as the atmosphere is circulated. When the box furnace has been rolled into position over the work in the basket on the second plate, cooling is achieved for the work on the first plate by transfer of heat to the surroundings, either by natural or forced circulation of air. Usually, natural air circulation is rapid enough to permit cooling and recharging before the box furnace is again available.

Box furnaces of similar design are in use in which the furnace is stationary and the locations for the work loads are movable. The cover that closes over the load is similar to the retort used with the bell-type furnace.

Tube Retorts. In nitriding the inside diameters of tubes, the tube itself may act as the retort after it has been sealed (usually by welded-on covers) at both ends. A calculated volume of ammonia is sealed in the tube (after the tube has been purged of air), and the tube is heated in a suitable furnace. After the heating cycle, the tube is cooled in still or recirculated air, and the covers are removed. Individual parts may be sealed in tube retorts and processed in this same manner (see the section of this article on pressure nitriding).

Temperature Control. Close control of nitriding temperatures is essential to prevent uneven heating and distortion of parts, many of which are finish machined prior to nitriding. Nitriding furnaces are equipped with two thermocouples: one to control and indicate temperature within the load, and another to control the heat source so that it does not exceed a maximum temperature--usually 5 to 15 °C (10 to 25 °F) above the nitriding temperature. These two thermocouples, in conjunction with fan circulation, normally result in control of furnace and load temperature to within ±3 to ±6 °C (±5 to ±10 °F). The override thermocouple arrangement also reduces the likelihood of overheating if the control couple or recorder fails.

Fixtures for nitriding are similar in design to those used in gas carburizing. Under nitriding conditions, ammonia and dissociation products can react chemically with materials in retorts, fans, work baskets, and fixtures. This reaction contributes to further dissociation of ammonia, robs the work of atomic nitrogen, and produces an excess of hydrogen. To reduce this reaction to a minimum, furnace parts and fixtures usually are made of alloys containing high percentages of nickel and chromium (see Table 5). Under certain conditions or after extended use, even these alloys develop a surface that interferes with normal processing; their usefulness can be restored, however, by heating them in an air atmosphere and holding them for a period of time at elevated temperature, followed by sandblasting to remove scale.

Table 5 Recommended materials for parts and fixtures in nitriding furnaces

Materials are recommended on the basis of maximum operating temperature of 565 °C (1050 °F).

Part	Material	
	Wrought	Cast
Retorts[a]	Type 330; Inconel 600	Not usually cast
Fans	Type 330; Inconel 600	35-15 or equivalent
Trays, baskets, fixtures	Types 310, 330; Inconel 600	35-15 or equivalent

(a) Periodic inspection of austenitic stainless steel retorts is mandatory because of embrittlement after long exposures to nitriding. Retorts of 18-8 stainless steel lined with high-temperature glass have been used successfully.

Enamel-coated carbon steel containers are satisfactory as long as the coating remains intact. Some alloys have been coated with high-temperature glass to extend their usefulness.

Low-carbon steel is unsatisfactory as a container material because it absorbs nitrogen, and the nitrided inside surface of the container becomes embrittled. Besides embrittling the container, the nitrided surface also catalyzes the decomposition of the ammonia in contact with it and thereby interferes with the proper nitriding of workpieces.

Equipment Requirements. Typical relations between production requirements and equipment requirements for gas nitriding loads of parts weighing less than 0.5 kg (1 lb) each and parts weighing from 0.5 to 5 kg (1 to 10 lb) each are given in Table 6. These data apply to single-stage nitriding at 525 °C (975 °F) for periods of 24 and 48 h, respectively.

Table 6 Typical equipment requirements for single-stage gas nitriding

Item	Parts less than 0.5 kg (1 lb) each	Parts from 0.5 to 4.5 kg (1 to 10 lb) each
Production requirements		
Pieces per cycle	800	300
Weight of pieces, kg (lb)	170 (375)	910 (2000)
Purging time, h	2	$2\frac{1}{2}$
Heating time, h	1	$1\frac{1}{4}$
Nitriding time, h	24	48
Cooling time, h	2	$2\frac{1}{2}$

Total cycle, h	29	$54\frac{1}{4}$
Equipment requirements		
Size of furnace	0.2 m^3 (6.7 ft^3)	0.5 m^3 (17 ft^3)
Retort dimensions	610 mm (24 in.) diam by 660 mm (26 in.) deep	710 mm (28 in.) diam by 1220 mm (48 in.) deep
Temperature	525 °C (975 °F)	525 °C (975 °F)
Electric supply:		
Elements	30 kW	48 kW
Motor, hp	1	3

Table 7 lists processing details and correlates production and equipment requirements for the single-stage nitriding of 5.3 kg (11.7 lb) transmission ring gears to a depth of 0.2 mm (0.008 in.).

Table 7 Requirements for nitriding transmission ring gears to a depth of 0.2 mm (0.008 in.)

Cycle	
Purge with raw ammonia	1.5 h
Heat to 525 °C (980 °F)	3.0 h
Nitride at 525 °C (980 °F) (40% dissociation)	32.0 h
Purge with ammonia and cool	2.0 h
Purge with air and continue cooling	1.5 h
Total cycle time	**40.0 h**
Production requirements	
Load weight	1340 kg (2950 lb)
Weight of each piece	5.3 kg (11.7 lb)
Total fixture weight	670 kg (1470 lb)
Pieces processed per hour	$7\frac{1}{2}$ (avg)
Furnace requirements	
Furnace	Electric bell-type batch
Hearth size	1525 mm (60 in.) diam, 1800 mm (71 in.) height
Heat input rate	360,000 kJ/h (340,000 Btu/h) (360 MJ/h, or 100 kW)
Temperature	530 °C (980 °F) (650 °C, or 1200 °F max)
Atmosphere equipment	
Ammonia dissociator capacity	2.8 m^3/h (100 ft^3/h)
Source: 3785 1 (1000 gal) tank for liquid NH_3 vaporizer	
Average ammonia consumption	
Purging	4.2 m^3/h (150 ft^3/h)
Nitriding	1.75 m^3/h (62 ft^3/h)

Ammonia Supply

Gas nitriding makes use of anhydrous liquid ammonia (refrigeration grade, 99.98% NH_3 by weight), which is available either in cylinders or in bulk (tank truck, trailer transport, and tank car). A typical, storage-tank installation with 1050 kg (2300 lb) capacity is shown in Fig. 15. Such a tank is replenished directly from a tank truck or tank car. Layouts for ammonia installation and engineering data pertaining to their operation and maintenance may be obtained from suppliers of ammonia.

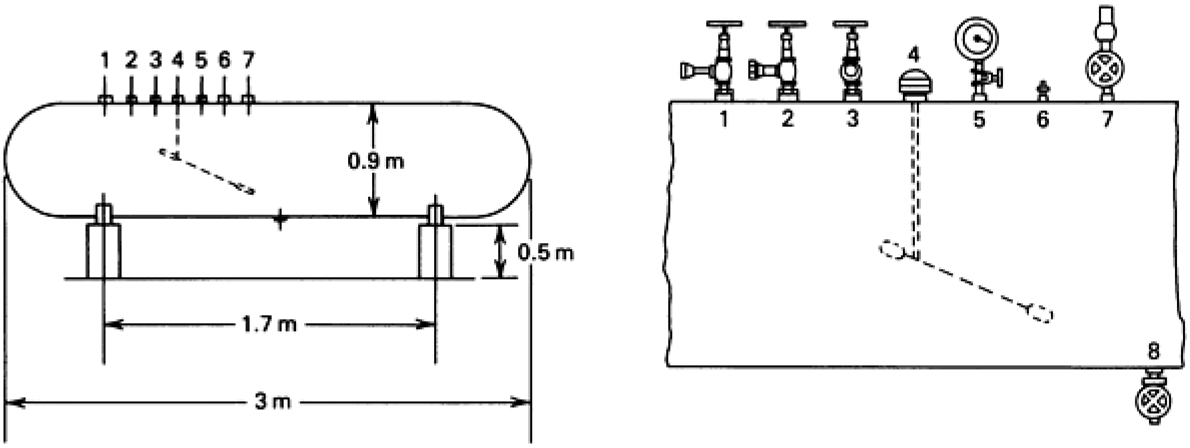

Fig. 15 Typical anhydrous ammonia storage-tank installation of 1045 kg (2300 lb) capacity. 1, pressure-equalizing valve; 2, liquid inlet valve; 3, gas outlet valve; 4, liquid level float gage; 5, pressure gage; 6, fixed level gage; 7, pressure-relief valves (2); and 8, liquid outlet valve

Usually a storage tank is situated outside the building in which the nitriding equipment is located. At moderate outdoor temperatures, the liquid ammonia will absorb enough heat from the atmosphere to vaporize and fulfill gas requirements. On very hot days, the pressure of the gas may build up enough to actuate the pressure-relief valves. On the other hand, when temperatures are below -7 °C (20 °F) or when very large volumes of gas are being used, an additional heat source is needed. This heat may be supplied by an electric immersion heater automatically actuated by gas pressures. Such a heater is started when gas pressure falls below 690 kPa (100 psi) and is stopped when a pressure of 1035 kPa (150 psi) is attained.

Special Precautions. To avoid leaks, exceptionally good pipe-fitting practice must be followed. Specific pipe-joint compounds must be used. One type of compound contains fine powdered lead, which is mixed in an insoluble, nonsetting lubricant; another type is an oxychloride mixture with graphite, which in setting, expands to form a very hard seal. When properly applied, certain high-strength, corrosion-resistant tapes also are satisfactory, as are welded joints.

Materials used for valves, piping, gages, regulators, and flow-measuring devices are similar for all installations; only iron, steel, stainless steel, and aluminum can be used because ammonia corrodes zinc, brass, and bronze. Piping should be made of extra-heavy black iron (except for vent lines, which may be made of standard-weight black iron or galvanized iron). Fittings should be made of extra-heavy malleable iron or forged steel. Valves should be made of steel and should be of the high-pressure, back-seating type.

Pressure Regulation. Ammonia gas from the supply tank or cylinder bank is under pressures up to 1380 kPa (200 psi), depending on the temperature of the gas. This pressure is reduced to about 14 to 105 kPa (2 to 15 psi) by means of pressure regulators.

Another reduction may be made just ahead of each furnace or dissociator to about 255 to 1015 mm (10 to 40 in.) water column, or an adequate pressure to supply from 1 m^3/h (approximately 35 ft^3/h) or more in small furnaces, to 40 m^3/h (1500 ft^3/h) on very large furnaces. Such supply lines are arranged to feed from a common line operating in manifold fashion at pressures not exceeding about 10 kPa (1.5 psi). Equipment to obtain this last reduction may be furnished with the dissociator or furnace.

The flow of gas into furnaces or dissociators is regulated by a suitable needle valve and is measured by a device such as a flowmeter. This device also serves to permit a visible check that gas is moving through the lines. Flow and pressure may be monitored by contact points that close and sound an alarm at predetermined settings. On very large furnaces where high gas flows may be required, it is desirable to manifold the gas downstream of the flowmeter and introduce it into the furnace at several locations, so as to prevent a local cool spot at a single point of entry.

Exhaust Gas. Depending on the stage of the cycle, the exhaust gas may contain air, air and ammonia, or ammonia plus hydrogen and nitrogen. Because of the variable composition of exhaust gas and the customary use of only a single exhaust line, the exhaust gas should be conducted to the outside atmosphere and released at as high an elevation as is practical. Terminating the exhaust line inside a building may be considered when all of the following conditions can be met:

- Nitrogen is used as the purge gas during heating and cooling
- The exhaust gas is flared (burned) at the terminal during the nitriding cycle
- The building is well ventilated so that nitrogen does not accumulate

Note that environmental considerations may dictate a more sophisticated approach to handling exhaust gas.

To provide a slight back pressure within the furnace, an oil-containing bubble bottle or water bubbler may be installed in the exhaust line. As an alternative, a throttle valve installed in the exhaust line may be used to restrict the flow of exhaust gases and maintain a slight back pressure in the furnace. This pressure is indicated on a manometer (water type) and maintained at about 25 to 50 mm (1 to 2 in.) water column.

Suitable piping and valves should be installed in the exhaust line to permit gas flow through a dissociation burette. See the "Appendix" of this article for analysis of exhaust gas procedures. Because water absorbs ammonia, dissociation checks must be made before the gas enters a water bubbler. If a throttle valve is used, gas can be sampled ahead of the valve and returned to the exhaust line past the valve.

Safety Precautions

Anhydrous ammonia is flammable with a narrow range; *Caution: concentrations of 15 to 25% ammonia in air produce explosive mixtures.* Ammonia is classified as a nonflammable compressed or liquefied gas by the Interstate Commerce Commission and is shipped under a green label. Because of the high coefficient of expansion of liquid ammonia, all containers must be filled in accordance with Department of Transportation (DOT) regulations to allow for this expansion in the event of temperature rise.

Dry ammonia is not corrosive to iron or steel and therefore entails no problems of internal corrosion in storage containers or piping. Moist ammonia in contact with air, however, is corrosive, and leaks in any portion of the system must be avoided. All storage containers, valves, and piping should be examined periodically for signs of external corrosion. Corrosion-preventive coatings should be applied to all parts of an ammonia storage or distribution system.

Ammonia gas is not harmful at low concentrations, and because of its pungent odor, leaks are readily noticed. Leak detection, using sulfur dioxide or sensitized papers, is simple and positive.

Ammonia constitutes a potential panic hazard. Because of the discomfort resulting from traces of ammonia in air, adequate ventilation and exhaust facilities should always be employed, particularly in enclosed areas. A gas mask approved for use in ammonia atmospheres should always be available for use in the event of bad leaks. Protective clothing, such as gloves, hats, and goggles, also should be provided for emergencies.

Ammonia is highly soluble in water. In case of severe leaks, spraying equipment is effective in carrying away the fumes. The gas is lighter than air and will rise; in emergencies, it should be remembered that the area closest to the floor will be lowest in ammonia content.

Hydrogen Hazard. *Caution: Although anhydrous ammonia is classed as a nonflammable gas, it produces considerable amounts of hydrogen (which is flammable) upon cracking. Cracking, or complete dissociation, does not occur in the nitriding furnace, but there is enough hydrogen contained in the exhaust gases to constitute a potential hazard.* Because of the concentrations of hydrogen and ammonia in exhaust gases, these gases must be vented to the outside atmosphere and not into an enclosed area. The exhaust line should never be terminated in a container of water, and it is not good practice to attempt to burn the exhaust gases indoors or outdoors, unless adequate precautions are taken.

Caution: Because of the presence of hydrogen in the nitriding furnace, the furnace should never be opened while it is heated up to nitriding temperature. If it is necessary to remove the work before the furnace has cooled to below 150 °C (300 °F),the furnace must be thoroughly purged with an inert gas, such as nitrogen. Even at 150 °C (300 °F)or below, the furnace should be thoroughly purged with air before it is opened.

Common Nitriding Problems

Some of the problems commonly encountered in nitriding are:

- Low case hardness or shallow case
- Discoloration of workpieces
- Excessive dimensional changes
- Cracking and spalling of nitrided surfaces
- Variations in percentage of ammonia dissociation
- White layer deeper than permitted
- Plugging of exhaust lines and pipette lines

A knowledge of the causes of these problems should be of assistance in avoiding, preventing, or correcting them. A number of possible causes are indicated below.

Low case hardness or shallow case may be caused by the characteristics of the steel or faulty processing. The steel characteristics affecting case hardness and depth include:

- Composition unsuitable for nitriding
- Improper microstructure
- Failure to quench and temper prior to nitriding
- Low core hardness
- Surface passivation, from machining, inadequate cleaning, or foreign matter

In terms of processing, a shallow case or low case hardness may be affected by:

- Excessively low or high nitriding temperature
- Insufficient ammonia flow
- Nonuniform circulation or temperature in furnace
- Prolonged exposure of furnace parts and work baskets to nitriding conditions such as ammonia (burnout required); see section on fixtures
- Insufficient time at temperature

Finally, low case hardness or shallow case may only be apparent--occurring as the result of inaccuracies in testing due to faulty adjustment of equipment, improper preparation or positioning of the test specimen, or the use of a test load excessive for the case depth.

Discoloration of workpieces may be caused by:

- Improper or inadequate prior surface treatment including etching, washing, degreasing, and phosphate coating
- Oil, air, or moisture in the retort

Oil in the retort can occur because of:

- Inadequate cleaning of parts, especially those with deep holes and recesses
- Loss of pressure at seal, or overheating of seal
- Leakage at the base, or other parts, of the furnace

Moisture in the retort can occur because of:

- Leakage from the cooling chamber

- Water being sucked in from water bottle during rapid cooling with inadequate gas flow

Air in the retort can occur because of:

- Inadequate seal
- Leakage due to inadequate sealing around pipes or thermocouple
- Introduction of air to purge ammonia while charge is at or above 175 °C (350 °F)

Excessive dimensional changes may be caused by:

- Inadequate stress relieving prior to nitriding
- Inadequate support of parts during nitriding
- Inappropriate design of parts, including nonsymmetry of design, wide variations in section thickness
- Unequal cases on various surfaces of parts, resulting from *nonuniform conditions* (created by furnace design or manner in which parts are arranged in load) or *variations in absorptive power of surfaces* (resulting from stop-off practices or from variations in surface metal removed, surface finishing technique, or in degree of cleanliness)

Cracking and spalling of nitrided surfaces may be caused by dissociation in excess of 85% and also (especially for aluminum-containing steels) by:

- Design (particularly sharp corners)
- Excessively thick white layer
- Decarburization of surface in prior heat treatment
- Improper heat treatment

Variations in percentage of ammonia dissociation may be caused by:

- Charge being too small for furnace area
- Overactive surface of furnace parts and fixtures
- Leakage or loss of sample from burette
- Change in gas flow caused by buildup of pressure in furnace
- Variations in furnace temperature

White layer deeper than permitted may be caused by:

- Nitriding temperature being too low
- Percentage of dissociation below the recommended minimum (15%) during the first stage
- First stage held too long
- Percentage of dissociation too low during the second stage
- Fast purging with raw ammonia instead of cracked ammonia or nitrogen, above 480 °C (900 °F) during slow cooling

Plugging of exhaust lines and pipette lines is caused by precipitates that are formed by the reaction of ammonia with many of the various chemical compounds commonly present in ordinary domestic water. These precipitates may plug lines and prevent proper sampling, or cause pressure to build up in the furnace by plugging exhaust lines or restricting valve openings.

Enlarging lines or treating them periodically with a dilute acid solution will correct this, especially if the solution is trapped in a low spot and drained. (The use of distilled water, or water of similarly low impurity, also will eliminate this difficulty.)

In some installations, water from pipettes can leak down into exhaust lines, flushing scale and other foreign material into low spots or restrictions and thus plugging the lines. A drop leg to trap such products will reduce trouble from this source, as will reduction of right-angle bends and elimination of pipes smaller than 19 mm ($\frac{3}{4}$ in.) in diameter, where possible.

Selective Nitriding

Many coatings are available as stopoffs to prevent gas nitriding of selected areas. The success of a coating depends on such variables as density and thickness of the coating, adhesion of coating to steel, surface finish of the part, and degree of leakage permitted.

Proprietary paints are effectively used in commercial heat-treating operations. They are also used to touch up other coatings that have been inadvertently removed or damaged during processing. These paints usually consist of a tin base suspended in a vehicle of lacquer, aromatic hydrocarbon, or a water glass. It is important that the constituents be mixed in the proper proportions (thick coatings may run, and thin coatings are not completely effective) and that the paints be applied to uniform thickness. The surface to be painted must be very clean. Ground or polished surfaces may be difficult to wet uniformly with paint.

Plated deposits of bronze or copper are the most common stopoff coatings. Nickel (including electroless nickel), chrome, and silver are effective also, but their higher cost restricts their use to special applications.

Thickness and density of plated coatings are important in determining their effectiveness as stopoffs. Minimum thickness of bronze or copper plate should be 18 μm (0.7 mil) for ground surface finishes of 1.6 μm (64 μin.) or smoother, 25 μm (1.0 mil) for finishes between 1.6 and 3.2 μm (64 and 125 μin.), and 38 μm (1.5 mil) for finishes of 3.2 μm (125 μin.) and rougher. Compared to copper and bronze, nickel is a more effective stopoff; therefore, a thinner coating is permitted.

Electroplated silver is 100% effective when the plate thickness is a minimum of 38 μm (1.5 mil); it is 95% effective even during long nitriding cycles, when as little as 25 μm (1.0 mil) of plate is used.

Surface finish of the base metal also influences the thickness of the coating. A finish of 3 μm (120 μin.) will require a thicker coating than a finish of 1.5 μm (60 μin.). Usually, a finish of 1.5 μm (60 μin.) or smoother is recommended.

Processing Procedures. Several processing procedures are employed to accomplish selective nitriding. One of the most widely used consists of rough machining, plating, machining, or grinding areas to be nitrided, nitriding, then finish machining or grinding wherever required. In another procedure, the areas to be nitrided are masked to prevent plating. When masking is difficult, the plating material is applied to all surfaces and then selectively stripped from the areas to be nitrided.

Fine threads (external or internal) on precision parts can be protected by a tin-lead solder. The threads should be cleaned and coated with a flux containing a tinning compound, then heated slowly until both solder and flux are melted. The excess solder and flux are blown out with compressed air, leaving a coating thin enough so that it does not run during nitriding and does not require cleaning or stripping after nitriding.

When the application does not permit the retention of any protective plate on the finished part after nitriding, selection of the coating is important from the standpoint of subsequent stripping. Copper and silver are the easiest to strip; bronze is more difficult. Nickel is very difficult to remove without detrimentally affecting the part. Stopoff paint residues may be reduced by brushing or washing, or may be removed by lightly blasting with fine abrasives.

Nitriding of Stainless Steels

Because of their chromium content, all stainless steels can be nitrided to some degree. Although nitriding adversely affects corrosion resistance, it increases surface hardness and provides a lower coefficient of friction, thus improving abrasion resistance.

Austenitic and Ferritic Alloys. Austenitic stainless steels of the 300 series are the most difficult to nitride; nevertheless, types 301, 302, 303, 304, 308, 309, 316, 321, and 347 have been successfully nitrided. These nonmagnetic alloys cannot be hardened by heat treating; consequently, core material remains relatively soft, and the nitrided surface is limited as to the loads it can support. This is equally true of the nonhardenable ferritic stainless steels. Alloys in this group that have been satisfactorily nitrided include types 430 and 446. With proper prior treatment, these alloys are somewhat easier to nitride than the 300 series alloys.

Hardenable Alloys. The hardenable martensitic alloys are capable of providing high core strength to support the nitrided case. Hardening, followed by tempering at a temperature that is at least 15 °C (25 °F) higher than the nitriding temperature, should precede the nitriding operation. Precipitation-hardening alloys, such as 17-4 PH, 17-7 PH, and A-286, also have been successfully nitrided.

Prior Condition. Before being gas nitrided, 300 series steels and nonhardenable ferritic steels should be annealed and relieved of machining stresses. The normal annealing treatments generally employed to obtain maximum corrosion resistance are usually adequate. Microstructure should be as nearly uniform as possible. Observance of these prior conditions will prevent flaking or blistering of the nitrided case. Martensitic steels, as previously noted, should be in the quenched and tempered condition.

A special pretreatment for 410 stainless is hardening from a lower-than-normal temperature; this results in a very uniform nitrided case with reduced internal stresses. Cracking or spalling of the case is avoided; formation of brittle grain-boundary carbonitrides is suppressed. Austenitizing at 860 °C (1580 °F), followed by tempering at 595 °C (1100 °F) uniformly distributes carbides and provides low residual stress. Case growth is accommodated by a hardness of about 25 HRC.

Surface Preparation. The nitriding of stainless steels requires certain surface preparations that are not required for nitriding low-alloy steels. Primarily, the film of chromium oxide that protects stainless alloys from oxidation and corrosion must be removed. This may be accomplished by dry honing, wet blasting, pickling, chemical reduction in a reducing atmosphere, or submersion in molten salts, or by one of several proprietary processes. Surface treatment must precede placement of the parts in the nitriding furnace. If there is any doubt of the complete and uniform depassivation of the surface, further reduction of the oxide may be accomplished in the furnace by means of a reducing hydrogen atmosphere or halogen-based proprietary agents. Of course, hydrogen must be dry (free of water and oxygen).

Before being nitrided, all stainless parts must be perfectly clean and free of embedded foreign particles. After depassivation, care should be exercised to avoid contaminating stainless surfaces with fingerprints. Sharp corners should be replaced with radii of not less than 1.6 mm ($\frac{1}{16}$ in.).

Nitriding Cycles. In general, stainless steels are nitrided in single-stage cycles at temperatures from about 495 to 595 °C (925 to 1100 °F) for periods ranging from 20 to 48 h, depending on the depth of case required. Dissociation rates for the single-stage cycle range from 20 to 35%; a two-stage cycle using 15 to 30% in first phase and 35 to 45% in the second phase is also used. Thus, except for the prior depassivation of the metal surface, the nitriding of stainless steels is similar to the single-stage nitriding of low-alloy steels.

Nitriding Results. Hardness gradients are given in Fig. 16 for types 302, 321, 430, and 446. These data are based on a 48-h nitriding cycle at 525 °C (975 °F), preceded by suitable annealing treatments. A general comparison of the nitriding characteristics of series 300 and 400 steels is presented in Fig. 17; the comparison reflects the superior results that we obtained with series 400 steels, as well as the effects of nitriding temperature on depth of case. Data are plotted for single-stage nitriding at temperatures of 525 and 550 °C (975 and 1025 °F). For steels of both series, greater case depths were obtained at the higher nitriding temperature.

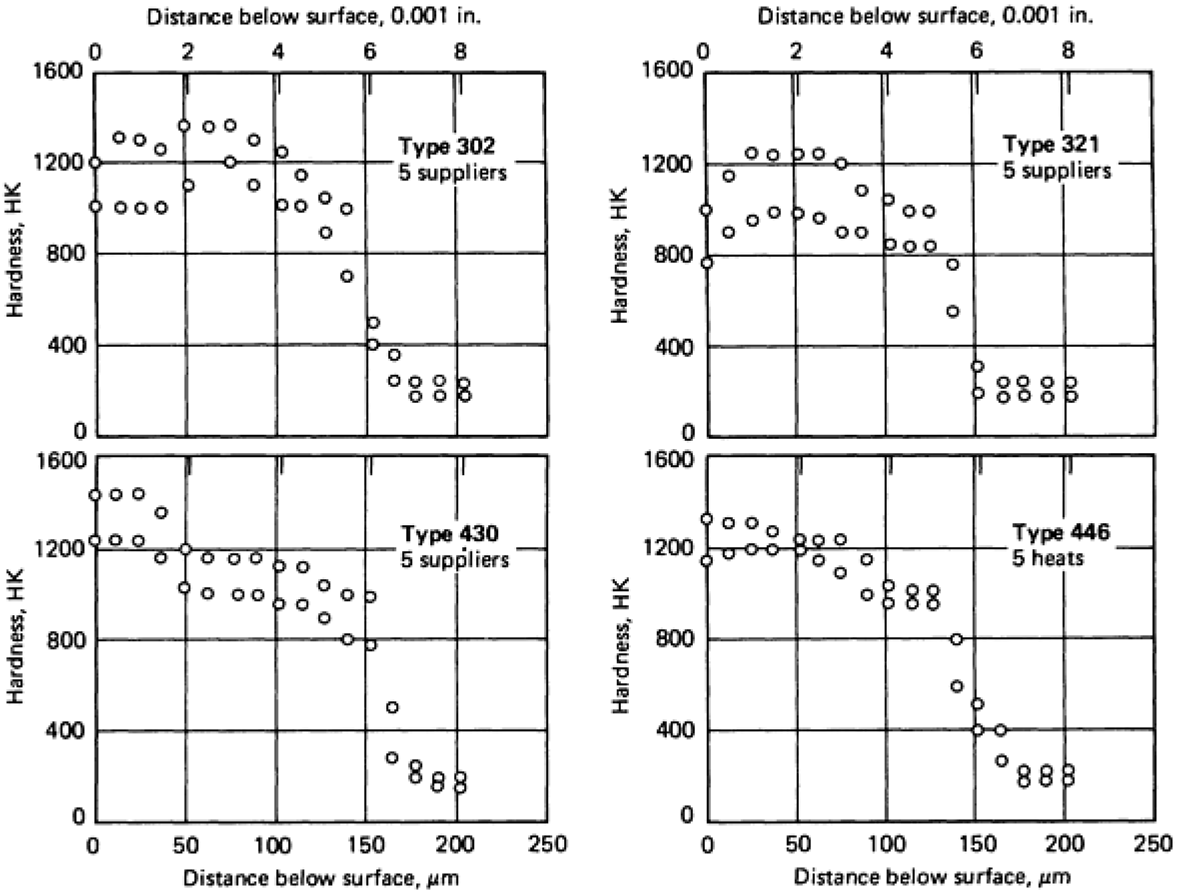

Fig. 16 Hardness range as a function of depth of case for four stainless steels that were annealed prior to nitriding. Annealing temperatures: type 302 and type 321, at 1065 °C (1950 °F); type 430, at 980 °C (1800 °F); and type 446, at 900 °C (1650 °F)

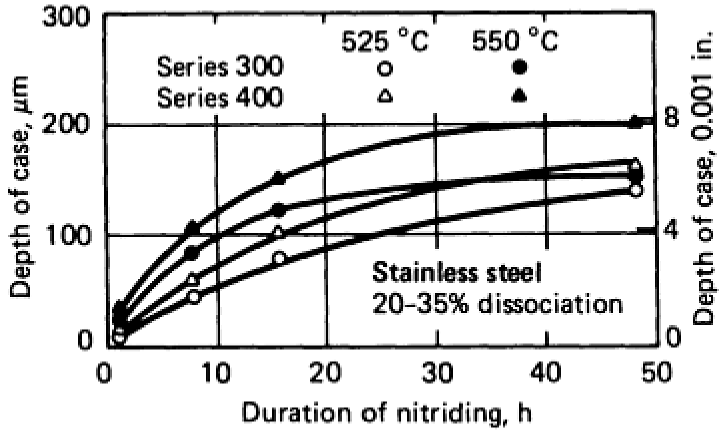

Fig. 17 Comparison of nitriding characteristics of series 300 and 400 stainless, single-stage nitrided at 525 and 550 °C (975 and 1025 °F)

Applications. Although nitriding increases the surface hardness and wear resistance of stainless steels, it decreases general corrosion resistance by combining surface chromium with nitrogen to form chromium nitride. Consequently, nitriding is not recommended for applications in which the corrosion resistance of stainless steel is of major importance. For example, a hot-air valve made of cast type 347 and used in the cabin-heating system of a jet plane was nitrided to improve its resistance to wear by the abrading action of a sliding butterfly. When the valve remained in the closed position for an extended period, the corrosive effects of salt air froze the valve into position so that it could not be opened.

In contrast, a manufacturer of steam-turbine power-generating equipment has successfully used nitriding to increase the wear resistance of types 422 and 410 stainless steel valve stems and bushings that operate in a high-temperature steam atmosphere. Large quantities of these parts have operated for 20 years or more without difficulty. In a few instances, a

light-blue oxide film has formed on the valve stem diameter, causing it to "grow" and thus reduce the clearance between stem and bushing; the growth condition, however, was not accompanied by corrosive attack.

Nitrided stainless is also being used in the food-processing industry. In one application, nitrided type 321 was used to replace type 302 for a motor shaft used in the aeration of orange juice. Because the unhardened 302 shaft wore at the rubber-sealed junction of the motor and the juice, leaks developed within three days. The nitrided 321 shaft ran for 27 days before wear at the seal resulted in leakage. In machinery used in the preparation of dog foods, nitrided type 420 gears have replaced gears made of an unhardened stainless and have exhibited a considerable increase in life.

Modern synthetic fibers, several of which are highly abrasive, have increased the wear of textile machinery. Mechanical parts in textile machines are subjected to high humidity, absence of lubrication, high-speed movements with repeated cycling, and the abrasive action of fibers traveling at high speeds. A shear blade made of hardened, 62 to 64 HRC, 1095 steel experienced a normal life of about one million cuts (four weeks of service) in cutting synthetic fibers at the rate of 90 cuts per minute. In contrast, a nitrided type 410 blade with 0.04 mm (0.0015 in.) case depth showed less wear after completion of five million cuts.

With nitrided stainless steels, the case almost always has lower corrosion resistance than the base material; nevertheless, the corrosion resistance of the case can be adequate for certain applications. For example, nitrided types 302 and 410 stainless steel resist attack from warp conditioner and size in the textile industry but do not resist attack from the acetic acid used in dyeing liquors.

Nitrided stainless is not resistant to mineral acids and is subject to rapid corrosion when exposed to halogen compounds. However, a nitrided type 302 piston lasted for more than five years in a liquid-ammonia pump; it replaced a piston made of an unnitrided 300 series alloy that lasted approximately six months. Nitrided 17-4 PH impellers have performed satisfactorily and without corrosion in various types of hydraulic pumps.

Pressure Nitriding

Pressure nitriding (U.S. Patents 2,596,981, 2,779,697, and 2,986,484) differs from conventional gas nitriding in that it requires the use of a sealed retort capable of withstanding high pressures to contain the parts being nitrided. Nevertheless, it has been determined that within practical limits, depth and quality of case obtained in pressure nitriding depend less on pressure than on the ratio of the available mass of ammonia to the area of the surface presented for reaction with the gas.

Procedure. Surfaces to be nitrided are cleaned and placed in a carbon steel retort that is first evacuated of air and then filled with ammonia to a predetermined pressure. The pressure chosen depends on the total surface area of parts to be nitrided and the volume of the retort. Approximately 50 to 100 g (1.8 to 3.5 oz) of ammonia are supplied per square meter of surface to be nitrided. When only the inside surface of a part is to be hardened, as with carbon steel tubing for bottom-hole oil-well pumps, the tube can act as its own retort. The retort is then heated in any furnace in which temperature can be controlled for the required time cycle, after which the retort can be air cooled, vented, and opened. Precise temperature control is not highly critical.

Advantages. Pressure nitriding provides a convenient method for nitriding part shapes that are difficult to handle by other methods. By varying the amount of ammonia added initially, the thickness of the white layer can be controlled.

Disadvantages include the following:

- Retort sealing is not always convenient
- After 45 h of operation, the ammonia content is about 50% expended, and further development of the case proceeds at a very slow rate
- To restrict the depth of the white layer to 0.00025 to 0.00050 mm (9.8 to 20 μin.), case depth must not exceed 0.50 to 0.63 mm (0.02 to 0.025 in.)
- In filling the welded retort with ammonia, dangerous pressures can develop if a sufficient quantity of ammonia is allowed to condense. This hazard can be avoided by keeping the retort warmer than the ammonia supply tank; however, a safety disk should be provided

Bright Nitriding

Bright nitriding (U.S. Patents 3,399,085 and 3,684,590) is a modified form of gas nitriding employing ammonia and hydrogen gases. Atmosphere gas is continually withdrawn from the nitriding furnace and passed through a temperature-controlled scrubber containing a water solution of sodium hydroxide (NaOH). Trace amounts of hydrogen cyanide (HCN) formed in the nitriding furnaces are removed in the scrubber, thus improving the rate of nitriding. The scrubber also establishes a predetermined moisture content in the nitriding atmosphere, reducing the rate of cyanide formation and inhibiting the cracking of ammonia to molecular nitrogen and hydrogen. By this technique, control over the nitrogen activity of the furnace atmosphere is enhanced, and nitrided parts can be produced with little or no white layer at the surface. If present, the white layer will be composed of only the more ductile Fe_4N (gamma prime) phase.

Pack Nitriding

Pack nitriding (U.S. Patent 4,119,444), which is a process analogous to pack carburizing, employs certain nitrogen-bearing organic compounds as a source of nitrogen. Upon heating, the compounds used in the process form reaction products that are relatively stable at temperatures up to 570 °C (1060 °F). Slow decomposition of the reaction products at the nitriding temperature provides a source of nitrogen. Nitriding times of 2 to 16 h can be employed. Parts are packed in glass, ceramic, or aluminum containers with the nitriding compound, which is often dispersed in an inert packing media. Containers are covered with aluminum foil and heated by any convenient means to the nitriding temperature.

Ion (or Plasma) Nitriding

Since the mid-1960s, nitriding equipment utilizing the glow-discharge phenomenon has been commercially available. Initially termed glow-discharge nitriding, the process is now generally known as ion, or plasma, nitriding. The term plasma nitriding is gaining acceptance.

Ion nitriding is an extension of conventional nitriding processes using plasma-discharge physics. In vacuum, high-voltage electrical energy is used to form a plasma, through which nitrogen ions are accelerated to impinge on the workpiece. This ion bombardment heats the workpiece, cleans the surface, and provides active nitrogen.

Metallurgically versatile, the process provides excellent dimensional control and retention of surface finish. Ion nitriding can be conducted at temperatures lower than those conventionally employed. Control of white-layer composition and thickness enhances fatigue properties. The span of ion-nitriding applications includes conventional ammonia-gas nitriding, short-cycle nitriding in salt bath or gas, and the nitriding of stainless steels.

Ion nitriding lends itself to total process automation, ensuring repetitive metallurgical results. The absence of pollution and insignificant gas consumption are important economic and public policy factors. Moreover, selective nitriding accomplished by simple masking techniques may yield significant economies. For further information on ion nitriding, see the article "Plasma (Ion) Nitriding" in this Volume.

Structure and Properties of Ion-Nitrided Steel. Ion nitriding, like other nitriding processes, produces several distinct structural zones as shown in Fig. 18, which include a light etching layer of iron-nitride compounds at the surface; a gradient zone of fine iron/alloy nitrides, Fe_4N, that constitutes the bulk of the case depth; and a gradient zone of interstitial nitrogen that extends to the parent material.

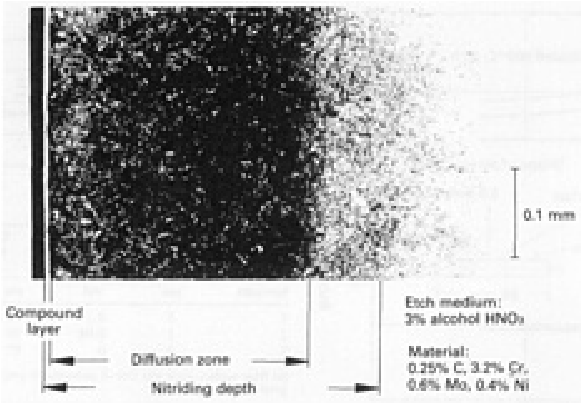

Fig. 18 Microstructure of ion-nitrided steel

The light etching surface layer, commonly termed white layer, has more recently been appropriately named compound zone. The ion-nitriding process offers the possibility of forming a single-phase compound zone with the structure Fe_4N, the gammaprime phase shown in Fig. 19(a). Depth of the gamma-prime compound zone is inherently process limited to about 10 μm (0.0004 in.) maximum. Steels with alloy contents greater than 6 to 8% inherently form compound zones with only thickness.

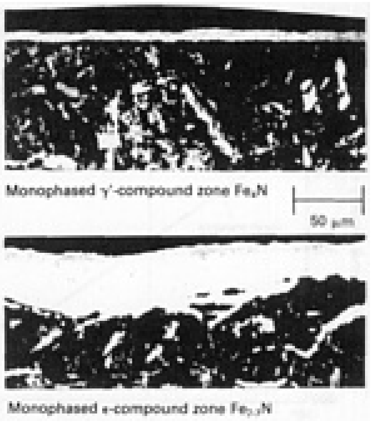

Fig. 19 Photomicrographs showing γ' and ε compound layers. (a) Single-phase γ' compound zone Fe_4N. (b) Single-phase ε compound zone Fe_2N-Fe_3N

Process-gas mixtures free of carbonaceous material are required to form compound zones having the gamma-prime structure. In the limiting condition, a diffusion zone is formed without an overlying compound zone. Gas compositions with less than the commonly used 25% nitrogen can completely suppress compound zone formation.

A shallow gamma-prime compound zone with an underlying diffusion zone is the desired structure for the majority of ion-nitriding applications, particularly where good fatigue properties are important.

Constructional alloy steels, nitriding steels, and tool steels containing nitride-forming alloying elements are used to fabricate workpieces. Nitride-forming elements are aluminum, chromium, molybdenum, vanadium, tungsten, titanium, and niobium. Hardening and tempering are performed prior to nitriding. In common with other nitriding methods, this allows quenching distortion and stresses to be corrected or removed prior to nitriding. Hardened and tempered, the steel has useful core strength and usually is machinable.

Single-phase epsilon iron-nitride compound zones having an Fe_2N-Fe_3N structure, as shown in Fig. 19(b), are formed when the process gas includes a carbonaceous component such as methane. The epsilon structure is slightly harder and less ductile than gamma prime.

Thickness of the epsilon compound zone is not process limited; a zone 50 μm (2 mil) deep can be formed. Industrially, zones 10 to 20 μm (0.4 to 0.8 mil) deep are applied to carbon steels and cast irons where core hardness is usually low. Applications with light loads or broad area contact predominate. In addition to providing increased mechanical strength, the thicker compound zone is a good barrier against corrosion.

Treatment time is typically 2 to 4 h at 570 °C (1060 °F), similar to other short-cycle nitrocarburizing processes. The compound zone is, however, pore-free with low surface roughness.

Comparison of Ion Nitriding and Ammonia-Gas Nitriding Compound Zone Structures. Ammonia-gas nitriding produces a compound zone that is a mixture of both epsilon and gamma-prime structures. High internal stresses result from differences in volume growth associated with the formation of each phase. The interfaces between the two crystal structures are weak. Thicker compound zones, formed by ammonia-gas nitriding, limit accommodation of the internal stresses resulting from the mixed structure. Thickness, internal stresses, and weak crystal boundaries allow the white layer to be fractured by small applied loads.

Under cyclic loading, cracks in the compound zone can serve as initiation points for the propagation of fatigue cracks. The single-phase gamma-prime compound zone, which is thin and more ductile, exhibits superior fatigue properties, as shown in Fig. 20. Reducing the thickness of the ion-nitrided compound zone further improves fatigue performance. Maximization occurs at the limiting condition, where compound zone depth equals zero (Fig. 21).

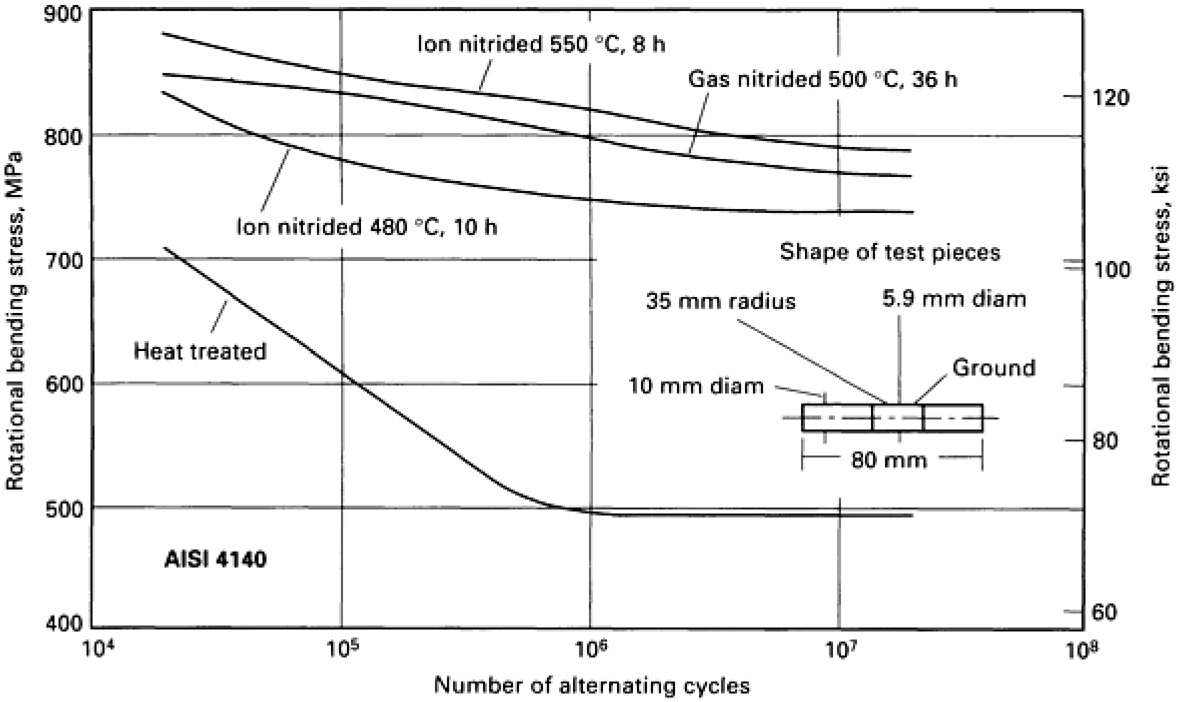

Fig. 20 Influence of nitriding on fatigue strength

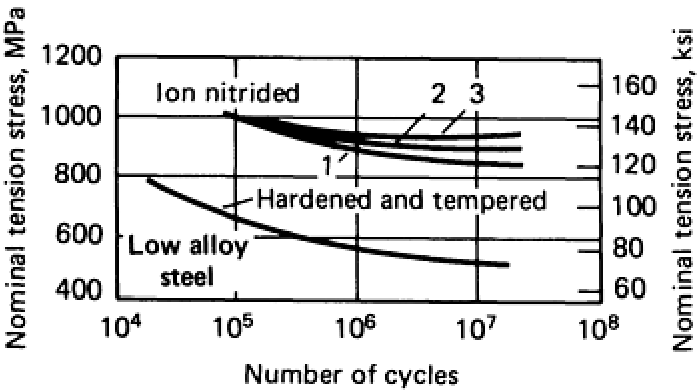

Specimen	Compound zone thickness		Thickness of nitride-free zone(a)	
	µm	mil	µm	mil
1	5	0.2	60	2.4
2	1	0.04	80	3.1

(a) Near-surface zone was free of carbonitride precipitates at the grain boundaries.

Fig. 21 Fatigue strengths of ion-nitrided, quenched and tempered steel specimen (unnotched rotating beam 6 mm, or 0.24 in., diam). See table for zone thickness of specimens.

Case Hardness. The bulk of the thickness of the nitride case is the diffusion zone where fine iron/alloy nitride precipitates impart increased hardness and strength. Compressive stresses are also developed, as in other nitriding processes. Hardness profiles resulting from ion nitriding are similar to ammonia-gas nitriding (Fig. 22), but near-surface hardness may be greater with ion nitriding, a result of lower processing temperature.

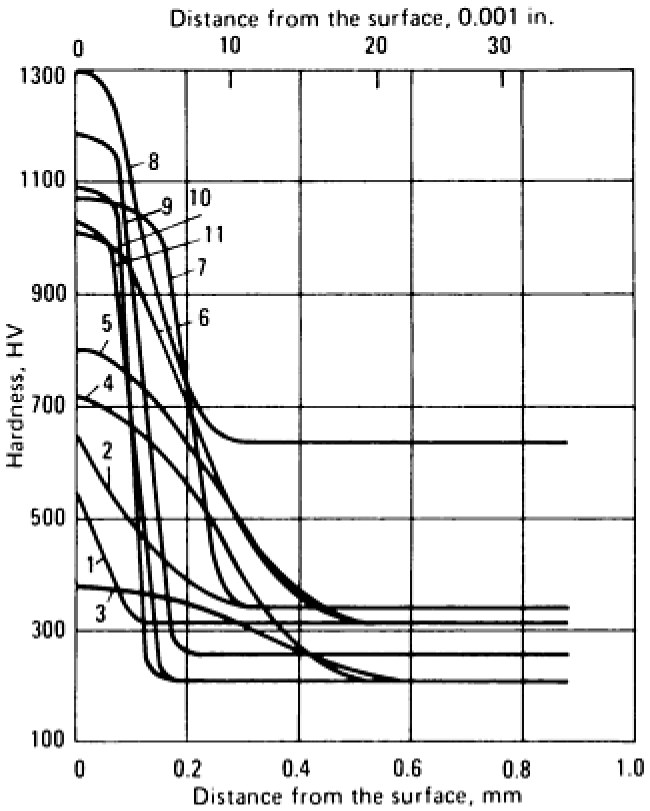

Fig. 22 Hardness profiles for various ion-nitrided materials. 1, gray cast iron; 2, ductile cast iron; 3, AISI 1040; 4, carburizing steel; 5, low-alloy steel; 6, nitriding steel; 7, 5% Cr hot-work steel; 8, cold-work die steel; 9, ferritic stainless steel; 10, AISI 420 stainless steel; 11, 18-8 stainless steel

The concentration and size of alloy nitride precipitates formed, together with parent material hardness, determine the hardness observed in a nitrided case. Figure 23 shows the results of ion nitriding a 0.32C-3Cr-1Mo-0.3V alloy steel at several temperatures, with time held constant. Case depth increases with temperature, and near-surface hardness is maximized near 450 °C (840 °F). Figure 24 shows a similar effect on M2 tool steel quenched and tempered to 62 HRC. Processing at temperatures just above the hardness maximum offers several advantages such as:

- Higher core hardness can be retained by reducing tempering temperatures
- The possibility of distortion is reduced
- Parts with low surface roughness remain virtually unchanged

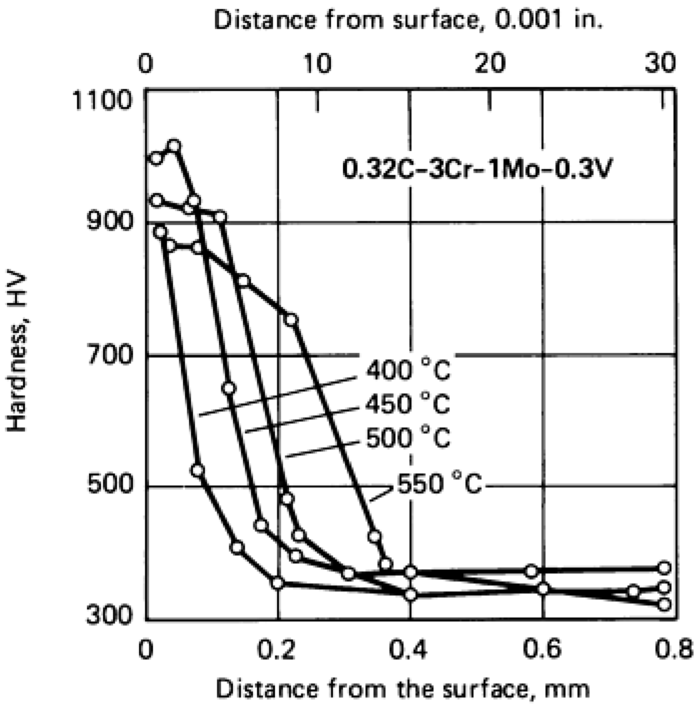

Fig. 23 Influence of treatment temperature on hardness profile

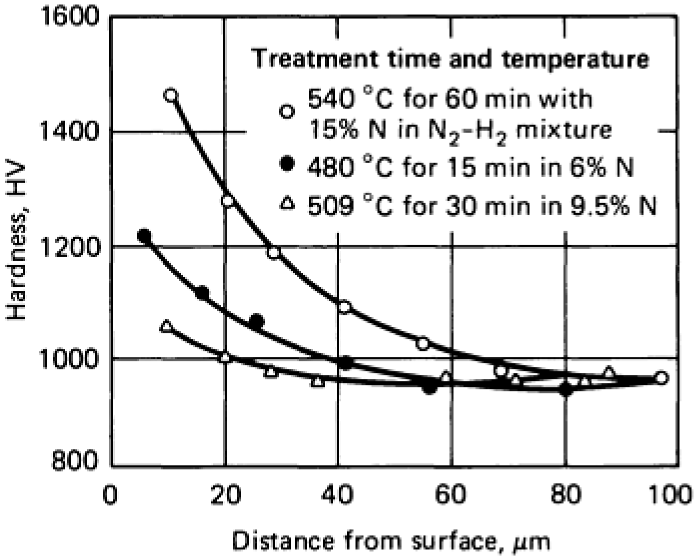

Fig. 24 Microhardness profile of nitrided layer in quenched and tempered M2 tool steel (tempered to 62 HRC) after various plasma nitriding conditions

Advantages and Disadvantages of Ion Nitriding. Ion nitriding achieves repetitive metallurgical results and complete control of the nitrided layers. This control results in superior fatigue performance, wear resistance, and hard layer ductility. Moreover, the process ensures high dimensional stability, eliminates secondary operations, offers low operating-temperature capability, and produces parts that retain surface finish. Among operating benefits are:

- Total absence of pollution
- Efficient use of gas and electrical energy
- Total process automation
- Selective nitriding by simple masking techniques
- Process span that encompasses all subcritical nitriding
- Reduced nitriding time

The limitations of ion nitriding include high capital cost, need for precision fixturing with electrical connections, long processing times compared to other short-cycle nitrocarburizing processes, and lack of feasibility of liquid quenching for carbon steels.

Applications. Among general applications requiring metallurgical properties obtainable by ion nitriding are:

- Structural elements subject to cyclic loading
- Workpieces requiring precision dimensions
- Components subject to sliding wear
- Parts exposed to mild corrosion

Metallurgical properties required by these applications are used frequently in combination for such products as: plastics processing machinery; automotive engine, transmission, chassis, and accessory components; cold-forming tools; and hot-forming tools.

Screws and cylinders for plastic extrusion require close dimensional tolerances. In service, they are subject to high mechanical loads and severe sliding wear. The hot plastic creates abrasive, corrosive, and erosive conditions at various locations along the length. Nitriding steel, pretreated for strength and toughness, receives a hard ductile layer by ion nitriding to meet this demanding service.

Components for Rotary Internal Combustion Engines. Side and middle housings of Wankel engines, made of gray iron, are stress relieved and finish machined prior to ion nitriding. Water passage areas are covered with sheet metal shields, so that only the rotor contact surfaces will be nitrided. Dimensional changes are extremely low, permitting direct use without a refinishing operation.

Similar to the Wankel engine housings are side plates for rotary automotive air-conditioning compressors. Also made of cast iron, they must be extremely flat, with good surface finish, and must be free of contamination. The epsilon layer produced by ion nitriding prevents seizure resulting from adversely hot operation.

Synchronizer components for transmissions are ion nitrided to meet close dimensional tolerances. Conventional techniques such as carbonitriding fail to meet dimensional requirements. A 10 μm (0.0004 in.) thick epsilon layer, with a superficial hardness of 550 HV (5 kg load), is typically produced. Ion nitriding has proved a satisfactory substitute for more expensive chrome plating on automobile shock absorber rods. The required wear and corrosion resistance is provided by an epsilon layer about 10 μm (0.0004 in.) thick.

Reduction gears for marine steam turbines were an early applications of ion nitriding, now firmly established as the preferred nitriding method. Dimensional accuracy and fatigue properties are superior to ammonia-gas nitriding. Nitriding is confined to the tooth area by masking with sheet metal covers. Significant labor economies are achieved.

Deep-drawing punches made of high-carbon, high-chrome steel are subjected to high compressive stresses in service. A core hardness of 62 HRC or higher is required after ion nitriding. Lowering the ion-nitriding temperature to 470 °C (880 °F) allows retention of the core hardness along with the hardness of the surface layer to about 1200 HV. The considerably reduced coefficient of friction results in a great increase in service life.

Hot-forging dies are an important application of ion nitriding. Die life is increased by improved resistance to thermal and mechanical cracking. The surface layer formed reduces the sticking of scale and inclusion of oxides.

Vacuum Nitrocarburizing

There are two main approaches to subatmospheric pressure thermochemical processing. One is known as the glow-discharge method, and the other involves use of conventional cold-wall vacuum furnaces. Because the processes are closely related to ion nitriding, they are discussed in this section. Further data on other types of nitrocarburizing processes are contained in the articles on gaseous ferritic nitrocarburizing.

Ion nitriding, which is being used increasingly as an alternative to conventional gas nitriding in ammonia atmospheres, was the first thermochemical treatment to use the glow-discharge technique. In glow-discharge nitrocarburizing, which is

a simple development of the ion-nitriding process, the components become the cathode of an electrical circuit. They are subsequently subjected to a glow discharge generated by applying a critical voltage between the furnace chamber, which acts as anode, and the components. Consideration of glow-discharge nitriding conditions indicates that a pressure in the range of 20 to 2000 Pa (0.15 to 15 torr) and a critical applied voltage of between 400 and 1000 V should be used.

The metallographic structure of pure iron after treatment in a nitrocarburizing atmosphere at 570 °C (1060 °F) for 15 h is shown in Fig. 25(a). A corresponding concentration analysis is given in Fig. 25(b), where the predominance of the epsilon carbonitride phase is shown.

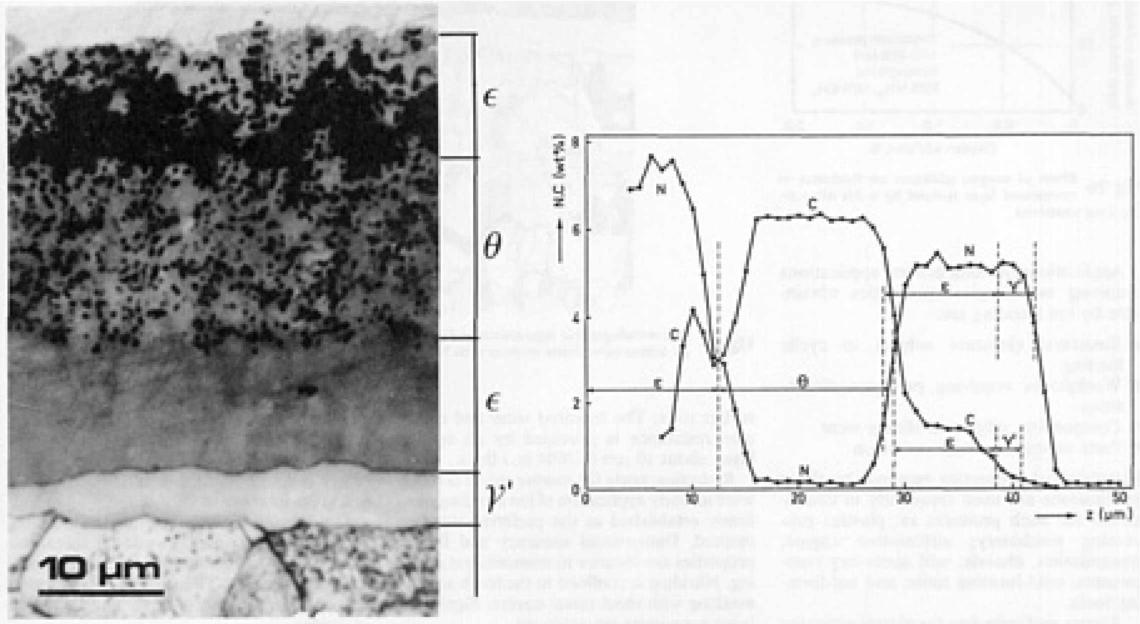

Fig. 25 (a) Compound layers and (b) concentration profiles of iron gas nitrocarburized at 570 °C (1058 °F) for 15 h

Cold-Wall Vacuum Furnaces. Extension of the use of cold-wall vacuum furnaces from purely thermal treatments, such as annealing and sintering, to thermochemical treatments was a natural development following introduction of such furnaces with oil-quench facilities. Although vacuum carburizing has received some attention in the literature, nitrocarburizing in a vacuum furnace is a more recent development. Although there was some evidence that the presence of oxygen gave a marginal improvement in the antiscuffing behavior of the epsilon carbonitride compound layer, the significance of the role of oxygen in the kinetics of compound layer growth was not at all clear.

It had been shown that oxygen was necessary to improve the carbon mass transfer characteristics of hydrocarbon carburizing gases, and that increasing the partial pressure of oxygen in the atmosphere speeded the kinetics of carbon exchange. Similarly, the presence of oxygen had been shown to increase the rate of compound layer formation during conventional gas nitriding. Consequently, with the advent of the capability of absolute atmosphere control using vacuum furnaces, investigations of vacuum nitrocarburizing were also able to evaluate the significance of oxygen in relation to the kinetics of compound layer formation. On the basis of earlier studies on gaseous nitrocarburizing treatments, a basic atmosphere of 50% ammonia/50% methane, containing controlled oxygen additions of up to 2%, was used for experiments in a laboratory vacuum furnace. The experiments were reproduced later using a semicontinuous industrial vacuum furnace. The furnace was evacuated to a pressure of 13 Pa (0.1 torr), and then heated to the process temperature under a low flow rate of ammonia balanced against a rotary vacuum pump to give a pressure of 3900 Pa (30 torr). Once the operating temperature of 570 °C (1060 °F) was reached, the hot zone was reevacuated, and the premixed gases were introduced into the hot zone at a pressure of 52 kPa (400 torr). To avoid either fixed flow patterns or stagnant gas pockets, a pulsed atmosphere technique was employed for the duration of the treatment. This involved pressure cycling between 13 to 52 kPa (100 to 400 torr), with 10-min dwells at 52 kPa (400 torr) throughout the treatment, after which the specimens were oil quenched. As a result of this treatment, a compound layer is formed that has a carbon/nitrogen ratio of about 1:7; it consists predominantly of the oxygen-bearing epsilon carbonitride phase.

Layer thickness formed after a 2-h treatment varies with the oxygen content of the atmosphere. Figure 26 shows the compound zone thickness as a function of the oxygen content of the atmosphere in a nominal 50% methane/50% ammonia atmosphere. The metallographic appearance after a typical subatmospheric treatment with a 1% oxygen addition is shown in Fig. 27. The compound zone shows very little porosity, and its overall metallographic appearance is very

similar to the layer formed by gaseous nitrocarburizing in an atmosphere consisting of 50% ammonia and 50% endothermic gas at a treatment temperature of 570 °C (1060 °F). When oxygen levels of about 2% are used, however, the compound zone is quite porous. Wear properties of AISI 1015 materials treated in this manner have been evaluated by standard Amsler wear tests, the results being compared to results of similar tests with other nitrocarburizing treatments (Fig. 28). Three of the treatments confer similar wear-improvement characteristics on low-carbon steels after a treatment time of 2 h at 570 °C (1060 °F).

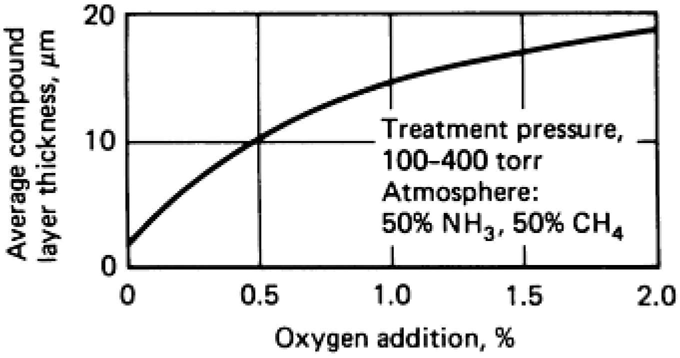

Fig. 26 Effect of oxygen additions on thickness of compound layer formed by a 2-h nitrocarburizing treatment

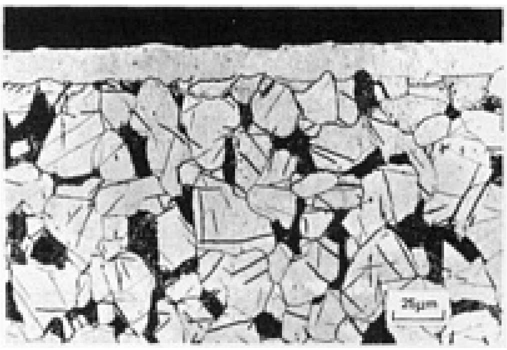

Fig. 27 The metallographic appearance of AISI 1015 material after a 2-h vacuum-nitrocarburizing treatment in an ammonia/methane mixture with 1% oxygen addition

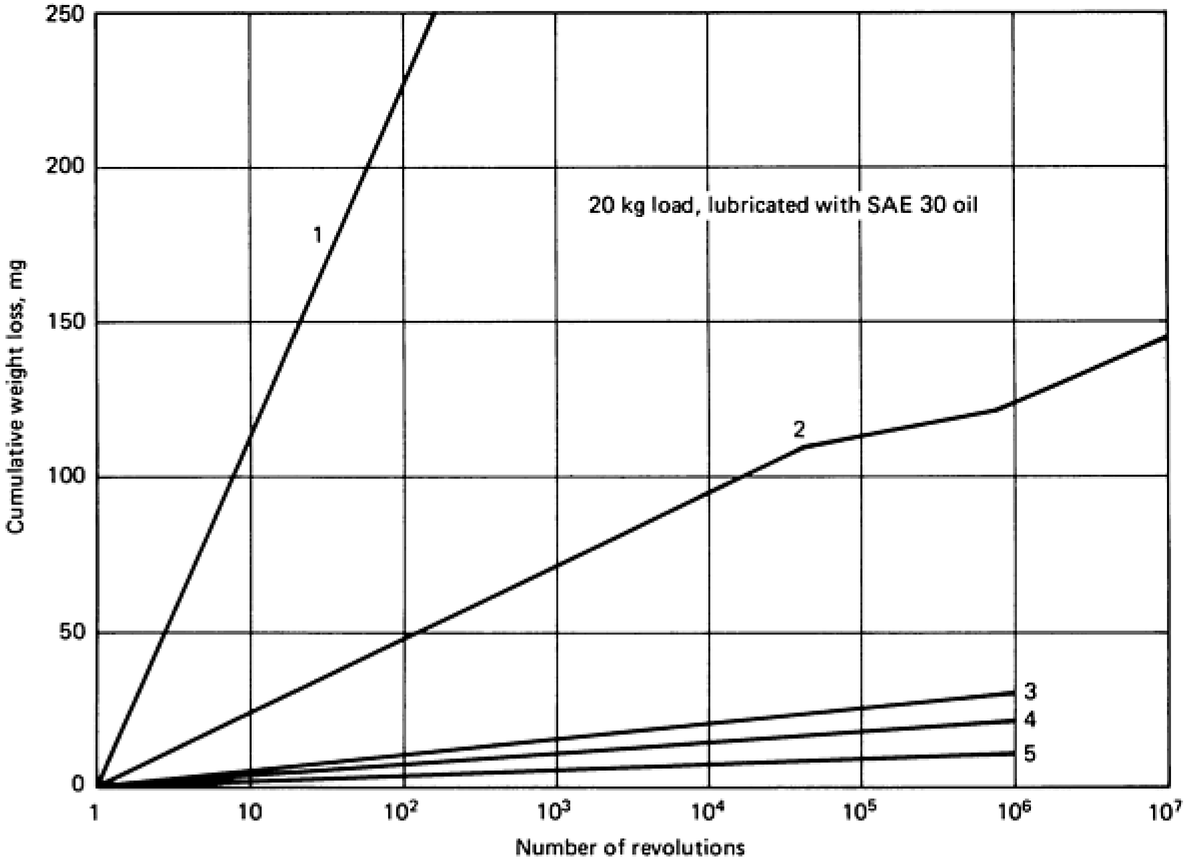

Fig. 28 Comparative Amsler wear tests on AISI 1015 after various ferritic nitrocarburizing treatments. 1, untreated; 2, cyanide-based salt bath nitrocarburizing with sulfur; 3, subatmospheric oxynitrocarburizing; 4, gaseous nitrocarburizing; and 5, cyanide-based salt bath nitrocarburizing (treatment 1)

Hardnesses of compound layers produced by subatmospheric pressure nitrocarburizing are compared (in Table 8) with hardnesses of layers resulting from other treatments. Hardness levels are high considering the ductile nature of the compound zone, and the layer hardness appears to be higher on alloy steel than on plain carbon material.

Table 8 Hardness of nitrocarburized specimens

Material	Treatment	Applied load		Microhardness of compound layer, HV		
		g	oz	Center region	Inner region	Average
Low-carbon steel	Toxic salt	. . .	. . .	. . .	. . .	500-600

Appendix

Analysis of Exhaust Gas from Gas-Nitriding Operations

Ammonia gas is completely soluble in water. When water is introduced into the dissociation pipette (burette) (Fig. 29), any ammonia present dissolves instantly, reducing the pressure within the burette. Water continues to enter the burette until it occupies a volume equivalent to that previously occupied by the ammonia. The remainder of the exhaust gas,

being insoluble in water, collects at the top of the burette. The height of the water level is read directly from the scale of graduations, and this reading indicates the percentage of non-water-soluble hydrogen-nitrogen gas in the sample. If the sample was generated solely by the breakdown of ammonia, this reading is correctly called percent dissociation. When air is present at the start or end of a cycle, however, no ammonia is being dissociated and the resulting reading is not percent dissociation, but percent air. Accordingly, it is proper to subtract the reading from 100% and refer to the remainder as percent ammonia present in the sample.

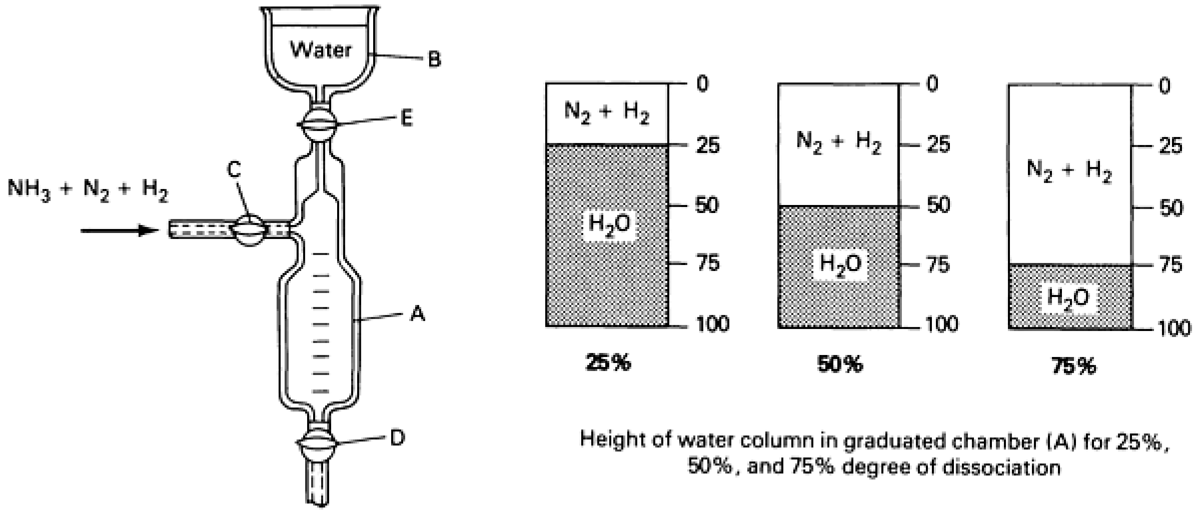

Fig. 29 Dissociation pipette (burette) schematic. To make a measurement, the ammonia gas in the nitriding box is first admitted into A by opening taps C and D. After the air has been expelled, taps C and D are closed. During the measurement, tap E is opened, and the water immediately absorbs the undissociated ammonia. The water takes up precisely the volume previously occupied by the ammonia, but the remaining N_2-H_2 gas (dissociated ammonia) does not dissolve in water.

Inspection and Quality Control

Visual Inspection. It is often evident from a cursory visual inspection that a part, or an isolated surface of a part, is not properly nitrided. Typically, gas-nitrided parts exhibit a uniform dull gray appearance. If surfaces are shiny after nitriding, it is likely that little or no nitrogen was diffused. This assessment should always be checked quantitatively and not assumed.

Indentation tests of the hardness of a nitrided case should be made using relatively light loads, regardless of case depth. These indentation methods include the superficial HR15-N (and to a limited extent, the HR30-N), and the Knoop and Vickers (diamond pyramid hardness, DPH) microhardness tests. The superficial Rockwell test is made on a surface that is ground prior to, and only polished lightly after, nitriding; whereas the Knoop and Vickers microhardness tests are generally performed on cross-sectional specimens that have been metallographically polished. Microhardness tests are generally made with loads of 100 to 500 g (0.2 to 1 lb).

Utilizing lighter loads than the superficial Rockwell test, but greater than are commonly used for microhardness testing, the Vickers test is used extensively in Europe for quality control. Superficial measurements with 2, 5, or 10 kg loads are made directly on nitrided surfaces. Loads in this range accurately reflect surface hardness and require only minimal surface preparation. Good accuracy results from optical measurement necessitated by the small impression.

The superficial Rockwell tests HR15-N or HR30-N should be used to check nitride case hardness. Depending on the depth and hardness of case present, as well as core hardness, it is possible for the diamond indenter to penetrate the case. This results in a misleading composite hardness of both case and core. When this occurs (usually if case is less than 0.13 mm, or 0.005 in.), microhardness testing should be used.

Because of metal flow or spalling, it is difficult to determine accurately by microhardness methods the case hardness at depths of less than 0.025 mm (0.001 in.) from the surface of a cross-section specimen, even when light loads are applied. For this reason, surface hardness is commonly measured by the HR15-N test; the values obtained may be converted to Knoop or Vickers values in accordance with the conversion table given in ASTM E 140.

Comparison of Hardness Measurements. When results of HR15-N and Knoop tests are compared, Knoop hardness is generally found to be higher than the equivalent HR15-N hardness of the higher-hardness portion of the depth of case measured from the nitrided surface, whereas the opposite is experienced for the lower-hardness portion of the case (see Fig. 30).

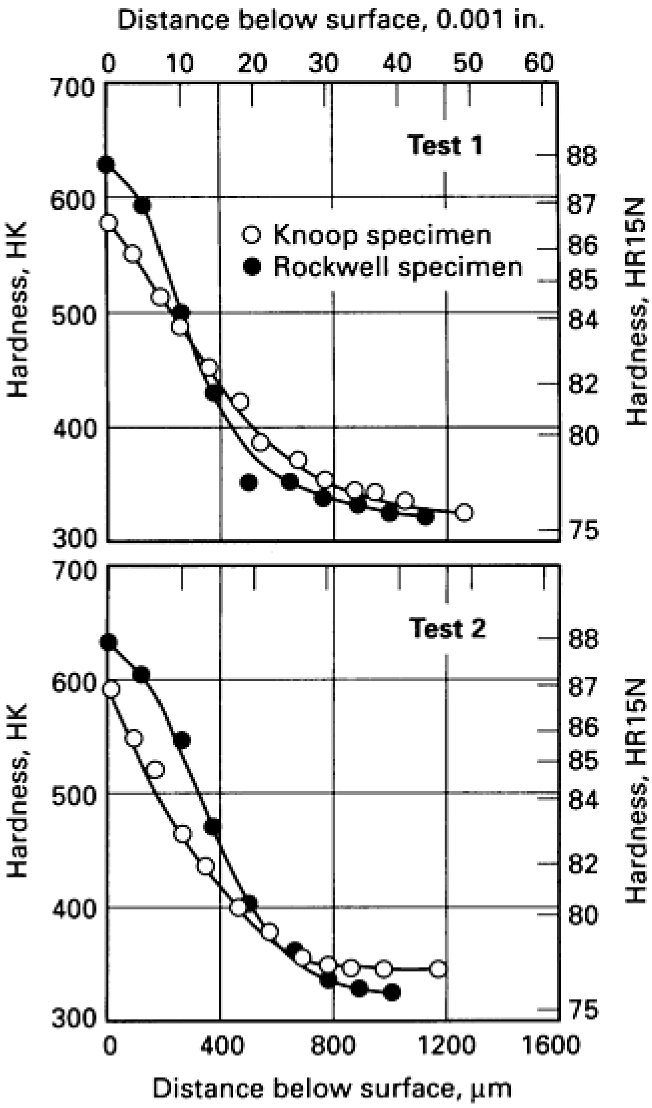

Fig. 30 Comparison between Knoop and HR15-N hardness. 4340 nitrided at 550 °C (1020 °F), 20 h, 20 to 50% dissociation. HR15-N was converted to Knoop hardness.

Evaluation of case depth may be accomplished by preparing a cross section of the case, etching with a suitable agent, and microscopically measuring the depth from the surface to a point of contrast between the case and core. Suitable etchants may be one of the following:

- Distilled water (250 cm^3), ammonium persulfate (109 g), sodium alkyl aryl sulfonate (1 g), and saturated solution of sodium thiocyanate (10 drops)
- 4% nital
- 3% picral plus 1% benzalkonium chloride (zephiran chloride)

Case depth may be determined also by microhardness testing an unetched cross section of the case, using either the Vickers or Knoop tester. Measurement consists of making a hardness survey from near the nitrided surface to the base metal (total case), or to a depth at which a predetermined hardness value (such as 60 HRC) is measured (effective case).

In general, case depth measurements determined by microhardness tests are more accurate and reproducible than those made by visual examination of etched specimens. Frequently, the depth of case determined by examination of an etched

specimen is less than that indicated by a microhardness survey, as shown by the data in Fig. 31. Also, etchants react differently on different steels. For example, the 3% picral and 1% benzalkonium chloride solution darkens the case of aluminum-bearing steels but does not have this effect on 4100 series.

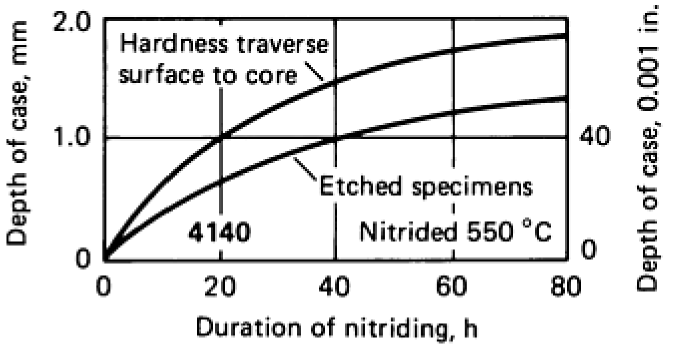

Fig. 31 Comparison of depth of nitrided case determined by hardness traverse and by etching specimens in 2% nital. Before being nitrided, the 4140 steel was oil quenched from 845 °C (1550 °F) and tempered at 595 °C (1100 °F).

When facilities for microhardness or etchant tests are not available, a tapered-wedge control specimen may be used in conjunction with the HR15-N tester to determine case depth of the nitrided parts. Such a specimen is of the same grade of steel as the parts being nitrided and has overall dimensions of 48 by 19 by 10 mm ($1\frac{7}{8}$ by $\frac{3}{4}$ by $\frac{3}{8}$ in.). It is heat treated with the parts to obtain the proper hardness. After removal of 3.2 mm ($\frac{1}{8}$ in.) of material from all surfaces, a 1.8 mm (0.070 in.) taper is ground by placing a 1.8 by 3 by 19 mm (0.070 by $\frac{1}{8}$ by $\frac{3}{4}$ in.) shim under one end of the specimen as indicated in Fig. 32.

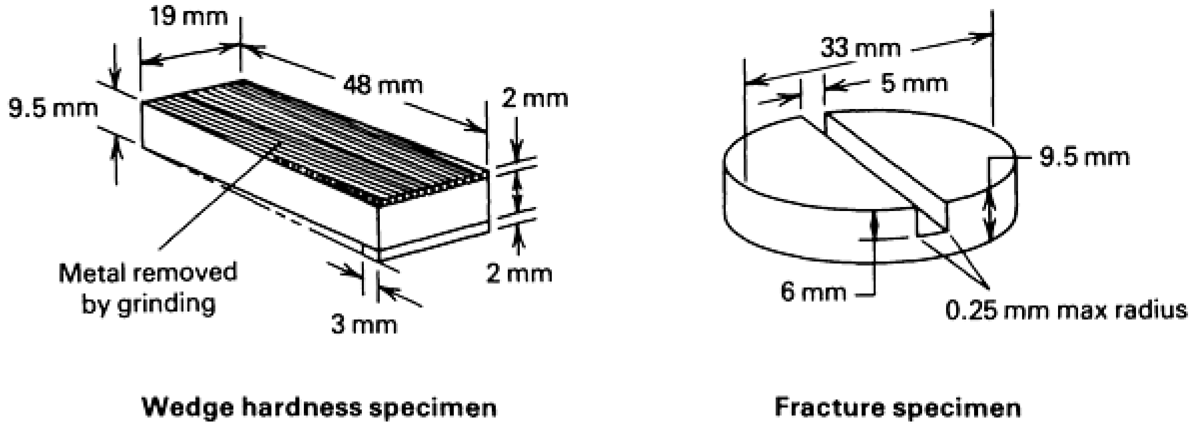

Fig. 32 Wedge specimen for determining case depth when facilities for microhardness or etchant tests are not available and fracture specimen for determining case depth

The tapered specimen is then nitrided with the parts, after which it is reground to remove the taper so that hardness measurements can be taken at right angles to the surface. (Heat generated from grinding must be kept at a minimum to prevent a change in hardness of the case.) This procedure results in a tapered cross section of the case. Thus, when superficial HR15-N hardness measurements are taken at 3.2 mm ($\frac{1}{8}$ in.) increments on this ground surface, each 3.2 mm ($\frac{1}{8}$ in.) increment represents a 0.13 mm (0.005 in.) increment in case depth. Results of this technique are biased, inasmuch as the relatively high load of 15 kg (33 lb) results in a series of case-core composite values.

Test Coupons. Quality control of nitrided parts is normally best accomplished by treating test coupons with each furnace load. One type of test coupon in common use is the fracture specimen illustrated in Fig. 32. Coupons must be of the same material heat treated to the same core hardness as the parts, and should be placed in locations that are

representative of the nitriding conditions of the furnace. Thus, when the material and heat treating are constant, any changes in the nitriding process that may develop may be easily detected.

After nitriding, the test coupons are fractured or sectioned for determination of case depth by means of a Brinell microscope or a hardness survey. They also are used in determining the depth of the white layer, the core hardness of parts that have been nitrided all over, and the case hardness of areas that are not accessible to a hardness test. However, when possible, actual parts should be used for hardness tests of the case and core.

The data obtained from test coupons should be recorded and filed with the furnace records. Furnace temperature charts should include the dissociation readings taken during the nitriding treatment of each load.

Measurement and Removal of White Layer. Normally, the surface of nitrided parts will contain a layer of iron nitride (white layer). This white layer ranges in thickness from 0.005 to 0.05 mm (0.0002 to 0.0020 in.), depending on the length of the cycle and whether single-stage or double-stage nitriding was employed. The thickness of the white layer is measured principally by metallographic methods. A prepared cross section of the nitrided surface is etched with an etchant that darkens the case but not the iron nitride layer; thus, this layer appears white and can be measured microscopically.

The white layer produced by single-stage nitriding is hard and brittle and should be carefully removed. Double-stage nitriding produces a shallower, softer, and more ductile white layer. For some applications, this type of white layer is beneficial; in certain gear systems, for example, it provides a good wear-in surface. The amount of stock removal required for elimination of the white layer should be determined by testing actual parts; however, Table 9 may be used as a guide.

Table 9 General guide to amount of stock removal required for elimination of white layer from nitrided parts

Nitriding cycle, h	Maximun amount of stock removal			
	Single-stage nitriding		Double-stage nitriding	
	mm	10^{-4} in.	mm	10^{-4} in.
12	0.01	5	0.01	5
24	0.03	10	0.03	10
36	0.04	15	0.03	10
48	0.05	20	0.03	10
60	0.06	25	0.04	15

The amount of expensive finish grinding or lapping required for removing white layer is significantly less for parts that are double-stage nitrided than for parts that are single-stage nitrided. The white layer formed during double-stage nitriding usually can be held to a maximum thickness of 0.019 mm (0.00075 in.), although this may still be excessive for certain applications.

One method (U.S. Patent 3,069,296) for totally removing the white layer uses a simple alkaline solution that decomposes the iron nitride, making it friable and easily removable by light blast cleaning. A 200-mesh aluminum oxide grit is recommended for blasting. Depending on surface finish requirements, either liquid-abrasive blasting or peening with glass beads may be substituted for grit blasting. The procedure does not harm the surface finish and has the added advantage of removing copper plate (during immersion in the alkaline solution) from parts plated for selective nitriding. Tests have shown no decrease in hardness, fatigue strength, or impact strength; etching or pitting of the nitrided surface does not occur. The process does not require close control.

Another method (U.S. Patent 2,960,421) removes the iron nitride white layer by a diffusion process. Parts are copper plated all over and then heated to and held at about 525 °C (975 °F) for periods up to 40 h, depending on the thickness of white layer to be removed.

Parts that have been processed for the removal of white layer may be inspected by observing the reaction of nitrided surfaces after swabbing them with a 5% solution of nital or a 10% solution of ammonium persulfate. Areas from which the white layer has been removed will etch dark, whereas areas where the white layer is still present in substantial quantity will not etch. This procedure is not absolutely accurate because areas that etch dark may still contain some white layer; however, the amount of white layer remaining is usually insufficient to affect the service performance of the part.

Liquid Nitriding of Steels

Revised by the ASM Committee on Liquid Nitriding*

Introduction

LIQUID NITRIDING (nitriding in a molten salt bath) employs the same temperature range as gas nitriding, that is, 510 to 580 °C (950 to 1075 °F). The case-hardening medium is a molten, nitrogen-bearing, fused-salt bath containing either cyanides or cyanates. Unlike liquid carburizing and cyaniding, which employ baths of similar compositions, liquid nitriding is a subcritical (that is, below the critical transformation temperature) case-hardening process; thus, processing of finished parts is possible because dimensional stability can be maintained. Also, liquid nitriding adds more nitrogen and less carbon to ferrous materials than that obtained through higher-temperature diffusion treatments.

The liquid nitriding process has several proprietary modifications and is applied to a wide variety of carbon, low-alloy steels, tool steels, stainless steels, and cast irons.

Liquid Nitriding Applications

Liquid nitriding processes are used primarily to improve wear resistance of surfaces and to increase the endurance limit in fatigue. For many steels, resistance to corrosion is improved. These processes are not suitable for many applications requiring deep cases and hardened cores, but they have successfully replaced other types of heat treatment on a performance or economic basis. In general, the uses of liquid nitriding and gas nitriding are similar, and at times identical. Gas nitriding may be preferred in applications where heavier case depths and dependable stopoffs are required (see the article "Gas Nitriding" in this Volume). Both processes, however, provide the same advantages: improved wear resistance and antigalling properties, increased fatigue resistance, and less distortion than other case-hardening processes employing through heating at higher temperatures. Four examples of parts for which liquid nitriding was selected over other case-hardening methods appear in Table 1.

Table 1 Automotive parts for which liquid nitriding proved superior to other case-hardening processes for meeting service requirements

Component	Requirement	Material and process originally used	Resultant problem	Solution
Thrust washer	Withstand thrust load without galling and deformation	Bronze, carbonitrided 1010 steel	Bronze galled, deformed; steel warped	1010 steel nitrided 90 min in cyanide-cyanate bath at 570 °C (1060 °F) and water quenched[(a)]
Shaft	Resist wear on splines and bearing area	Induction harden through areas	Required costly inspection	Nitride for 90 min in cyanide-cyanate salt bath at 570 °C (1060 °F)
Seat bracket	Resist wear on surface	1020 steel, cyanide treated	Distortion; high loss in straightening[(b)]	1020 nitrided 90 min in cyanide-cyanate salt bath and water quenched[(c)]
Rocker arm shaft	Resist water on surface; maintain geometry	SAE 1045 steel, rough ground, induction hardened, straightened, finish ground, phosphate coated	Costly operations and material	SAE 1010 steel liquid-nitrided 90 min in low-cyanide fused salt at 570 to 580 °C (1060 to 1075 °F)[(d)]

(a) Resulted in improved product performance and extended life, with no increase in cost.

(b) Also, brittleness.

(c) Resulted in less distortion and brittleness, and elimination of scrap loss.

(d) Eliminated finish grinding, phosphatizing, and straightening

The degree to which steel properties are affected by liquid nitriding may vary with the process used and the chemical control maintained. Thus, critical specifications should be based on prior test data or documented information.

Liquid Nitriding Systems

The term liquid nitriding has become a generic term for a number of different fused-salt processes, all of which are performed at subcritical temperature. Operating at these temperatures, the treatments are based on chemical diffusion and influence metallurgical structures primarily through absorption and reaction of nitrogen rather than through the minor amount of carbon that is assimilated. Although the different processes are represented by a number of commercial trade names, the basic subclassifications of liquid nitriding are those presented in Table 2.

Table 2 Liquid nitriding processes

Process identification	Operating range composition	Chemical nature	Suggested post treatment	Operating temperature		U.S. patent number
				°C	°F	
Aerated cyanide-cyanate	Sodium cyanide (NaCN), potassium cyanide (KCN) and potassium cyanate (KCNO), sodium cyanate (NaCNO)	Strongly reducing	Water or oil quench; nitrogen cool	570	1060	3,208,885
Casing salt	Potassium cyanide (KCN) or sodium cyanide (NaCN), sodium cyanate (NaCNO) or potassium cyanate (KCNO), or mixtures	Strongly reducing	Water or oil quench	510-650	950-1200	
Pressure nitriding	Sodium cyanide (NaCN), sodium cyanate (NaCNO)	Strongly reducing	Air cool	525-565	975-1050	
Regenerated cyanate-carbonate	Type A: Potassium cyanate (KCNO), potassium carbonate (K_2CO_3); Type B: Potassium cyanate (KCNO), potassium carbonate (K_2CO_3), 1-10 ppm, sulfur (S)	Mildly oxidizing	Water, oil, or salt quench	580	1075	4,019,928
		Mildly oxidizing	Water, oil quench, or salt	540-575	1000-1070	4,006,643

A typical commercial bath for liquid nitriding is composed of a mixture of sodium and potassium salts. The sodium salts, which comprise 60 to 70% (by weight) of the total mixture, consist of 96.5% NaCN, 2.5% Na_2CO_3, and 0.5% NaCNO. The potassium salts, 30 to 40% (by weight) of the mixture, consist of 96% KCN, 0.6% K_2CO_3, 0.75% KCNO, and 0.5% KCl. The operating temperature of this salt bath is 565 °C (1050 °F). With aging (a process described in the section "Operating Procedures" in this article), the cyanide content of the bath decreases, and the cyanate, and carbonate contents increase (the cyanate content in all nitriding baths is responsible for the nitriding action, and the ratio of cyanide to cyanate is critical). This bath is widely used for nitriding tool steels, including high-speed steels, and a variety of low-alloy steels, including the aluminum-containing nitriding steels.

Another bath for nitriding tool steels has a composition as follows:

Component	Amount, %
NaCN	30.00 max
Na_2CO_3 or K_2CO_3	25.00 max
Other active ingredients	4.00 max
Moisture	2.00 max
KCl	rem

A proprietary nitriding salt bath has the following composition by weight: 60 to 61% NaCN, 15.0 to 15.5% K_2CO_3, and 23 to 24% KCl.

Several special liquid nitriding processes employ proprietary additions, either gaseous or solid, that are intended to serve several purposes, such as accelerating the chemical activity of the bath, increasing the number of steels that can be processed, and improving the properties obtained as a result of nitriding.

Cyanide-free liquid nitriding salt compositions have also been introduced. However, in the active bath, a small amount of cyanide, generally up to 5.0%, is produced as part of the reaction. This is a relatively low concentration, and these compositions have gained widespread acceptance within the heat-treating industry because they do contribute substantially to the alleviation of a potential source of pollution.

Three processes, liquid pressure nitriding, aerated bath nitriding, and aerated low-cyanide nitriding, are described in the sections that follow.

Liquid Pressure Nitriding

Liquid pressure nitriding is a proprietary process in which anhydrous ammonia is introduced into a cyanide-cyanate bath. The bath is sealed and maintained under a pressure of 7 to 205 kPa (1 to 30 psi). The ammonia is piped to the bottom of the retort and is caused to flow vertically. The percentage of nascent nitrogen in the bath is controlled by maintaining the ammonia flow rate at 0.6 to 1 m^3/h (20 to 40 ft^3/h). This results in ammonia dissociation of 15 to 30%.

The bath contains sodium cyanide and other salts, which permits an operating temperature of 525 to 565 °C (975 to 1050 °F). Because the molten salts are diffused with anhydrous ammonia, a new bath does not require aging and may be put into immediate operation employing the recommended cyanide-cyanate ratio, namely, 30 to 35% cyanide and 15 to 20% cyanate. Except for dragout losses, maintenance of the bath within the preferred ratio range is greatly simplified by the anhydrous ammonia addition, which serves continuously to counteract bath depletion.

The retort cover may be opened without causing complete interruption of the nitriding process. Loss of pressure within the retort results in a reduction in the nitriding rate. However, when the retort is sealed and pressure is reinstated through the resumption of ammonia gas flow, nitriding proceeds at the normal rate.

Depth of case depends on time at temperature. The average nitriding cycle is 24 h, although total cycle time may vary between 4 and 72 h. To stabilize core hardness, it is recommended that all parts be tempered at a temperature at least 28 °C (50 °F) higher than the nitriding temperature before they are immersed in the nitriding bath.

Hardness gradients and case depths resulting from pressure nitriding of 410 stainless steel, AISI type D2, and SAE 4140 are shown in Fig. 1, 2, and 3.

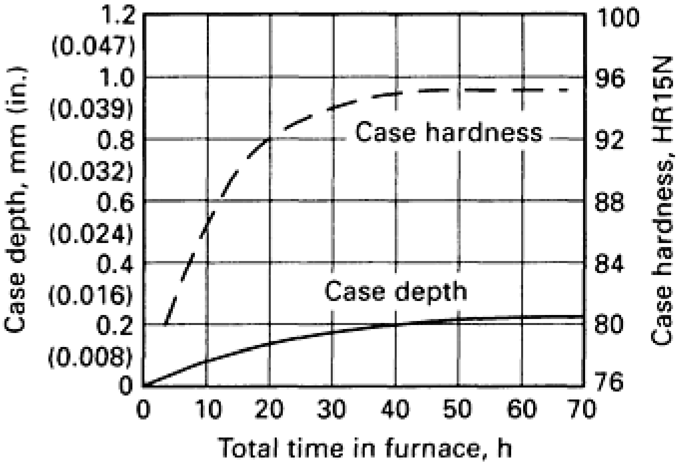

Fig. 1 Results of liquid pressure nitriding on type 410 stainless steel (composition, 0.12C-0.45Mn-0.41Ni-11.90Cr; core hardness, 24 HRC)

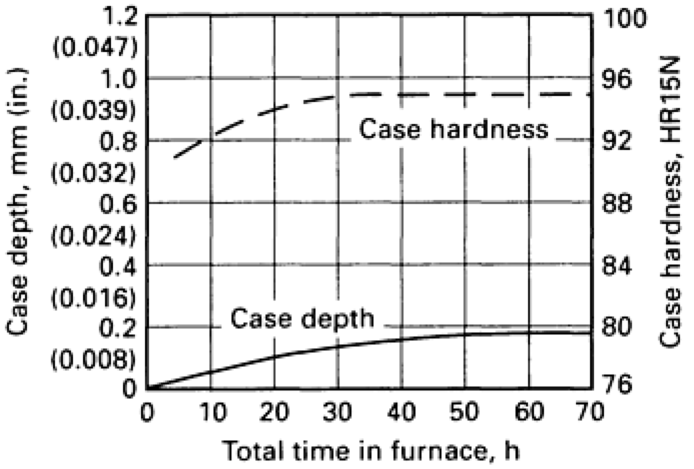

Fig. 2 Results of liquid pressure nitriding on AISI type D2 tool steel (composition, 1.55C-0.35Mn-11.50Cr-0.80Mo-0.90V; core hardness, 52 HRC)

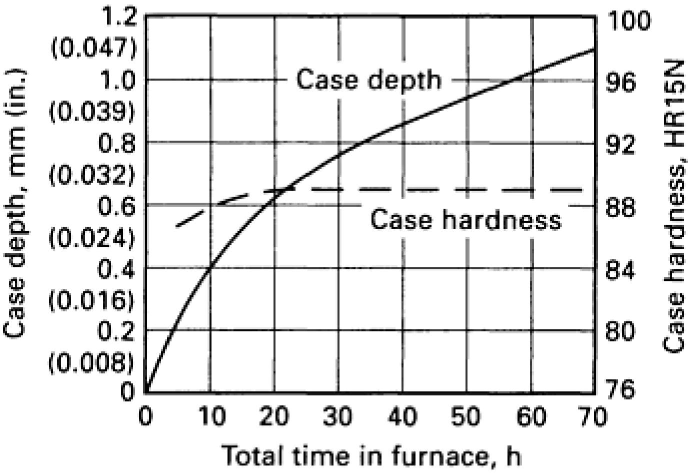

Fig. 3 Results of liquid pressure nitriding on SAE 4140 low-alloy steel (composition, 0.38C-0.89Mn-1.03Cr-0.18Mo; core hardness, 35 HRC)

Aerated Bath Nitriding

Aerated bath nitriding is a proprietary process (U.S. Patent 3,022,204) in which measured amounts of air are pumped through the molten bath. The introduction of air provides agitation and stimulates chemical activity. The cyanide content of this bath, calculated as sodium cyanide, is maintained at preferably about 50 to 60% of the total bath content, and the cyanate is maintained at 32 to 38%. The potassium content of the fused bath, calculated as elemental potassium, is between 10 and 30%, preferably about 18%. The potassium may be present as the cyanate or the cyanide, or both. The remainder of the bath is sodium carbonate.

This process produces a nitrogen-diffused case 0.3 mm (0.012 in.) deep on plain carbon or low-alloy steels in a $1\frac{1}{2}$ h cycle. The surface layer (0.005 to 0.01 mm, or 0.0002 to 0.0005 in. deep) of the case is composed of ε Fe_3N and a nitrogen-bearing Fe_3C; the nitrided case does not contain the brittle Fe_2N constituent.

Beneath the compound zone of Fe_3N, a diffusion zone exists that consists of a solid solution of nitrogen in the base iron. Depth of nitrogen diffusion in 1015 steel as a function of nitriding time at 565 °C (1050 °F) is shown in Fig. 4. The outer compound layer provides wear resistance, while the diffusion zone improves fatigue strength.

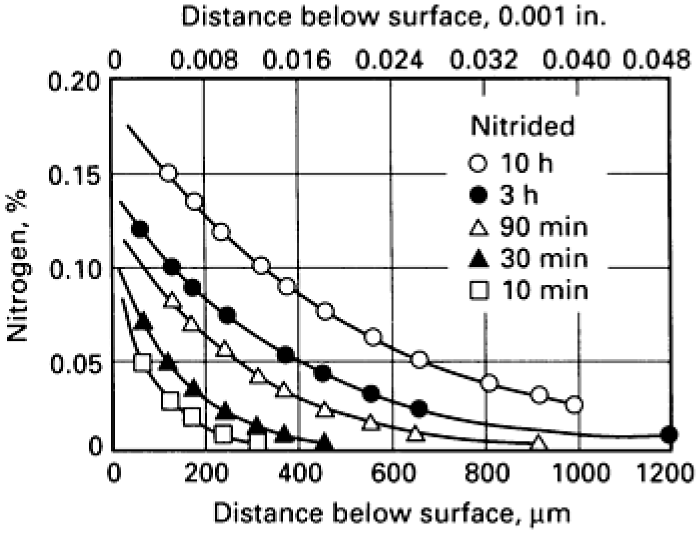

Fig. 4 Nitrogen gradients in 1015 steel as a function of time of nitriding at 565 °C (1050 °F), using the aerated bath process

It should be noted that only chromium-, titanium-, and aluminum-alloyed steel respond well to conventional bath nitriding. Plain carbon (nonalloyed) steels respond well to aerated bath nitriding but not to conventional nitriding. Thus, the aerated process should be specified for nitriding all plain carbon steels because test data show that plain carbon steel will not develop adequate hardness in a nonaerated nitriding bath. However, the full effect of nitriding will not be realized unless an alloy steel is selected. See the section "Hardness of Compound Layer" in Appendix 1 of this article.

Aerated Cyanide-Cyanate Nitriding. Another aerated process for liquid nitriding is a high-cyanide, high-cyanate system that is proprietary (U.S. Patent 3,208,885). The cyanide content of the fused salt is maintained in the range of 45 to 50% calculated as potassium cyanide, and the cyanate content is maintained in the range of 42 to 50% calculated as potassium cyanate. Makeup salt consists of a precise mixture of sodium and potassium cyanides that are oxidized by aeration to the mixed cyanate. The ratio of sodium ions to potassium ions is important in duplicating the integrity of the compound zone and the diffusion zone.

The process is performed in a titanium-lined container, and it produces a compound zone of ε iron nitride to a depth of 0.010 to 0.015 mm (0.0004 to 0.0006 in.) and a diffusion zone of 0.356 to 0.457 mm (0.014 to 0.018 in.) in plain carbon steels with a 90-min treating time, as shown in Fig. 5. The surface hardness of the compound zone may vary between 300 HK and 450 HK if carbon or low-alloy steels are being treated. Surface hardness of stainless steels treated by this process may reach 900 HK as shown in AMS 2755B, a portion of which is reproduced in Appendix 2 of this article.

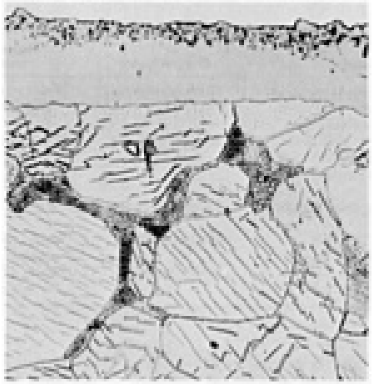

Fig. 5 Nitrided case and diffusion zone produced by cyanide-cyanate liquid nitriding. The characteristic needle structure is seen only after a 300 °C (570 °F) aging treatment.

Aerated Low-Cyanide Nitriding. Environmental concerns have led to the development of cyanide-free processes for liquid nitriding. In these proprietary processes, the base salt is supplied as a cyanide-free mixture of potassium cyanate and a combination of sodium carbonate and potassium carbonate, or sodium chloride and potassium chloride. Minor percentages of cyanide develop during use in these compositions. The problem is overcome in one process (U.S. Patent 4,019,928), by quenching in an oxidizing quench salt that destroys the cyanide and cyanate compounds (which have pollution capabilities) and produces less distortion than that resulting from water quenching. An alternate method utilized

by U.S. Patent 4,006,643 is the incorporation of lithium carbonate plus minute amounts of sulfur (1 to 10 ppm) in the base salt to hold cyanide formation to below 1.0%.

These low-cyanide processes have been shown in tests to produce the same results as those developed in the previously mentioned liquid nitriding processes. The diffusion curves and case depths are quite similar to those shown in Fig. 1, 2, and 3. Because a high cyanate (65 to 75% KCNO) level in the absence of cyanide would be expected to produce iron nitride compound zones slightly lower in carbon and slightly higher in nitrogen, it is good practice to develop new tests and operational data when converting to one process from another. Excerpts from the AMS 2753 specification developed for low-cyanide liquid salt bath nitriding are shown in Appendix 1 .

Case Hardness. According to AMS 2755C, case hardness varies markedly with the alloy being nitrided. Hardness and other requirements of this specification are summarized in Appendix 2 .

Effects of Steel Composition. Although the properties of alloy steels are improved by the compound and diffusion layers, relatively greater improvement is achieved with plain carbon steels of low and medium carbon content. For example, the improvement in fatigue strength of unnotched test bars of 1015 steel nitrided by this process for 90 min at 565 °C (1050 °F) and water quenched (to further enhance fatigue properties) is roughly 100%. Improvement obtained with similarly treated test bars made of 1060 steel is about 45 to 50%.

The diffusion of nitrogen in carbon steels is directly affected by carbon content, as shown in Fig. 6. The nitride-forming alloying elements also inhibit nitrogen diffusion. For example, the inhibiting effect of chromium on diffusion is shown in Fig. 7, which compares nitrogen in a low-carbon steel (1015) and a chromium-containing low-alloy steel (5115).

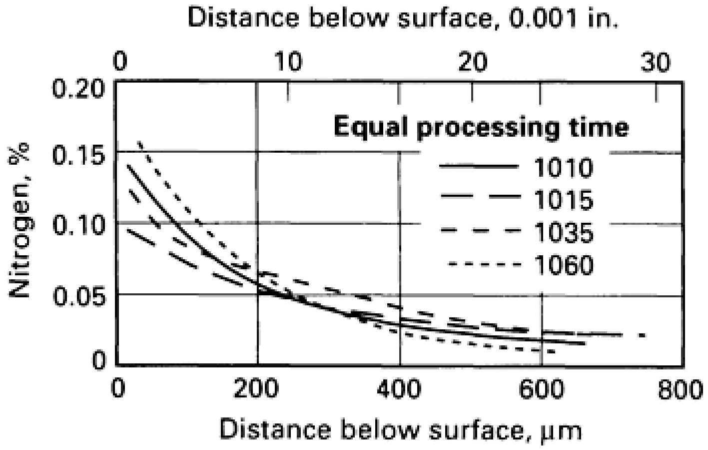

Fig. 6 Effect of carbon content in carbon steels on the nitrogen gradient obtained in aerated bath nitriding

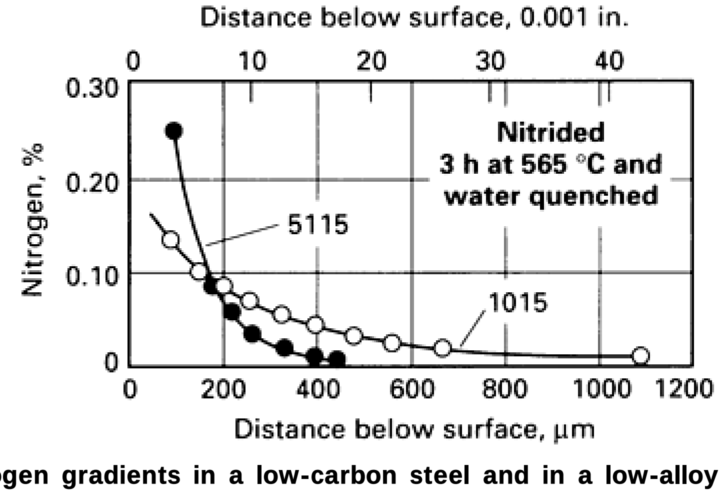

Fig. 7 Comparison of nitrogen gradients in a low-carbon steel and in a low-alloy steel containing chromium, both nitrided by the aerated bath process

Although the visible nitrogen diffusion zone shown by the Fe_4N needles in Fig. 5 can be measured under the microscope to a depth of approximately 0.41 mm (0.016 in.), actual nitrogen penetration can be measured up to 1.02 mm (0.040 in.) as shown in Fig. 8. This nitrogen is in solution, is under stress, and is precipitated as Fe_4N. It is responsible for the fatigue

improvement resulting from liquid nitriding. The improvement is more apparent in plain carbon steels, resulting in the substitution of these steels for high-carbon and low-alloy steels in many applications (Table 3).

Table 3 Improvement in fatigue properties of low-temperature liquid nitrided ferrous materials

Steel type	Property improvement, %
Low-carbon steels	80-100
Medium-carbon steels	60-80
Stainless steels	25-35
Low-carbon, chrome manganese steels	25-35
Chrome alloy, medium-carbon steels	20-30
Cast irons	20-80

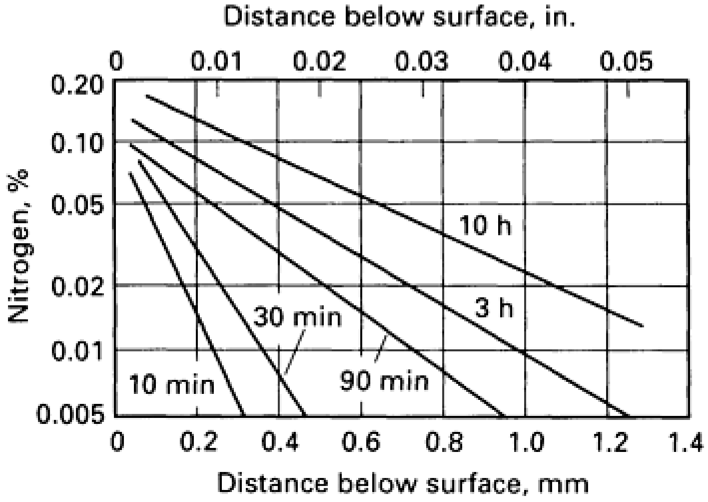

Fig. 8 Nitrogen diffusion in AISI 1015 steel

Case Depth and Case Hardness

Data indicating depth of case obtained in liquid nitriding various steels in a conventional bath at 525 °C (975 °F) for up to 70 h are shown in Fig. 9. The steels include three chromium-containing low-alloy steels (4140, 4340, and 6150), two aluminum-containing nitriding steels (SAE 7140 and AMS 6475), and four tool steels (H11, H12, M50, and D2). All were nitrided in a salt bath with an effective cyanide content of 30 to 35% and a cyanate content of 15 to 20%. Case depths were measured visually on metallographically prepared samples that were etched in 3% nital. Before being nitrided, samples were tempered to the core hardnesses indicated.

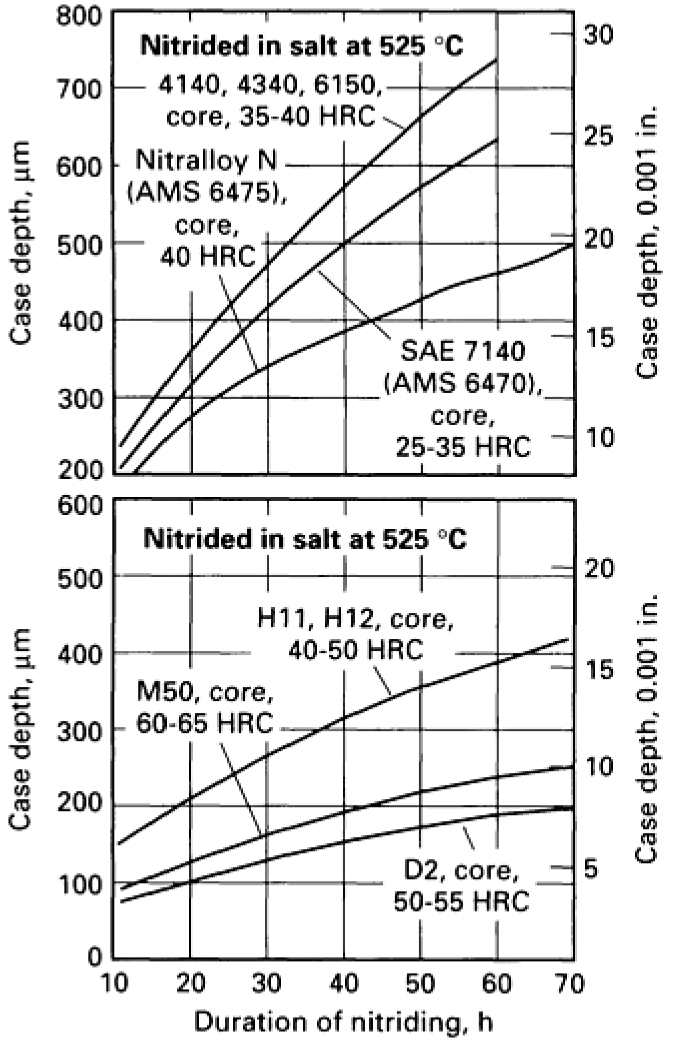

Fig. 9 Depth of case for several chromium-containing low-alloy steels, aluminum-containing steels, and tool steels after liquid nitriding in a conventional salt bath at 525 °C (975 °F) for up to 70 h

Figure 10 presents data on case hardness obtained in liquid pressure nitriding the following alloy steels and tool steels: SAE 7140, AMS 6475, 4140, 4340, medium-carbon H11, low-carbon H11, H15, and M50. The various core hardnesses, nitriding temperatures, and cycle times were as noted in the graphs in Fig. 10. Case depth and hardness results are comparable to those obtained in single-stage gas nitriding.

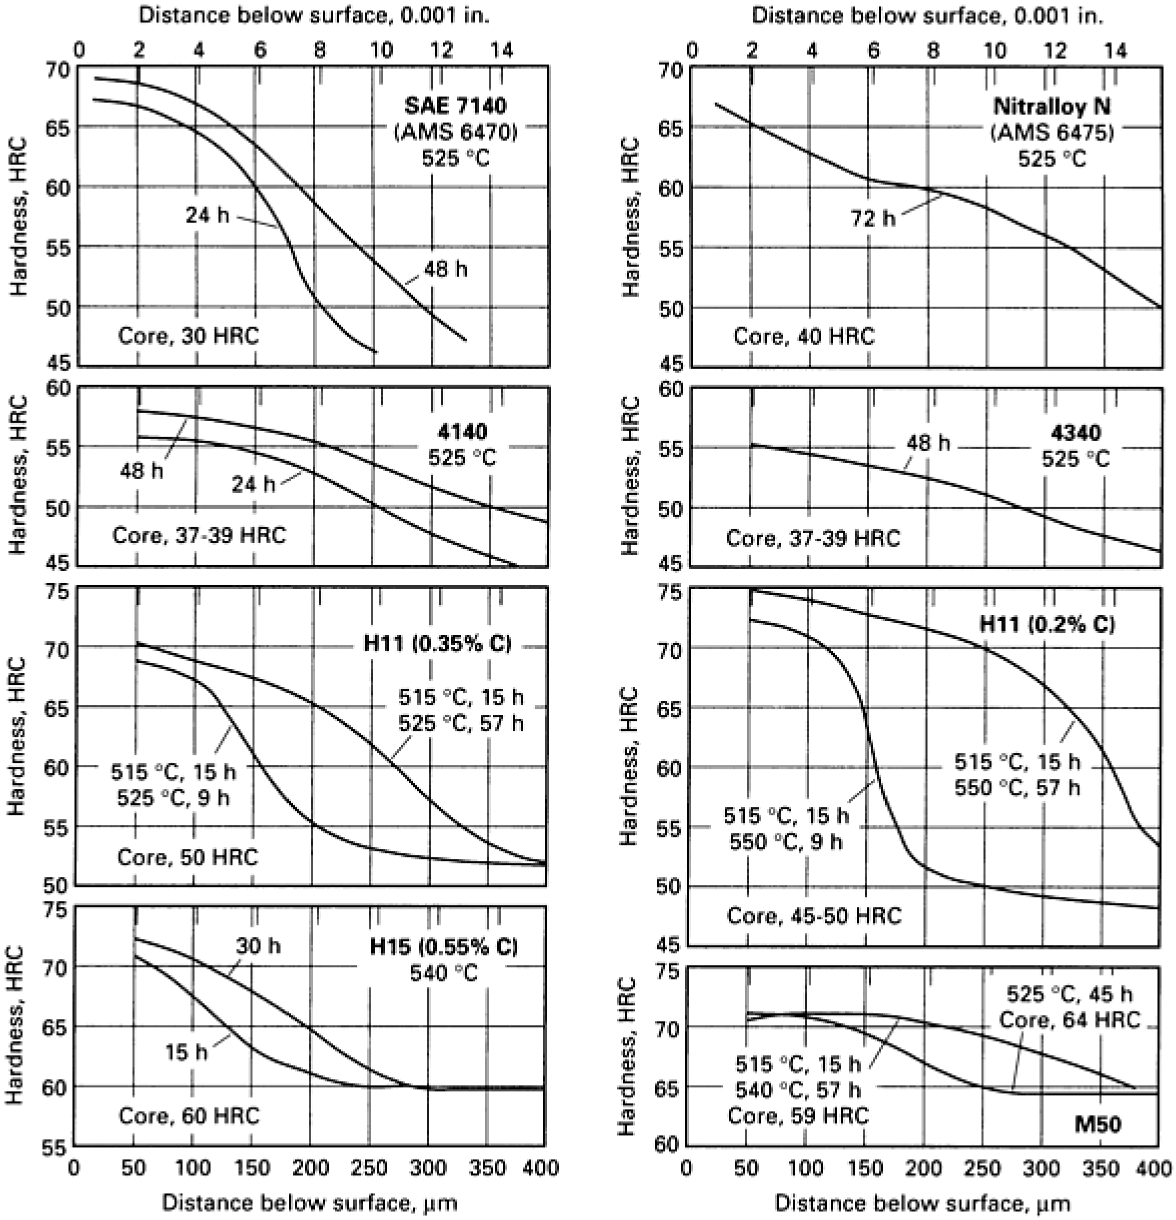

Fig. 10 Hardness gradients for several alloy and tool steels nitrided in salt by the liquid pressure process. Rockwell C hardness values are converted from Knoop hardness measurements made using a 500 g load. Temperatures are nitriding temperatures.

High-Speed Steels. Compared to gas nitriding of high-speed steel cutting tools, liquid nitriding can produce a more ductile case with a lower nitrogen content. Nitrided case hardness data, together with details of liquid nitriding these materials, are given in the Section "Heat Treating of Tool Steels" in this Volume.

Operating Procedures

Among the important operating procedures in liquid nitriding are the initial preparation and heating of the salt bath, aging of the molten salts (when required), and analysis and maintenance of salt bath composition. Virtually all steels must be quenched and tempered for core properties before being nitrided or stress relieved for distortion control. So prior heat treatment may be considered an essential part of the operating procedure.

Prior Heat Treatment. Alloy steels usually are given a prior heat treatment similar to that preferred for gas nitriding (see the article "Gas Nitriding" in this Volume). Maintenance of dimensional and geometric stability during liquid nitriding is enhanced by hardening of parts prior to nitride treatment. Tempering temperatures should be no lower than the nitriding temperature and preferably slightly above.

Depending on steel composition, the effect of core hardness is similar to that encountered in gas nitriding.

Starting the Bath. Case-producing salt compositions may vary with respect to manufacturers, but they are basically sodium and potassium cyanides, or sodium and potassium cyanates. Cyanide, the active ingredient, is oxidized to cyanate by aging as described below. The commercial salt mixture (60 to 70% sodium salts, 30 to 40% potassium salts) is melted at 540 to 595 °C (1000 to 1100 °F). *Caution: During the melting period, a cover should be placed over the retort to guard against spattering or explosion of the salt, unless the equipment is completely hooded and vented. It is mandatory that the salts be dry before they are placed in the retort; the presence of entrapped moisture may result in an eruption when the salt mixture is heated.*

Externally versus Internally Heated Salt Baths. Salt baths may be heated externally or internally. For externally heated salt baths, startup power should be limited to 37% of total capacity until signs of melting are apparent on all sides of the salt bath. For internally heated salt baths, natural gas flame torches having a moderate flame are effective in melting a pool of molten salt for a conductive path between electrodes.

Aging the Bath. Liquid nitriding compositions that do not contain a substantial amount of cyanate in the original melt must be aged before use in production. Aging is defined as the oxidation of the cyanide to cyanate. Aging is not merely a function of temperature alone, but also depends on the surface-to-volume ratio of the molten bath. It is the surface air (oxygen)-to salt contact that oxidizes cyanide to cyanate.

Molten salts in conventional baths should be aged by being held at 565 to 595 °C (1050 to 1100 °F) for at least 12 h, and no work should be placed in the bath during the aging treatment. Aging decreases the cyanide content of the bath and increases the cyanate and carbonate contents. Before nitriding is begun, a careful check of the cyanate content should be made. Nitriding should not be attempted until the cyanate content has reached at least the minimum operating level recommended for the bath.

Bath Maintenance. To protect the bath from contamination and to obtain satisfactory nitriding, all work placed in the bath should be thoroughly cleaned and free of surface oxide. An oxide-free condition is especially important when nitriding in low-cyanide salts. These compounds are not strong reducing agents and therefore are incapable of producing a good surface on any oxidized work. Either acid pickling or abrasive cleaning is recommended prior to nitriding. Finished clean parts should be preheated before being immersed in the bath to rid them of surface moisture.

A high cyanate content (up to about 25%) will provide good results, but carbonate content should not exceed 25%. Carbonate content can be readily lowered by cooling the bath to 455 °C (850 °F) and allowing the precipitated salt to settle to the bottom of the salt pot. It can then be spooned from the bottom by means of a perforated ladle.

To minimize corrosion at the air-salt interface, salts should be completely changed every three or four months (replacement of salt is usually far more economical than replacement of the pot). When the bath is not in use, it should be covered; excessive exposure to air causes a breakdown of cyanide to carbonate and adversely affects pot life.

The ratio of cyanide content to cyanate content varies with the salt bath process and the composition of the bath. The commercial NaCN-KCN bath, after aging for one week, achieves a ratio of 21 to 26% cyanide to 14 to 18% cyanate. The bath used in liquid pressure nitriding operates with a cyanide content of 30 to 35% and a cyanate content of 15 to 20%. The aerated bath is controlled to a ratio of 50 to 60% cyanide to 32 to 38% cyanate. The aerated noncyanide nitriding process is controlled to a ratio of 36 to 38% cyanate to 17 to 19% carbonate.

Oxidation products that promote unfavorable temperature gradients must be periodically removed from all baths. In normal operation, overheating of any bath (above 595 °C, or 1100 °F) should be avoided.

Safety. Some of the compositions employed in liquid nitriding processes contain sodium cyanide or potassium cyanide, or both. These compounds can be handled safely with proper equipment and neutralized by chemical means before discharge. *Caution: The compounds are highly toxic, however, and great care should be exercised to avoid taking them internally or allowing them to be absorbed through skin abrasions. Contact between the compounds and mineral acids also generates another hazard: the formation of hydrogen cyanide (HCN) gas, an extremely toxic product. Exposure to hydrogen cyanide can be fatal.*

Neutralization of Cyanide Waste. The destruction of cyanide by chlorine is believed to proceed in three steps, according to the following equations:

$$NaCN + Cl_2 \rightarrow CNCl + NaCl \quad \textbf{(Eq 1)}$$

$$CNCl + 2NaOH \rightarrow NaCNO + NaCl + H_2O \quad \textbf{(Eq 2)}$$

$$2NaCNO + 4NaOH + 3Cl_2 \rightarrow 6NaCl + 2CO_2 + 2H_2O \quad \textbf{(Eq 3)}$$

The first reaction (Eq 1), oxidation to cyanogen chloride, is almost instantaneous, occurring at all pH levels. The second reaction (Eq 2) is hydrolysis of the cyanogen chloride to cyanate. The rate of hydrolysis is primarily dependent upon the pH, and at a pH of 11 or higher, is virtually completed in minutes. At pH values lower than 10.5 the rate of hydrolysis is slowed considerably, and pHs below this value should be avoided due to the toxicity of the cyanogen chloride.

The third step (Eq 3), oxidation of the cyanate to harmless nitrogen and carbon dioxide, is pH dependent and is accelerated by a decreasing pH. At a pH of 7.5 to 8.0, about 10 to 15 min are required for the reaction to go to completion. At a pH of 9.0 to 9.5, about 30 min are required.

In practice, about 8.0 parts of chlorine and 7.3 parts of sodium hydroxide per part of cyanide are required for the overall reaction. Occasionally, chlorination to cyanate only is sufficient because the cyanate ion is only 1/1000th as toxic as cyanide. About 3.2 parts of chlorine and 3.8 parts of sodium hydroxide per part of CN are required for the oxidation of cyanides to cyanates.

The waste will also contain small amounts of heavy metal cyanides in addition to the sodium or potassium cyanide. These will be broken down and the metal salts precipitated in reactions analogous to those for the sodium cyanide. Some metal complexes react much more slowly with the chlorine as oxidant. Silver cyanide, for instance, may require at least an hour of retention time for complete destruction.

Equipment

Salt bath furnaces used for nitriding may be heated by gas, oil, or electricity, and are essentially similar in design to salt bath furnaces used for other processes. Although batch installations are most common, semi-continuous and continuous operations are feasible. Generally, the same furnace equipment can be used for other heat-treating applications by merely changing the salt. Further details on specific types of furnaces may be found in the article "Liquid Carburizing and Cyaniding" in this Volume.

A variety of materials are used for the pots, electrodes, thermocouple protection tubes, and fixtures employed in salt bath nitriding, depending primarily on the salt mixture and process. For example, low-carbon steel is sometimes used for furnace liners although titanium is recommended for one of the processes (U.S. Patent 3,208,885). Inconel 600 is presently being applied to the noncyanide process described in U.S. Patent 4,019,928. Type 430 stainless steel is recommended for a low-cyanide process described in U.S. Patent 4,006,643. Cast HT alloy is a satisfactory fixture material, and type 446 stainless steel has been used for fixtures and thermocouple protection tubes. One plant reports the successful use of Inconel pots in liquid pressure nitriding; the same plant reports also that electrodeposited nickel performs satisfactorily as a stopoff in the liquid pressure bath. In general, however, nickel-bearing materials are not recommended for nitriding salt baths.

Maintenance Schedules

Certain maintenance procedures should be performed on a daily and weekly basis to ensure optimum operation of the salt bath used for nitriding.

Daily. The following procedures should be done on a daily basis:

- Check temperature-measuring instruments
- Check flowmeters, if these are required for air or anhydrous ammonia
- Check surface condition of work for desired steel-gray color and possible pitting

- Check case depth and case hardness to determine operating condition of the bath

Weekly. The following procedures should be done on a weekly basis:

- Analyze salt bath composition at least once a week; a semiweekly analysis is preferred. Make necessary additions to maintain level
- Check air-salt interface on pot for undercutting. Remove salts and recharge whenever undercutting is observed
- Check bath for nickel content. To remove traces of nickel, a steel plate-out panel should be placed in the bath overnight
- Contamination in the form of $Na_4Fe(CN)_6$ (a complex ferrocyanide that forms in cyanide-type baths) should be removed from the bath by holding the bath at 650 °C (1200 °F) for about 2 h to settle out the compound in the form of sludge

Safety Precautions

The following safety precautions should be observed when operating salt bath furnaces for nitriding steels:

- Operating personnel must be carefully instructed in handling the poisonous cyanide-containing salts
- All chemical containers must be clearly /marked to indicate contents
- Personnel should be provided with facilities for washing their hands thoroughly to prevent contamination by the cyanide salts
- Shields, gloves, aprons, and eye protection should be worn by operating personnel
- Parts and workpiece support fixtures should be preheated to drive off any moisture that may be present before they are immersed in the molten salt bath
- Proper venting of furnace and rinse tanks to the outdoors is recommended in order to provide safety against fumes and spattering and to minimize corrosion in the work area
- *Caution: Nitrate-nitrite salts must not come in contact with nitriding salts in the molten state. Contact will result in an explosion. Storage of these salts should be properly labeled and stored apart*

Liquid Nitrocarburizing

In liquid nitrocarburizing processes, both carbon and nitrogen are absorbed into the surface. High-cyanide nitrocarburizing baths have been in use since the late 1940s. Initially, the sulfur-containing variant was used to produce a wear-resistant surface of iron sulfide (see Process 2). A sulfur-free high-cyanide bath was developed in the mid-1950s, now known as aerated bath nitriding (Process 1). This process and a low-cyanide variant of it (Process 4) are commonly used.

Both Processes 1 and 2 are similar in that components are typically preheated to about 350 to 480 °C (660 to 900 °F), and then transferred to the nitrocarburizing salt bath at 570 °C (1060 °F). The major components of the baths for both processes are normally alkali metal cyanide and cyanate. Salts are predominately potassium, with sodium.

Liquid nitrocarburizing processes are used to improve wear resistance and fatigue properties of low-to-medium carbon steels, cast irons, low-alloy steels, tool steels, and stainless steels. For additional information on nitrocarburizing treatments, see the article "Gaseous and Plasma Nitrocarburizing" in this Volume.

Process 1: High Cyanide without Sulfur. At the treatment temperature of 570 °C (1060 °F), the process is controlled largely by two reactions, an oxidation reaction and a catalytic reaction. The oxidation reaction involves transformation of cyanide to cyanate:

$$4NaCN + 2O_2 \rightarrow 4NaCNO \quad \textbf{(Eq 4)}$$

$$2KCN + O_2 \rightarrow 2KCNO \quad \textbf{(Eq 4a)}$$

Though this reaction can proceed by natural oxidation of the cyanide bath, eventually leading to the desired cyanate content, the mechanism of natural aging does not provide the higher cyanate level made possible with aeration. To provide agitation and stimulate chemical activity, therefore, dry air is introduced into the bath.

The catalytic reaction involves breaking down cyanate in the presence of the steel components being treated, thus supplying carbon and nitrogen to the surface:

$$8NaCNO \rightarrow 2Na_2CO_3 + 4NaCN + CO_2 + (C)_{Fe} + 4(N)_{Fe} \quad \textbf{(Eq 5)}$$

$$8KCNO \rightarrow 2K_2CO_3 + 4KCN + CO_2 + (C)_{Fe} + 4(N)_{Fe} \quad \textbf{(Eq 5a)}$$

As a result of this treatment, a wear-resistant compound zone, rich in nitrogen and carbon, is formed on component surfaces (Fig. 11).

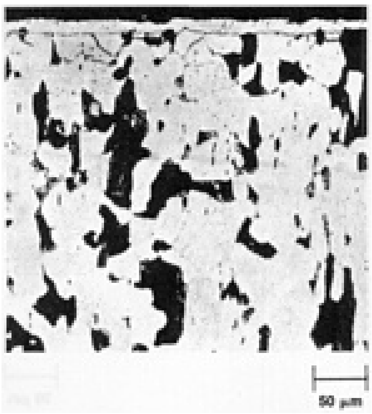

Fig. 11 Metallographic appearance of salt bath nitrocarburized mild steel after 1.5 h at 570 °C (1060 °F) followed by water quenching

Process 2: High Cyanide with Sulfur. The same basic oxidation and catalytic reactions of Process 1 also occur in this process. In addition, further reactions take place because of sulfites in the melt. These sulfites are reduced to sulfides, in conjunction with the oxidation of the cyanide to cyanate, as follows:

$$Na_2SO_3 + 3NaCN \rightarrow Na_2S + 3NaCNO \quad \textbf{(Eq 6)}$$

$$K_2SO_3 + 3KCN \rightarrow K_2S + 3KCNO \quad \textbf{(Eq 6a)}$$

Thus, the sulfur present in the bath acts as an accelerator, with the result that the cyanate is produced more readily than if the sulfur compounds were absent. Consequently, external aeration is not normally used in the process. Potassium and sodium cyanates produced by the reactions in Eq 4 and 6 catalytically decompose at the surface of ferrous materials to liberate carbon monoxide and nascent nitrogen. The carbon monoxide dissociates to liberate active carbon. The carbon, in conjunction with the nascent nitrogen, diffuses into the material being treated to form the compound zone.

The exact mechanism by which sulfur is impregnated into the material is not clear. Various sulfides react with the component being treated to form iron sulfide; this is the black deposit observed on the surface of components after treatment.

The compound layer formed on mild steel after a 90-min treatment, followed by water quenching, is shown in Fig. 12. The compound layer formed by cyanide salt bath nitrocarburizing treatments, and, in particular, by the sulfur-containing

high-cyanide process, contains an outer region of microporosity. These pores, which readily absorb oil, may assist the antiscuffing properties of treated components under lubrication conditions.

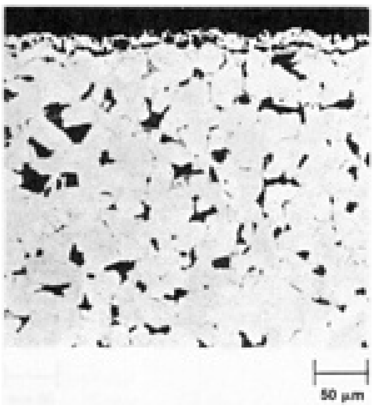

Fig. 12 Metallographic appearance of mild steel after similar treatment to Fig. 11. Iron-sulfide inclusions in the outer region of the compound zone are apparent after this treatment, in which sulfur acts as an accelerator.

Although little systematic investigation has been done to establish the optimum thickness of the compound layer for maximum improvement in wear and antiscuffing properties, it is believed that comparable results are obtained provided the layer is 10 to 20 μm (400 to 800 μin.) thick.

Composition and Structural Analysis of the Compound Layer. X-ray diffraction investigations into the structure of the compound layer formed by the two high-cyanide salt bath nitrocarburizing processes have indicated a variety of carbon and nitrogen-base phases.

One study of cyanide nitrocarburizing treatments indicated that the best antiscuffing properties were obtained when the compound layer consisted mainly of a hexagonal close-packed (hcp) phase of variable carbon and nitrogen concentration. Examination of the appropriate isothermal section of the iron-carbon-nitrogen ternary phase diagram (Fig. 13) indicates that this phase is the ε carbonitride phase. Furthermore, it is believed that provided the ε phase was predominant within the compound layer, small amounts of other phases, particularly Fe_4N and Fe_3C, had no serious adverse effects on antiscuffing behavior. It has been shown that with Process 1, compound layers with less than about 2% C and less than about 6% N contained a mixture of the ε iron carbonitride and Fe_4N. With these processing times in excess of 3 h, the proportion of Fe_4N was found to decrease. Furthermore, when more than 2% C was in the compound layer, a compound with the structure of cementite, $Fe_3(CN)$, could also be detected.

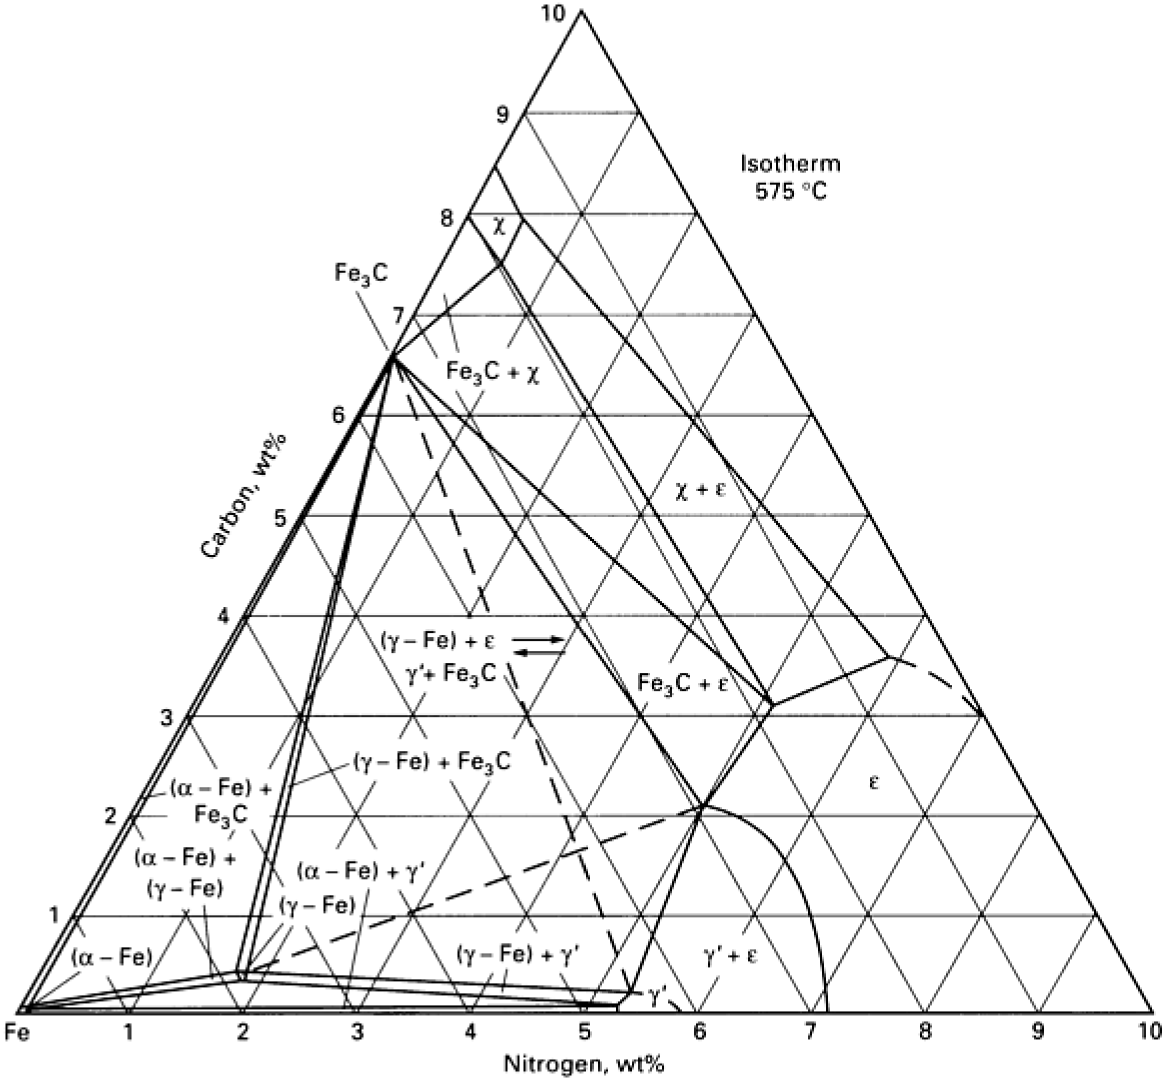

Fig. 13 Phase diagram at 575 °C (1065 °F) of the ternary iron-carbon-nitrogen system

In samples treated by Process 1, a high level of oxygen within the compound layer has been reported. But whether the presence of oxygen, which is known to accelerate the formation of the compound layer by promoting the cyanide-to-cyanate oxidation reaction, is essential for improved frictional properties has not been rigorously established.

Similarly, the question arises as to whether sulfur, present in Process 2, contributes significantly to enhanced antiscuffing properties. The predominant presence of an ε carbonitride phase is required for enhanced antiscuffing properties. Electron probe microanalysis of the compound layers formed by the two processes are presented in Fig. 14.

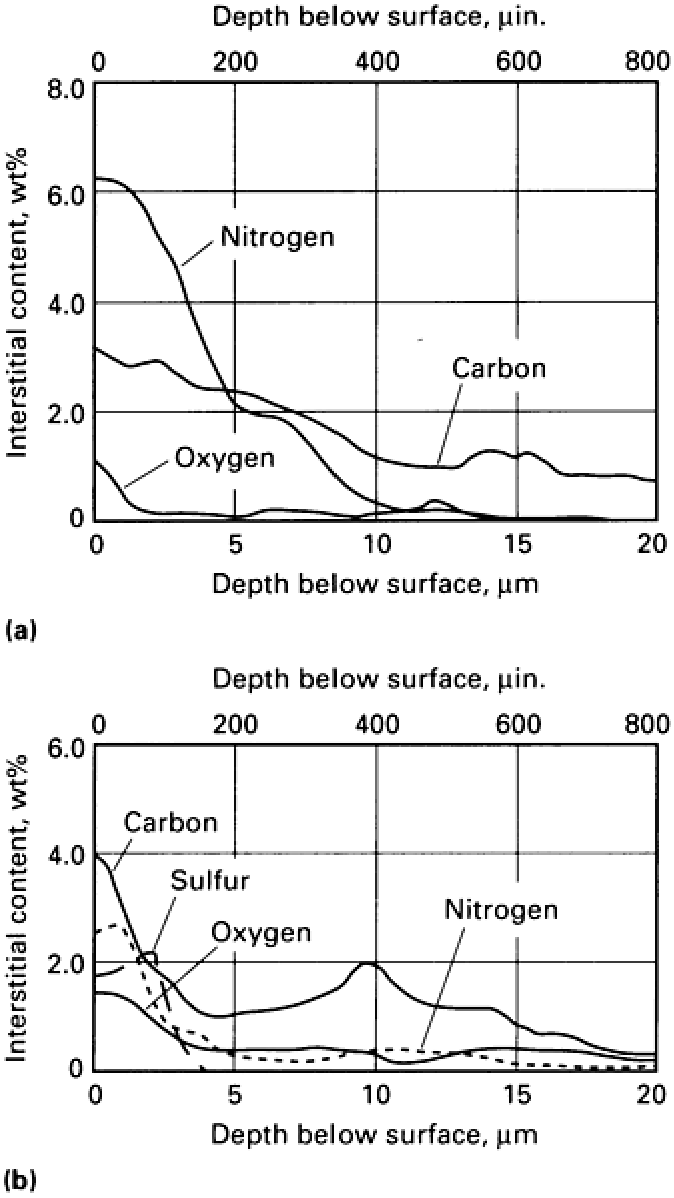

Fig. 14 Electron microprobe traces of compound layers. (a) Nitrogen, carbon, and oxygen in the compound layer formed by Process 1. (b) Nitrogen, carbon, oxygen, and sulfur in the compound layer formed by Process 2. Both treatments, 90 min

Nontoxic Salt Bath Nitrocarburizing Treatments

Environmental considerations and the increased cost of detoxification of cyanide-containing effluents have led to development of low-cyanide salt bath nitrocarburizing treatments.

Cyanates are the active nitriding constituent of both high-cyanide and low-cyanide nitrocarburizing baths. Reduction of the cyanide content permits markedly higher cyanate concentrations in the low-cyanide baths; this results in greatly increased nitriding activity. Unlike the reducing high-cyanide baths, the nominal cyanate and carbonate composition of the low-cyanide baths is oxidizing. The baths are composed of primarily potassium salts with some sodium salts. During nitriding, cyanates yield nitrogen to the steel and form carbonates. Cyanate concentration is maintained by the use of organic regenerators, which supply nitrogen to reform cyanates from carbonates.

Process 3: Low Cyanide with Sulfur. This patented process confers sulfur, nitrogen, and presumably, carbon and oxygen to surfaces of ferrous materials. The process is unique in that lithium salts are incorporated in the bath composition. Cyanide is held to very low levels: 0.1 to 0.5%. Sulfur species, present in the bath at concentrations of 2 to 10 ppm, cause sulfidation to occur simultaneously with nitriding. Sulfur levels near 10 ppm result in an apparently porous compound zone (Fig. 15); the dark areas are actually iron sulfide nodules, not voids. This compound zone is similar to the high-cyanide, sulfur-containing nitrocarburizing process that has, however, columnar iron-sulfide inclusions.

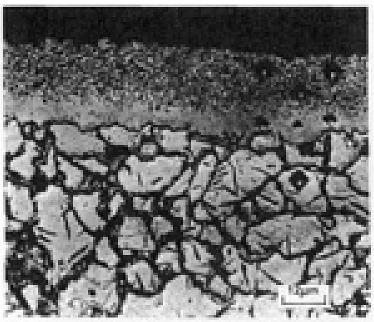

Fig. 15 Sample of plain carbon steel after low-cyanide salt bath nitrocarburizing treatment (Process 3). The high level of apparent porosity is a characteristic of high sulfur content in the compound zone; dark areas are actually iron-sulfide nodules, not voids.

Bath composition can be adjusted to lower sulfur levels (2 ppm) to form a less porous layer with a lower iron sulfide content.

A compound layer 20 to 25 μm (800 to 1000 μin.) thick forms in 90 min at 570 °C (1060 °F) on AISI 1010 steel, compared with the 8 to 10 μm (320 to 800 μin.) layer formed by the high-cyanide sulfur-bearing nitrocarburizing process in the same time. Figure 16 shows the thickness of the compound layer as a function of the treatment time for the nontoxic and cyanide-based treatments.

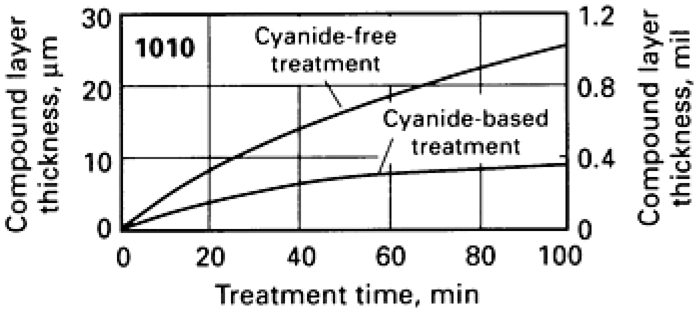

Fig. 16 Comparison of compound zone thickness produced by low-cyanide and cyanide-based treatments containing sulfur

Process 4: Low Cyanide without Sulfur. A low-cyanide alternative to the cyanide-based Process 1 has been developed. This process, like Process 3, is a cyanate bath with no lithium or sulfur compounds and very low cyanide levels (2 to 3%). Melon, an organic polymer, is used for bath regeneration.

When water quenching is employed, the low level of cyanide permits easier detoxification. Alternatively, quenching into a caustic-nitrate salt bath at 260 to 425 °C (500 to 795 °F) may be used for cyanide/cyanate destruction.

Processing temperature for Process 4 is 570 to 580 °C (1060 to 1080 °F); the rate of compound zone formation is comparable to that of Process 3. Metallurgical results are virtually identical with the cyanide-based Process 1.

Wear and Antiscuffing Characteristics of the Compound Zone Produced in Salt Baths

The resistance to scuffing after salt bath nitrocarburizing treatments has been frequently tested with a Falex lubricant testing machine (Fig. 17, 18, 19). A 32 by 6.4 mm (1.25 by 0.25 in.) test piece is attached to the main drive shaft by means of a shear pin, and two anvils or jaws having a 90° V-notch fit into holes in the lever arms. During testing, the jaws are clamped around the test piece, which rotates at 290 rpm, and the load exerted by the jaws is gradually increased. Both test pieces and jaws can be immersed totally in a small tank containing lubricant or other fluid, or tests can be carried out dry.

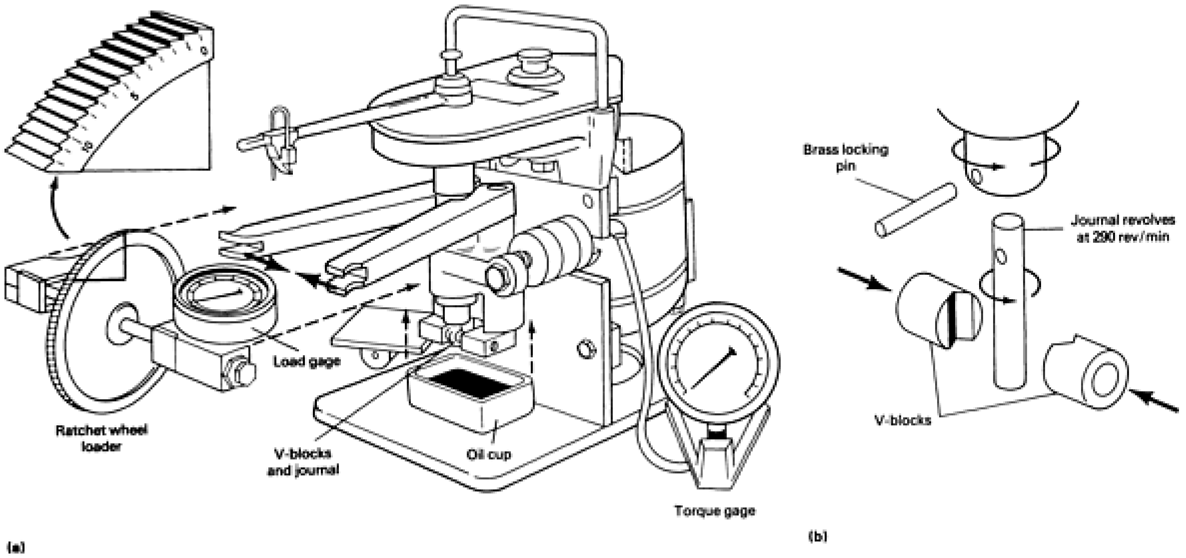

Fig. 17 Lubricant tester used to measure endurance (wear) life and load-carrying capacity of either dry solid-film lubricants or wet lubricants in sliding steel-on-steel applications. (a) Key components of instrument. (b) Exploded view showing arrangement of V-blocks and rotating journal

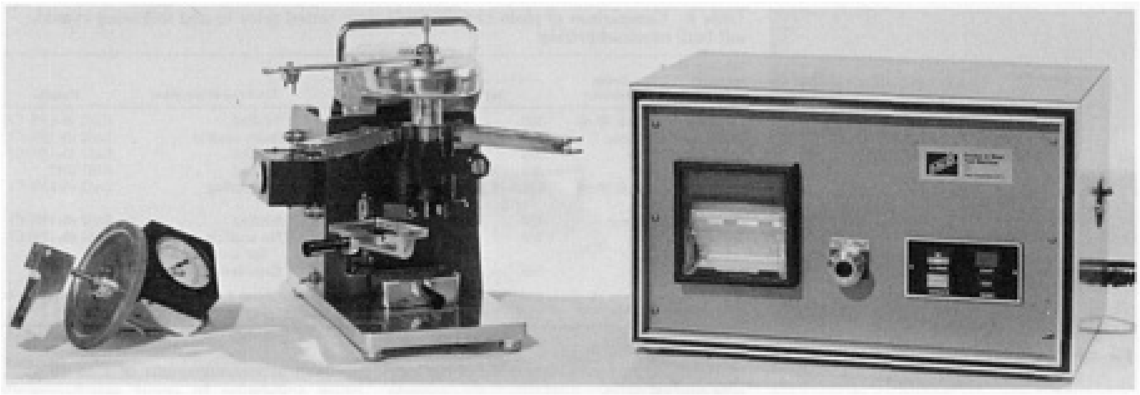

Fig. 18 State-of-the-art lubricant-testing machine incorporating a recorder to monitor the torque data used to determine wear life of the sample journal. The instrument provides both an instantaneous readout of the torque via a digital display and a continuous permanent record of torque values during the test on a strip chart. Workpiece failure is indicated by a torque rise of 1.1 N · m (10 lbf · in.) above the steady-state value or breakage of the shear pin, whichever failure criteria is reached first (per ASTM D 2625-83). Fig. 19 Close-up view of a journal and V-block setup ready for testing in a lubricant-testing machine. Wear is indicated by a reduction or distortion in the diameter of the journal as well as deformation of the notch in the V-block. Courtesy of Falex Corporation

Table 4 lists results of a few representative Falex tests for plain low-carbon steels both before and after cyanide salt bath nitrocarburizing treatments. The untreated low-carbon steel specimens do not show any significant scuffing resistance even when tested under oil-lubricated conditions. After treatment, however, even when tested dry, there is a considerable improvement in antiscuffing properties. Specimens tested in the dry condition after salt bath nitrocarburizing generate so much heat that they eventually become red hot and are extruded under the applied load. Untreated test pieces seize at relatively low loads before becoming red hot, whereas treated samples, even after extrusion, show no signs of scuffing.

During testing in oil, the specimens become highly polished. Similar Falex test results are reported for low-cyanide salt bath nitrocarburizing treatments.

Appendix 1**: Liquid Salt Bath Nitriding Noncyanide Baths

Hardening. Parts requiring core hardness shall be heat treated to the required core hardness before processing. Tempering to produce the specified core hardness shall be at a temperature not lower than 590 °C (1090 °F), except when tempering is conducted in conjunction with nitriding.

Stress Relief. Parts in which residual stresses may cause cracking or excessive distortion due to thermal shock or dimensional change because of metallurgical transformations during nitriding shall be stress relieved prior to final machining. Stress relieving shall be performed at a temperature not lower than 590 °C (1090 °F).

Cleaning. Parts, at the time of nitriding, shall be clean and free of scale or oxide, entrapped sand, core material, metal particles, oil, and grease, and shall be completely dry.

Preheating. Parts shall be preheated in air at 260 to 345 °C (500 to 650 °F) to maintain bath temperature and to avoid thermal shock upon immersion in the nitriding salt.

Nitriding. Parts shall be immersed in an aerated cyanate bath as indicated in Table 5.

Table 5 Recommended procedures for liquid salt bath nitriding in noncyanide baths

Material	Recommended time, h		Temperature	
	min	max	°C	°F
Carbon and low-alloy steels	1	2	580 ± 5	1075 ± 10
Tool and die steels (structural)	$\frac{1}{2}$	3	540-580	1000-1075
Tool steels (cutting)	$\frac{1}{12}$	1	540-580	1000-1075
Corrosion- and heat-resistant steels	1	2	580 ± 5	1075 ± 10
Ductile, malleable, and gray cast iron	1	4	580 ± 5	1075 ± 10

Quenching. Following treatment, parts shall be quenched in fused salts, water, oil, soluble oil solution, or air. Parts, except those made of air-hardening tool steels, may be cooled to 290 to 400 °C (550 to 750 °F) prior to actual quenching, when permitted by the purchaser.

Depth of compound layer shall be determined in accordance with SAE J423, microscopic method, at magnification of 500×, as indicated in Table 6.

Table 6 Depth of compound layer after liquid salt bath nitriding in a noncyanide bath

Material	Case depth[a]	
	mm	in.
Carbon and low-alloy steels	0.0038-0.02	0.00015-0.001
Tool and die steels (structural)	0.003-0.012	0.0001-0.0005
Tool and die steels (cutting)	. . . 0.003	. . . 0.0001
Corrosion- and heat-resistant steels	0.0038-0.02	0.00015-0.001
Ductile, malleable, and gray cast iron	0.0038-0.02	0.00015-0.001

(a) Ranges show minimum and maximum case depth.

Quality of Compound Layer. Any continuous surface porosity present shall not extend deeper than one-half the observed depth of the compound layer, determined by examining specimens metallographically at 500× magnification.

Hardness of compound layer shall be determined by microhardness measurements in accordance with ASTM E 384 on the nitrided surface or on metallographically prepared cross sections of the nitrided case using Knoop or another appropriate hardness tester, as agreed upon by purchaser and vendor (see Table 7).

Table 7 Hardness of the compound layer obtained after liquid salt bath nitriding in a noncyanide bath

Appendix 2† : Liquid Salt Bath Nitriding

Nitriding salts shall consist of a mixture of sodium and potassium cyanide and other salts.

Salt Bath. The cyanate, cyanide, and iron contents of the bath shall be controlled within percentages by weight:

Content	Concentration, %	
	min	max
Cyanate determined as KNCO	42	50
Cyanide determined as KCN	45	50

Nitriding. Parts shall be immersed in an aerated cyanide-cyanate bath as indicated in Table 8.

Table 8 Recommended procedures for liquid salt bath nitriding in cyanide-cyanate baths

Material	Recommended time, h		Temperature	
	min	max	°C	°F
Carbon and low-alloy steels	1	2	570 ± 5	1060 ± 10

Tool and die steels (structural)	$\frac{1}{2}$	3	540-570	1000-1060
Tool steels (cutting)	$\frac{1}{12}$	1	540-570	1000-1060
Corrosion- and heat-resistant steels	1	2	570 ± 5	1060 ± 10
Ductile, malleable, and gray cast iron	2	4	570 ± 5	1060 ± 10
Powder metal products (ferrous)	$\frac{1}{2}$	2	570 ± 5	1060 ± 10

Quenching. Following treatment, the parts shall be quenched in water, oil, soluble oil solution, or air. Parts, except those made of air-hardening tool steels, may be cooled to 290 to 400 °C (550 to 750 °F) prior to actual quenching, when permitted by the purchaser.

Depth of case shall be determined in accordance with SAE J423 (microscopic method) at 500× magnification as indicated in Table 9.

Table 9 Depth of case measurements obtained following liquid salt bath nitriding in cyanide-cyanate baths

Material	Case depth	
	mm	in.
Plain carbon and low-alloy steels	0.004-0.03	0.00015-0.001
Tool and die steels (structural)	0.003-0.0	0.0001-0.0005
Tool and die steels (cutting)	. . . 0.003	. . . 0.0001
Corrosion- and heat-resistant steels	0.004-0.03	0.00015-0.001
Ductile, malleable, and gray cast iron	0.004-0.03	0.00015-0.001

Plasma (Ion) Nitriding of Steels

James M. O'Brien, O'Brien & Associates; Dan Goodman, Surface Combustion, Inc.

Introduction

PLASMA, OR ION, NITRIDING, is a method of surface hardening using glow discharge technology to introduce nascent (elemental) nitrogen to the surface of a metal part for subsequent diffusion into the material. In a vacuum, high-voltage electrical energy is used to form a plasma, through which nitrogen ions are accelerated to impinge on the workpiece. This ion bombardment heats the workpiece, cleans the surface, and provides active nitrogen. Ion nitriding provides better control of case chemistry and uniformity and has other advantages, such as lower part distortion than conventional (gas) nitriding. A key difference between gas and ion nitriding is the mechanism used to generate nascent nitrogen at the surface of the work.

Case Structures and Formation

The case structure of a nitrided steel, which may include a diffusion zone with or without a compound zone (Fig. 1), depends on the type and concentration of alloying elements and the time-temperature exposure of a particular nitriding treatment. Moreover, because the formation of a compound zone and/or a diffusion zone depends on the concentration of nitrogen, the mechanism used to generate nascent nitrogen at the surface of the workpiece also affects the case structure. These factors are discussed below, with emphasis on the differences between gas and plasma nitriding.

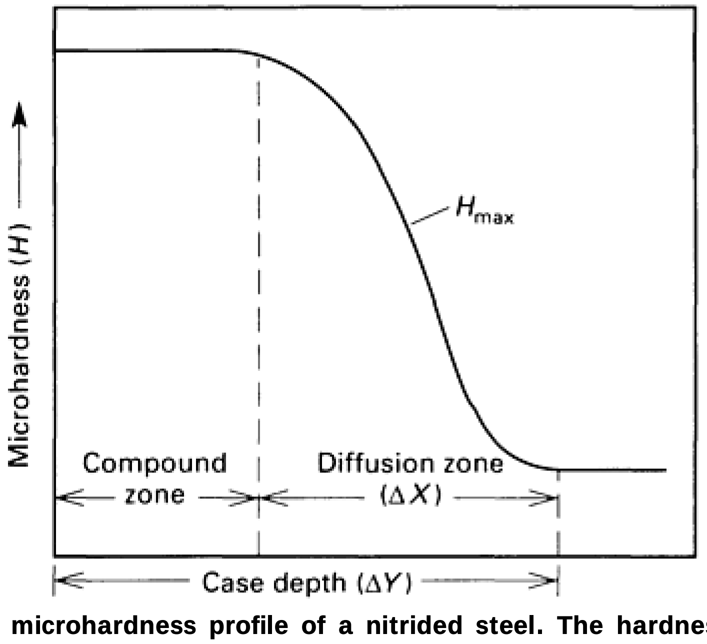

Fig. 1 Factors affecting the microhardness profile of a nitrided steel. The hardness of the compound zone is unaffected by alloy content, while the hardness of the diffusion zone is determined by nitride-forming elements (Al, Cr, Mo, Ti, V, Mn). ΔX is influenced by the type and concentration of alloying elements; ΔY increases with temperature and decreases with alloy concentration.

Diffusion Zone of a Nitrided Case. The diffusion zone of a nitrided case can best be described as the original core microstructure with some solid solution and precipitation strengthening. In iron-base materials, the nitrogen exists as single atoms in solid solution at lattice sites or interstitial positions until the limit of nitrogen solubility (; 0.4 wt% N) in iron is exceeded. This area of solid-solution strengthening is only slightly harder than the core. The depth of the diffusion zone depends on the nitrogen concentration gradient, time at a given temperature, and the chemistry of the workpiece.

As the nitrogen concentration increases toward the surface, very fine, coherent precipitates are formed when the solubility limit of nitrogen is exceeded. The precipitates can exist both in the grain boundaries and within the lattice structure of the

grains themselves. These precipitates, nitrides of iron or other metals, distort the lattice and pin crystal dislocations and thereby substantially increase the hardness of the material.

In most ferrous alloys, the diffusion zone formed by nitriding cannot be seen in a metallograph because the coherent precipitates are generally not large enough to resolve. In Fig. 2, for example, martensite in the diffusion zone cannot be visually distinguished from that in the core. In some materials, however, the nitride precipitate is so extensive that it can be seen in an etched cross section. Such is the case with stainless steel (Fig. 3), in which the chromium level is high enough for extensive nitride formation.

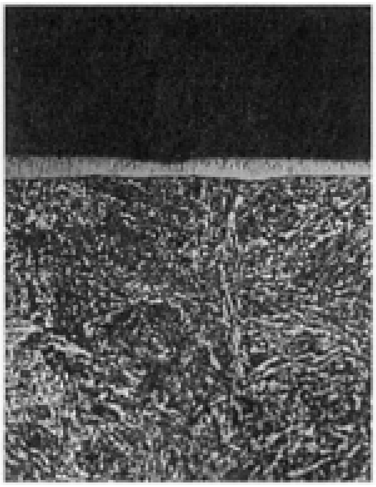

Fig. 2 Compound layer of γ' (Fe_4N) on the ion-nitrided surface of quenched and tempered 4140 steel. The γ' compound layer is supported by a diffused case, which is not observable in this micrograph. Nital etched. 500×

Fig. 3 Observable diffusion zone on the unetched (white) portion of an ion-nitrided 416 stainless steel. Nital etched. 500×

Compound Layers in Nitrided Steels. The compound zone is the region where the γ' (Fe_4N) and ε($Fe_{2-3}N$) intermetallics are formed. Because carbon in the material aids ε formation, methane is added to the process gas when an ε layer is desired. Hydrogen also tends to catalyze Fe_2N formation. These compound layers are called white layers because they appear white on a polished, etched cross section.

Structure of Gas-Nitrided Steel Case. Gas nitriding with ammonia produces a compound zone that is a mixture of the γ' and ε compounds; the mixture is due to the variability of ammonia dissociation, and therefore of nitriding potential, as the compound layer is formed. In conventional gas nitriding, the nascent nitrogen is produced by introducing ammonia (NH_3) to a work surface that is heated to at least 480 °C (900 °F). Under these conditions, the ammonia, catalyzed by the metal surface, dissociates to release nascent nitrogen into the work and hydrogen gas into the atmosphere of the furnace. The nitriding potential, which determines the rate of introduction of nitrogen to the surface, is determined by the NH_3 concentration at the work surface and its rate of dissociation. This nitriding potential, which can vary significantly in the gas process, is responsible for the limited control of microstructure in the nitrided case.

X-ray diffraction has shown that from the outer surface to the beginning of the diffusion zone the dominant compound changes from ε to γ'. However, both phases exist throughout the entire white layer, which is referred to as a dual-phase layer.

The dual-phase layer has two characteristics that make it susceptible to fracture:

- Weak bonding at the interface between phases
- Different thermal-expansion coefficients in the two phases

Layers that are particularly thick or that are subjected to temperature fluctuation in service are particularly prone to failure.

Another mechanical weakness in the gas-nitrided white layer is porosity in the outer region of the layer. As the compound zone builds, ammonia dissociation becomes more sluggish without the catalytic action of the steel surface, and gas bubbles begin to form in the layer.

Structure of Ion-Nitrided Steel Case. In the ion-nitriding process, nitrogen gas (N_2) can be used instead of ammonia because the gas is dissociated to form nascent nitrogen under the influence of the glow discharge. Therefore the nitriding potential can be precisely controlled by the regulation of the N_2 content in the process gas. This control allows precise determination of the composition of the entire nitrided case, selection of a monophase layer of either ε or γ', or total prevention of white-layer formation (Fig. 4)

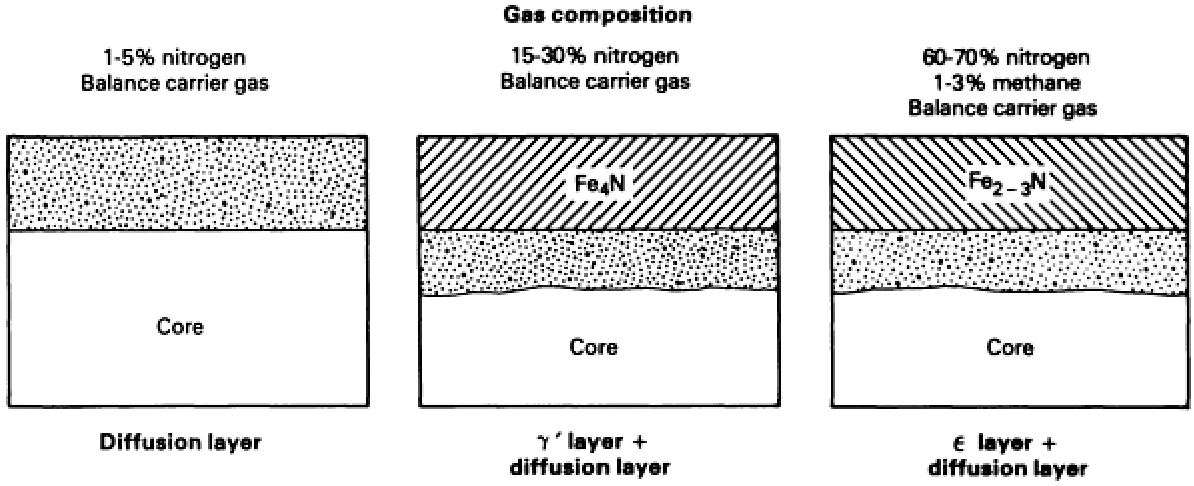

Fig. 4 Typical gas compositions and the resulting metallurgical configurations of ion-nitrided steel

General Process Description

An ion-nitriding system is shown in Fig. 5. The parts to be nitrided are cleaned, usually by vapor degreasing, loaded into the vacuum vessel, and secured. The subsequent process of plasma nitriding can be broken down into four steps: vessel evacuation, heating to nitriding temperature, glow-discharge processing at nitriding temperatures, and cooling.

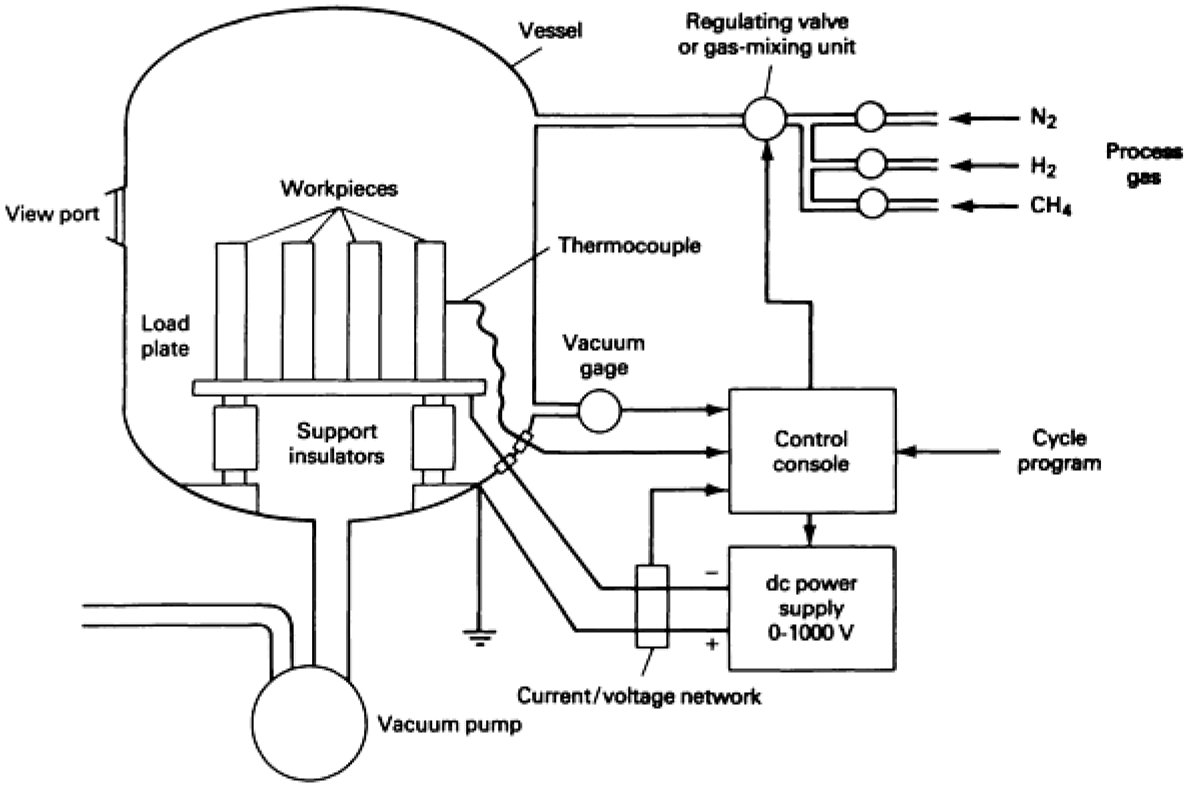

Fig. 5 Typical ion-nitriding vessel

Vessel evacuation is performed by a roughing pump or roughing pump-blower combination so that pressure is reduced to a level of 0.05 to 0.1 torr (mm of mercury). This is necessary to remove most of the initial air and any contaminants. Harder vacuum levels can be achieved but are not necessary for most materials.

The method of heating the load to nitriding temperature has evolved over the years. In the past, loads were heated only by the glow discharge itself. This method presented some difficulty because moisture and other impurities on the work surface tended to cause arcing to the parts in the early stages of the heating cycle. The methods applied to extinguish or prevent arcs also tended to lengthen the heating cycle significantly.

Today, resistance heaters or cathode shields are normally used to bring the load to nitriding temperatures (375 to 650 °C, or 700 to 1200 °F) before glow discharge. Heating of the load can be with glow discharge only, using a cathode preheating shield arrangement up to an intermediate temperature, and then switching to glow discharge on the parts using resistance heating elements or convection. The most common approach is with resistance heating. While heating, the pressure is increased so that the glow seam does not get too thick and cause localized overheating.

Glow-Discharge Process. After the work load is heated to desired temperature, process gas is admitted at a flow rate determined by the load surface area. Pressure is regulated in the 1 to 10 torr range by a control valve just upstream from the vacuum pump. The process gas is normally a mixture of nitrogen, hydrogen, and, at times, small amounts of methane.

In the presence of this process gas, the load is maintained at a high negative dc potential (500 to 1000 V) with respect to the vessel, which is grounded. Under the influence of this voltage, the nitrogen gas is dissociated, ionized, and accelerated toward the workpiece (the cathode). Within a short distance of the workpiece, the positively charged nitrogen ion then acquires an electron from the cathode (workpiece) and thus emits a photon. This photon emission during the return of nitrogen ions to their atomic state results in the visible glow discharge that is characteristic of plasma techniques. Upon impact with the workpiece, the kinetic energy of the nitrogen atoms is also converted into heat, which can totally (or in combination with an auxiliary heating source) bring the load to nitriding temperature.

The glow discharge surrounding negatively charged workpieces forms at voltages of 200 to 1000 V (Fig. 6) with gas pressures of 1 to 10 torr. The thickness of the glow envelope (or glow seam) can be altered by pressure, temperature, gas mix composition, dc voltage, and current. Typically a large or thick glow envelope is created with higher temperature, lower pressure, high hydrogen concentration in the gas mix, and higher dc voltage and current. A desirable glow-discharge thickness is about 6 mm (0.25 in.), unless parts with holes or slots require a thinner glow envelope.

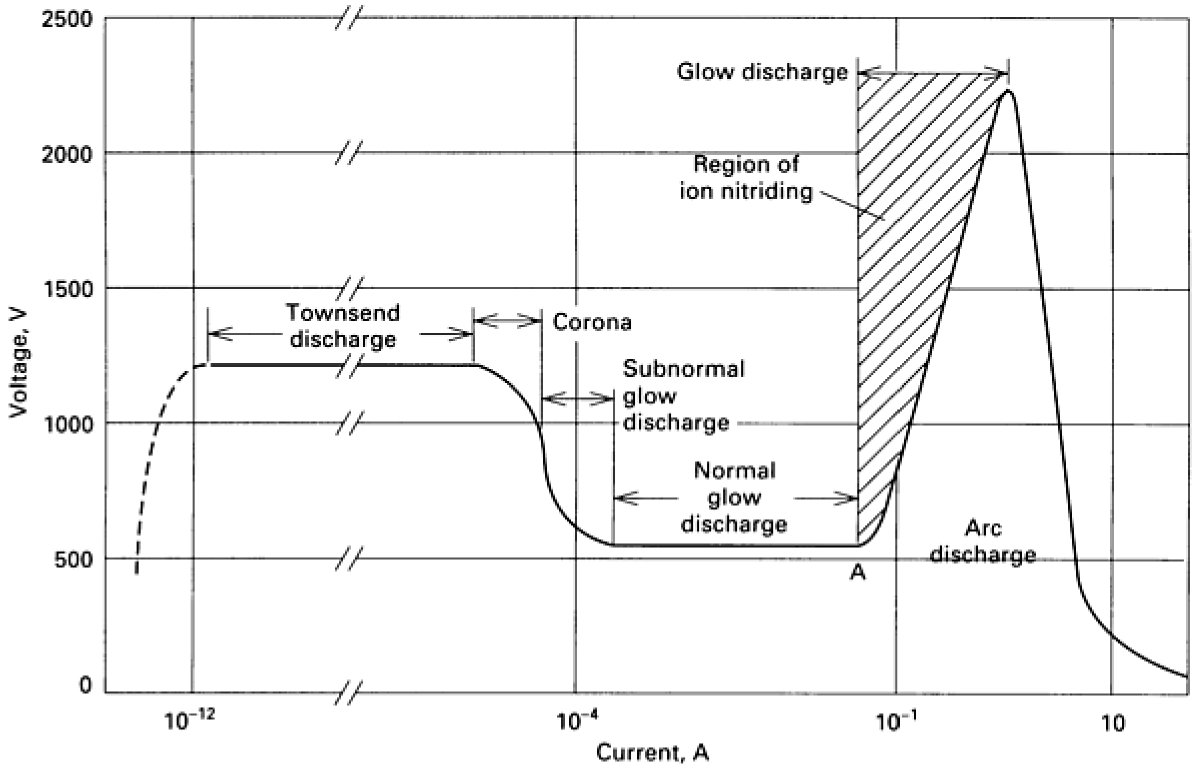

Fig. 6 Voltage versus current characteristics of different types of discharge in argon

During the glow-discharge process, different alloy or iron atoms combine with the nitrogen as it diffuses into the material, forming a hardened surface and case. Figure 7 shows these mechanisms for iron. The nitriding current (proportional to the nitrogen ion flux), temperature, and process time determine the depth of the nitride case achieved. A uniform glow-discharge envelope is also necessary for proper case uniformity, especially when part geometry is complex (as with a gear or fuel injector).

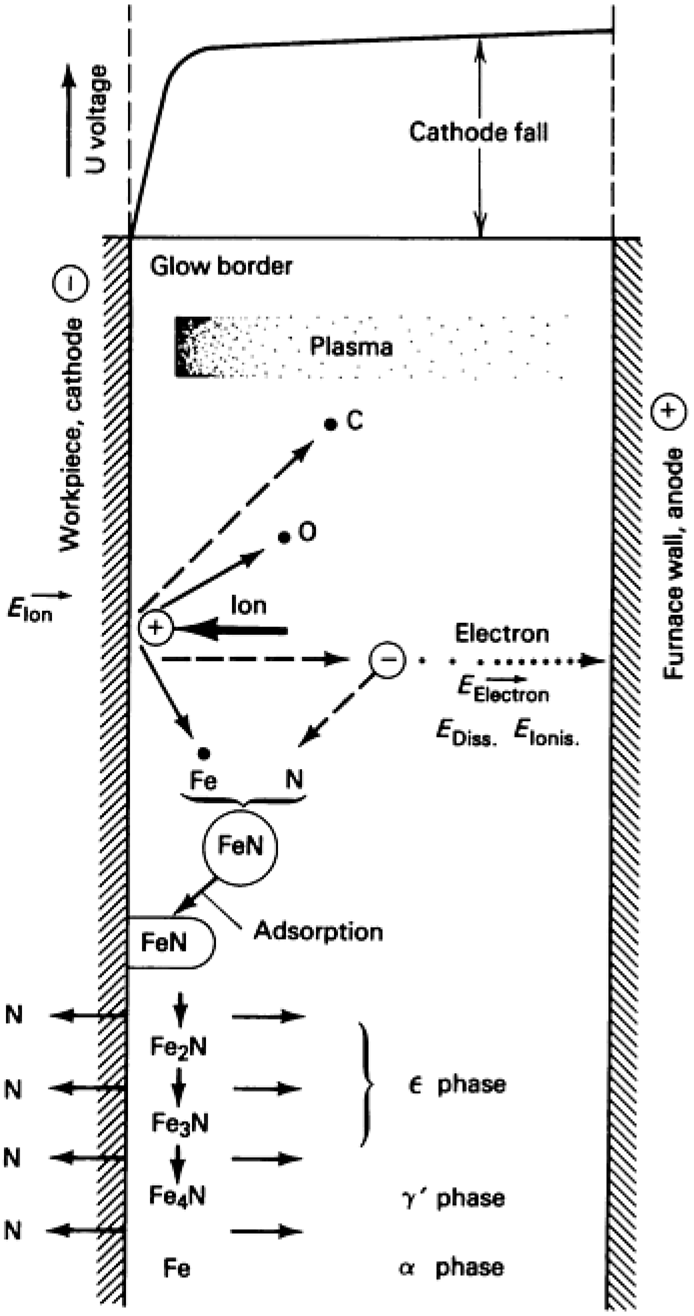

Fig. 7 Glow-discharge ion-nitriding mechanisms (Koelbel's model)

Cooling. After the glow-discharge process, the voltage and process gas flow are terminated, and the load is cooled by inert-gas circulation. Cooling is accomplished by backfill ing with nitrogen or other inert gases and recirculating the gas from the load to a cold surface such as the cold wall. From that point, the heat can be transferred and removed via the water in the cooling jacket.

Equipment

A basic ion-nitriding system (Fig. 5) consists of a vacuum chamber, a power supply, and a process gas system with a gas-mixing panel or other mass flow controls. An isolated hearth or work support fixturing is also required to ensure electrical isolation between the workpiece and vacuum vessel. An auxiliary heating system and a rapid cooling system can also be included to improve cycle time.

Ion-nitriding control systems may vary in complexity. Microprocessor systems are generally used to control or monitor several parameters. These include the work temperature, vessel wall temperature, vacuum (absolute pressure) level, glow-discharge voltage and current, auxiliary heating source voltage and current, and gas mix composition. The microprocessor will also control the various inputs and outputs necessary for activating/stopping or sequencing valves and motors.

Vessel Construction. The vessel is a vacuum chamber, which can be a hot-walled design, but is more often a dual-walled and water-cooled design. The vessel can be horizontally or vertically loaded in a drop-bottom, pit, or bell arrangement. Typically, no internal insulation is required because of the lower temperature (less than 650 °C, or 1200 °F) and the desire to create sufficient heat loss to support a steady dc power supply output to the work load.

The isolated-hearth arrangement is divided into three basic areas:

- High-voltage feed-through arrangement, which carries the voltage through the vessel wall while maintaining a good vacuum seal
- Load support insulators, which carry the actual load weight while providing good dielectric qualities
- Charge plate or fixture, which has the workpieces placed on it or provides mechanical masking if desired

Sight ports placed around the vessel provide a view of the ion-nitriding process and are necessary for checking the load and ensuring that the selected parameters are accurate and that no detrimental hollow cathode disturbances (overlapping glow-discharge envelopes) have developed.

Power Supply and Control. The dc power supply is the most important component of an ion-nitriding system. The power supply must provide an output voltage from 0 to 1000 V and an output current matched to the size of the vessel and work load. Typical current ratings range from 25 to 450 A (dc). The amount of power applied to the load determines the temperature. Most power supplies provide proportional output control through silicon-controlled rectifiers (SCRs).

Another important design consideration in the power supply is arc detectioni suppression controls. Arcing can occur because the glow-discharge process causes the removal of surface impurities, which are always present. The impurities are removed in the form of an arc, in which there is a sudden decrease in voltage and increase in current. Because of this, both minimum and maximum current levels and voltage rate of change (dV/dt) and voltage/current relationships (slope) must be constantly monitored. When an arc is detected, the power output is momentarily shut off and the existing power diverted from the work load to avoid any possible damage. This is accomplished by placing an inductive load (choke) in line with the output of the power supply and using a crowbar SCR to short the output and momentarily dissipate the power.

Atmosphere and Pressure Control. The gas-mixing panel is used for blending gases, usually nitrogen, hydrogen, and methane. A typical composition for a γ' compound layer would be 75% H and 25% N. For an ε compound layer, a typical gas mixture would be 70% N, 27% H, and 3% methane. The mixing can be accomplished by injecting the gases through orifices at an equal pressure and varying the time of flow to establish the correct percentage concentration, or mixing can be done with mass flow control systems.

Ion nitriding is generally performed at absolute pressure levels of 130 to 1300 Pa (1 to 10 torr), necessitating a means of controlling pressure levels. Control is accomplished in two stages. First, a motorized needle valve on the inlet line to the vessel, in series with the gas-mixing panel, proportionally controls the gas flow up to a maximum level. At this point, a reverse-acting valve on the evacuation line between the vessel and the vacuum pump controls the amount of gas being evacuated until the desired pressure set point is met.

Fixturing to hold or mask the workpieces mechanically can be designed to optimize load placement or performance. Fixturing must minimize gaps between areas of glow discharge to avoid overlapping (hollow cathode disturbances) of the glow envelope. Also, the cross section of masking should resemble that of the workpieces to allow better temperature uniformity.

Auxiliary Heating. If the workpiece is large, auxiliary heating is necessary when the glow-discharge process is insufficient for direct heating. Auxiliary heating can be accomplished in several ways, the most common of which are cathode preheating and resistance heating.

Cathode preheating, which occurs during the beginning stages of the ion-nitriding process, requires an internal shield that is electrically isolated from the vessel wall. This shield is electrically charged and heats up and radiates the heat to the work load, allowing a faster heat-up time.

Resistance heating generally uses a low-voltage ac power supply such as a variable reactance transformer connected to graphite or alloy heating elements. As with cathode preheating, the elements heat up and radiate to the workpieces to speed the heat-up time.

Workpiece Factors

As mentioned in the section "Case Structures and Formation," the nitrogen concentration achieved during nitriding affects the depth and hardness of the case. In addition, the microstructure and resulting mechanical properties of a nitrided case also depend on the original composition and microstructure of the workpiece.

Suitability of Materials. In general, the response of a material to nitriding depends on the presence of strong nitride-forming elements. Plain carbon steels can be nitrided, but the diffused case is not significantly harder than the core. The strongest nitride formers are aluminum, chromium, molybdenum, vanadium, and tungsten. Because the white-layer constituents are only compounds of iron and nitrogen, the hardness of these layers is essentially independent of alloy content.

The premier nitriding steels are the Nitralloy series, which combine approximately 1 wt% Al with 1.0 to 1.5 wt% Cr. Other alloys that form excellent diffused cases are the chromium-bearing alloys, such as the 4100, 4300, 5100, 6100, 8600, 8700, 9300, and 9800 series. Other good nitriding materials include most of the tool and die steels, stainless steels, and precipitation-hardening alloys.

Parts made by powder metallurgy (P/M) can also be ion nitrided, but precleaning is more critical than with wrought alloys because of the porosity characteristic. A baking operation should precede the ion nitriding P/M parts to break down or release agents and/or to evaporate any cleaning solvents.

Significant hardening in the diffusion zone cannot be developed in carbon steels or cast iron. However, a compound zone can be formed and is often excellent for wear resistance in lightly loaded parts. Because the compound zone is supported by a relatively soft diffusion zone, applications involving high localized stresses should be avoided with these materials.

Effect of Prior Microstructure. As with other diffusion methods, the initial microstructure can also influence the response of a material to nitriding. In the case of alloy steels, a quenched and tempered structure is considered to produce the optimum nitriding results. The tempering temperature should be 15 to 25 °C (30 to 50 °F) above the anticipated nitriding temperature to minimize further tempering of the core during the nitriding process.

If the nitriding of a nonmartensitic matrix is desired, it is important that prior heat treatment be accompanied by as fast a cooling as possible to provide a relatively low-temperature austenite transformation and retain a high percentage of the nitride-forming element in solution for subsequent precipitation.

Hardness profiles for typical ion-nitrided alloys are shown in Fig. 8. The hardness increase of an ion-nitrided layer is virtually the same as for any nitriding process that provides the same nitrogen concentration profile. As previously mentioned, the hardness of the diffused case depends on precipitation hardening, while that of the white layer depends on the type and thickness of the compound formed. Because the white layers are compounds of only iron and nitrogen, the hardness of these layers is essentially independent of alloy content.

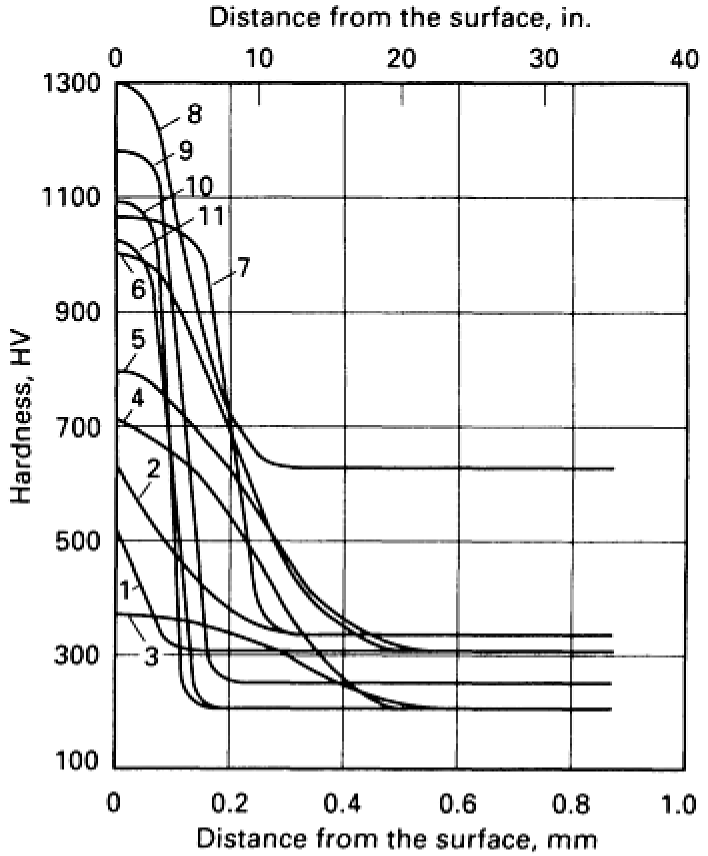

Fig. 8 Hardness profile for various ion-nitrided materials. 1, gray cast iron; 2, ductile cast iron; 3, AISI 1040; 4, carburizing steel; 5, low-alloy steel; 6, nitriding steel; 7, 5% Cr hot-work steel; 8, cold-worked die steel; 9, ferritic stainless steel; 10, AISI 420 stainless steel; 11, 18-8 stainless steel

White-Layer Properties. In general, case depth and white-layer composition should be selected for the anticipated operating conditions of the nitrided component. The ε layer is best for wear and fatigue applications that are relatively free of shock loading or high localized stresses. The γ' layer is somewhat softer and less wear resistant, but is tougher and more forgiving in severe loading situations. The white layer also provides increased lubricity. In addition to mechanical properties, the white layer, which is relatively inert, provides increased corrosion resistance in a variety of environments.

Fatigue strength, in addition to hardness and wear resistance, is significantly improved by nitriding (Fig. 9). The formation of precipitates in the diffused case results in lattice expansion. The core material, in an attempt to maintain its original dimension, holds the nitrided case in compression. This compressive stress essentially lowers the magnitude of an applied tensile stress on the material and thus effectively increases the endurance limit of the part.

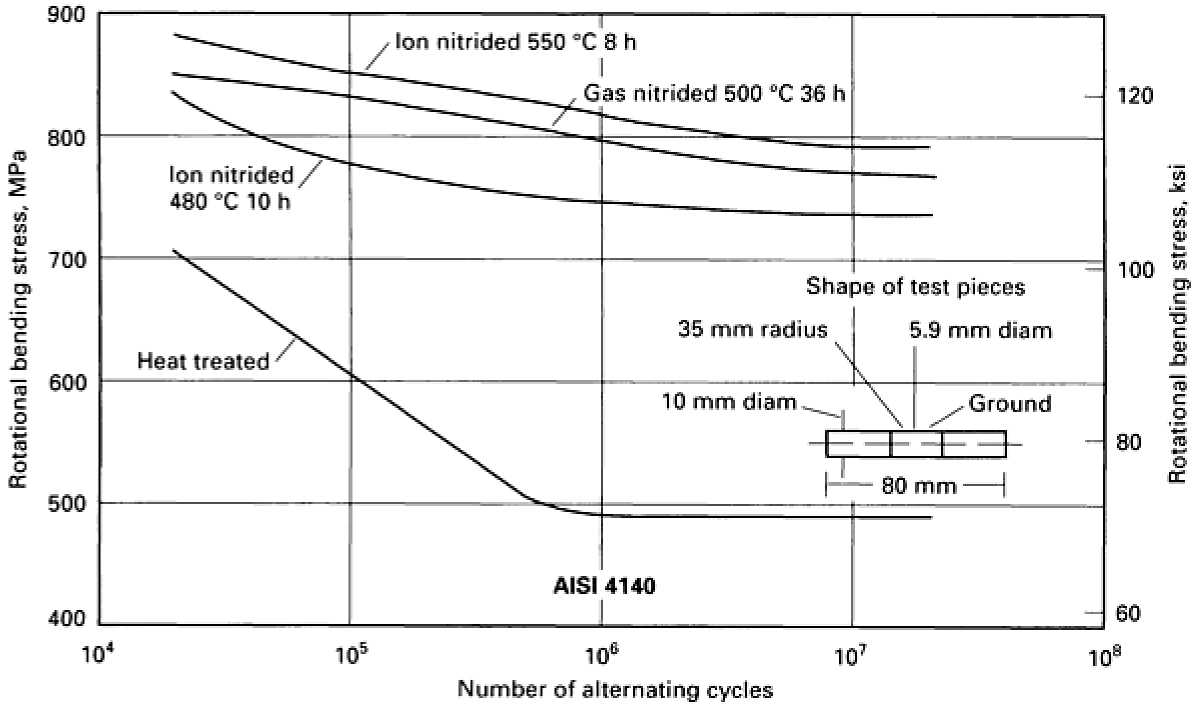

Fig. 9 Effect of nitriding on fatigue strength

Ion-Nitriding Applications

Various alloy steel and cast iron wear components, including gears, crankshafts, cylinder liners, and pistons, are excellent candidates for the ion process. In one case, P/M transmission gears are being ion nitrided to improve mechanical properties. In general, case depth and white-layer composition should be selected for the anticipated operating conditions of the nitrided component.

One rapidly growing area of ion nitriding is the fuel systems industry. Components used in fuel injection systems experience erosive wear from the fuel and fatigue from rapid cycling of fuel pressure. Ion nitriding greatly enhances the resistance to both of these effects.

The increased lubricity of white layers combined with hardness and fatigue strength has generated significant growth of the ion process in the tool and die industry. Hot work dies, which usually fail by thermal fatigue and sticking, have particularly benefited from ion nitriding following quenching and tempering.

Advantages and Disadvantages. Ion nitriding, when compared to conventional (gas) nitriding, offers more precise control of the nitrogen supply at the workpiece surface and the ability to select either an ε or a γ' monophase layer or to prevent white-layer formation entirely (Fig. 4). Other advantages of ion nitriding are:

- Improved control of case thickness
- Lower temperatures (as low as 375 °C, or 700 °F, due to plasma activation, which does not exist in gas nitriding)
- Lower distortion
- No environmental hazard (freedom from handling ammonia)
- Reduced energy consumption
- Ability to automate
- Ability to shield areas where nitriding is not desired by simple mechanical masking

A disadvantage of the ion process is the need to fixture parts to avoid localized overheating.

Sputtering and Ion Nitriding of Stainless Steels. Ion nitriding has a strong advantage over competing processes in the case of stainless steels, particularly austenitic or 300 series materials. The chromium-oxide passive layer on the surface of these materials represents a barrier to nitriding and must be removed prior to processing. With the gas nitriding

of stainless steels, several processes, such as wet blasting, pickling, and chemical reduction, have been developed to remove the oxide. With ion nitriding, however, this passive layer can be removed by sputtering in hydrogen in the vessel itself just prior to introducing the process gas. With most materials, even the sputtering that occurs naturally during the actual nitriding process is enough to yield good nitriding results.

When nitriding stainless alloys by any method, the hardening mechanism involves the formation of chromium-nitrides, decreasing the chromium content in the alloy. This chromium depletion in turn lowers the corrosion resistance of the case.

Alternative to Carbonitriding for Dimensional Control. Ion nitriding is becoming a replacement for carbonitriding in some areas. The driving force for this decision is the growing industry focus on dimensional control and the desire to reduce or eliminate machining after heat treatment.

The distortion of carbonitrided parts occurs in three ways:

- Heating to the austenitic range relieves residual stress
- Oil quenching introduces high thermal stresses and some localized plastic deformation
- The expansion of the case during martensite formation can cause some part distortion

Ion nitriding can be performed at temperatures as low as 375 °C (700 °F), which minimizes the amount of residual stress relieved. Because loads are gas cooled, they do not experience distortion from temperature gradients or martensite formation.

Gaseous and Plasma Nitrocarburizing of Steels

Tom Bell, Wolfson Institute for Surface Engineering, University of Birmingham, United Kingdom

---

Introduction

FERRITIC NITROCARBURIZING processes are those thermochemical treatments which involve the diffusional addition of both nitrogen and carbon to the surface of ferrous materials at temperatures completely within the ferrite phase field (Ref 1, 2). The primary object of such treatments is usually to improve the anti-scuffing characteristics of ferrous engineering components by producing a "compound layer" on the surface which has good tribological properties (Fig. 1). In addition, the fatigue characteristics of the material can be considerably improved, particularly when nitrogen is retained in solid solution in the "diffusion zone" beneath the compound layer. This is normally achieved by quenching into oil or water from the treatment temperature, usually 570 °C (1060 °F).

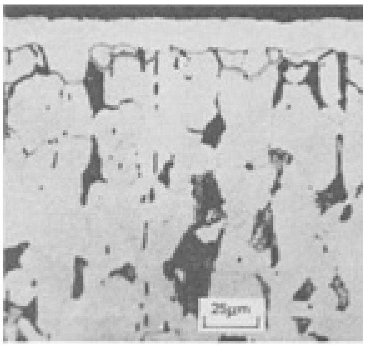

Fig. 1 Mild steel after 3 h gaseous nitrocarburizing in an ammonia/endothermic gas mixture at 570 °C (1060 °F) followed by oil quenching. Source: Ref 2

Nitrocarburizing treatments were first introduced in the early 1950s; since that time an extremely wide range of engineering components, such as rocker-arm spacers, textile machinery gears, pump cylinder blocks and jet nozzles, have been treated for wear resistance, while components such as crankshafts and drive shafts have been treated for improved fatigue properties.

Ferritic nitrocarburizing treatments have been successfully applied to most ferrous materials, including wrought and sintered plain carbon and alloy steels, stainless steels, and cast irons. However, the most marked Improvement in both anti-scuffing and fatigue properties, relative to untreated material, is found with plain low-carbon steels.

Until the late 1960s, the only nitrocarburizing processes available used a medium of molten cyanide-based salts to confer the property improvements required. However, since then concern about the overall environmental aspects of heat-treatment processing with cyanide-based salts has been increasing. Consequently, there has been intense interest in the development of cyanide-free nitrocarburizing treatments as technically and economically viable alternatives to the cyanide-based processes.

Considerable progress has been made over the last 25 years in the development of essentially toxic-free salt bath nitrocarburizing treatments (see the discussion of liquid nitrocarburizing in the article "Liquid Nitriding" in this Volume). However, it is the purpose of this article to review only those scientific and technological studies which have led to both the widespread introduction and greater appreciation of gaseous nitrocarburizing treatments and more recently available plasma methods.

Gaseous Ferritic Nitrocarburizing

As described in the introduction, gaseous ferritic nitrocarburizing involves the introduction of carbon and nitrogen into a steel in order to produce a thin layer of iron carbonitride and nitrides, the "white layer" or compound layer, with an underlying diffusion zone containing dissolved nitrogen and iron (or alloy) nitrides. The white layer enhances surface resistance to galling and wear. The diffusion zone increases the fatigue endurance limit significantly, especially in carbon and low-alloy steel.

The compound layer may contain varying amounts of γ', ε phase, cementite, and various alloy carbides and nitrides. The exact composition is a function of the nitride-forming elements in the material and the composition of the atmosphere as discussed below.

Gaseous nitrocarburizing is performed near 570 °C (1060 °F), a temperature just below the austenite range for the Fe-N system. Treatment times generally range from 1 to 3 h.

Preliminary Treatments.

The surface to be nitrocarburized must be free of contaminants such as oxides, scales, oil, and decarburization, if optimum results are to be obtained. Vapor degreasing is adequate for most applications. It may be necessary, especially on high-chromium materials and cast irons that have been burnished or otherwise highly finished, to grit blast with fine abrasive, to apply a light phosphate coating, or both, before nitrocarburizing. Highly finished surfaces are often associated with superficial metal flow at the surface, with the result that the initiation of nitriding is difficult. Surfaces having very low surface roughness can respond well to nitriding, provided that surface burnishing has been avoided. Finishing techniques with good cutting action are required.

Preliminary heat treatments range from simple stress relieving in order to control distortion to hardening and tempering in order to increase the core strength of the material. Stress relief and tempering temperatures should be at least 25 °C (45 °F) above the nitrocarburizing temperature to prevent alteration of core properties during the nitrocarburizing process.

Furnace Condition and Safety Precautions.

Batch furnaces with integral oil quenches are ideally suited for performing gas nitrocarburizing; however, the overall condition of the furnace is somewhat more critical than when the same furnace is used for other heat-treating operations such as hardening, carburizing, and carbonitriding. The hot chamber temperature should be controllable within ±5 °C (±

10 °F) at 570 °C (1060 °F) throughout the entire volume. Thermocouple and instrument systems designed to operate at the higher temperatures of other heat-treating processes are not always adequate for lower temperatures. Gas leaks in the furnace and around doors must be minimized. *Caution: Safety precautions must be carefully considered and rigorously enforced, because the process involves a combustible atmosphere that is explosive when operated below the self-ignition temperature*. Only minor gas leaks can be allowed, and double pilots should be provided at all doors. An interlock between door operation and pilot function provides added safety. Precautions must be taken to ensure that gas burn-off ports are properly sized, free of clogging, well vented from the building, and equipped with dependable pilots. All outside doors must be equipped with flame screens of sufficient capacity to cover the entire door opening.

The usual precautions also must be practiced with the quench oil:

- Adequate extinguisher equipment
- Assurance that the oil is free from water
- Maintenance of adequate temperature controllers and over-temperature devices to ensure that the oil does not become overheated

Steps also must be taken to ensure that atmosphere flow is sufficient to maintain positive pressure in the furnace during quenching to prevent the egress of air through burn-off or small leaks. At start-up, atmosphere gas may be introduced by heating the furnace above self-ignition temperature--760 °C (1400 °F)--and introducing atmosphere in the usual manner or by purging all the air from the furnace with nitrogen before introducing the reactive atmosphere. On shutdown, the furnace should be heated above self-ignition temperature of 760 °C (1400 °F) before burning the furnace out, or it should be purged with nitrogen.

Physical Metallurgy of Gaseous Ferritic Nitrocarburizing

A particularly important and detailed study into the scientific understanding of gaseous nitrocarburizing treatment was published by Prenosil in 1965 (Ref 3). He investigated the structure and composition of the compound layer formed on relatively pure iron after a gaseous nitrocarburizing treatment at 580 °C (1075 °F) in atmospheres containing approximately 50% ammonia (NH_3) and 50% propane (C_3H_8). In this investigation, it was reported that the presence of a high-carbon content, in what otherwise would be a simple ε nitride compound layer, considerably improved its hardness and wear resistance. These observations have recently been confirmed in more detailed structural studies (Ref 4). Earlier work by Prenosil had shown that conventional nitriding atmospheres with a high dew point led to the presence of oxygen in the ε phase. This oxygen content was found to increase with increasing partial pressure of oxygen, and it was further indicated that a similar saturation of the ε carbonitride phase was to be expected. Although the catalytic effect of oxygen on the rate of absorption of nitrogen into the surface of iron had been reported as early as 1935 by Bramley (Ref 5), the significance of oxygen in gaseous nitriding treatments was not really appreciated until it was investigated in detail by Eckstein and Lerche in 1968 (Ref 6), who showed that it increased the rate of ε nitride formation. On the basis of this evidence, it was concluded by Bell that oxygen should also increase the rate of ε carbonitride formation (Ref 7).

The nitrogen, carbon, and oxygen activities of the nitrocarburizing atmosphere necessary to achieve the desired oxygen-bearing ε carbonitride layer have recently been evaluated scientifically for a range of commercial steels by Slycke and Sproge (Ref 8). The basic consideration behind all gaseous nitrocarburizing processes is the type of atmosphere which can be used to cause carbon and nitrogen to be added simultaneously to the surface of ferrous materials and so produce the desired ε phase. The compositions and activity relations of various types of typical industrial nitrocarburizing atmospheres in quasiequilibrium are shown in Table 1 and are based on data derived from an unpublished mathematical model by Slycke (Ref 9).

Table 1 Calculated quasiequilibrium composition of various nitrocarburizing atmospheres at 580 °C (1075 °F)

Added gas mixture	Quasiequilibrium composition, vol%							Activities[(a)]		
	N_2	H_2	CO	H_2O	CO_2	NH_3	HCN	a_N	c_C	a_O
50% endogas 50% NH_3	24.1	25.9	9.0	0.76	0.68	38.4	1.16	1620	22.4	0.072
40% endogas 10% air 50% NH_3	29.2	24.3	6.7	2.46	1.77	35.4	0.244	1650	4.81	0.25
5% CO_2	58.8	15.5	2.9	2.98	1.45	18.4	0.045	1680	1.09	0.48

60% N_2 35% NH_3

5% CO_2 20% H_2 45% N_2 30% NH_3	45.4	26.6	3.4	3.50	1.16	19.9	0.049	806	1.88	0.33

Source: Ref 9

(a) The reference states for the activity values are nitrogen gas at 1 atm, graphite, and wustite for nitrogen, carbon, and oxygen, respectively.

Ammonia is the most readily available source of active nitrogen and at 570 °C (1060 °F) dissociates on ferrous surfaces according to the following reaction:

$$NH_3 \rightarrow N + \frac{3}{2} H_2 \qquad \textbf{(Eq 1)}$$

with the nitriding activity given by:

$$a_N^{'} = K_1 \frac{r\,NH_3}{r\,H_2^{2/3}}$$

where K is the equilibrium constant for the nitriding activity, and pNH_3 and pH_2 are the partial pressures of ammonia and hydrogen, respectively.

In addition, there are small levels of hydrogen cyanide in the furnace atmosphere present as a result of ammonia interaction with carbon monoxide. This has been shown recently by Slycke and Sproge (Ref 8) to supply nitrogen in parallel to the above reaction (Eq 1) as follows:

$$HCN \rightarrow C + N \frac{1}{2} H_2 \qquad \textbf{(Eq 2)}$$

with the nitriding activity given by:

$$a_N^{''} = K_2 \frac{r\,HCN}{a_{cp} H_2^{1/2}}$$

where a_c is the carbon activity and pHCN is the partial pressure of hydrogen cyanide.

The reaction described in Eq 2 is now regarded as the principal source for the mass transfer of nitrogen in the rapid build-up of the compound layer. In practice, the nitrogen activity of endogas-based atmospheres tends to be lower than shown in Table 1. This table also shows that the nitrogen activity of mixed atmospheres can be easily varied by, for example, additions of hydrogen.

The contents of carbon- and oxygen-bearing constituents of the nitrocarburizing atmosphere depend on the reverse water-gas reaction:

$H_2 + CO_2$ € $H_2O + CO$ **(Eq 3)**

The production of carbon monoxide by means of this reaction (Eq 3) is of particular importance in obtaining an atmosphere of sufficiently high carbon activity when carbon dioxide is used as a carbon-bearing feedstock. If the

atmosphere is composed of ammonia and endogas mixture with an inherent high content of carbon monoxide, then the carbon activity will be high and the dominant carburizing reaction at 570 °C (1060 °F) is (Ref 10, 11):

$$CO + H_2 \ \text{€} \ C + H_2O \qquad \textbf{(Eq 4)}$$

with the carburizing activity given by:

$$a_c = K_3 \frac{r\,CO.r\,H_2}{r\,H_2O}$$

The presence of carbon during nitrocarburizing stabilizes the ε phase so that it will form at much lower nitrogen activities than in the absence of carbon. It can be seen from Table 1 that the carbon activity for an endogas-ammonia mixture is markedly higher compared to that of nitrogen-based atmospheres. However, the carbon activity of endogas-based atmospheres can be reduced, if required, by means of, for example, the addition of air. For nitrogen-based atmospheres, the carbon activity can be increased by the addition of, for example, carbon monoxide.

The carbon activity and oxygen activity are related to each other when equilibrium conditions prevail. The effect of oxygen or combined oxygen additions to a nitrocarburizing atmosphere is to lower the carbon activity in the gas phase. Hence the presence of oxygen is now recognized as an important constituent in the atmosphere if good quality nitrocarburizing is to result, that is, with a monophase ε structure. The importance of this has been emphasized by Slycke and Sproge through their studies of the hydrogen cyanide/carbon mass transfer reaction (Eq 2). In this reaction, it can be seen that for each nitrogen atom transferred, one carbon atom is also transferred. This leads to a buildup of carbon in the compound layer and eventually to the formation of cementite (which is undesirable), unless carbon is removed by the decarburizing reaction (Eq 4) with a sufficiently low carbon activity, which can be brought about by the presence of oxygen in the atmosphere.

Compound Layer Formation

Traditionally, it has been accepted that the range of solubilities of carbon and nitrogen for a stable ε carbonitride phase can be derived from the isothermal section of the Fe-C-N phase diagram published by Nauman and Langerscheid in 1965 (Ref 12). However, in 1983 Wells and Bell (Ref 13) demonstrated that stable ε phases can be produced with lower interstitial contents than those predicted by the ternary phase diagram and their data are included in Fig. 2. It is not known whether the presence of oxygen within the ε phase influences the phase limits, but Xu and Li have expressed the opinion that a reduction in the partial pressure of oxygen would considerably change the structure of the phase field (Ref 14). However, it is clear that the structure of the compound layer resulting from a nitrocarburizing treatment cannot necessarily be predicted or explained by reference to the Naumann and Langenscheid version of the Fe-C-N system. Accordingly, there has been considerable interest in recent years in a reappraisal of the Fe-C-N system. In 1987 Xu and Li showed by thermodynamic calculation that the Fe_4N region of the Naumann and Langenscheid Fe-C-N ternary phase diagram was correct, but that the ε region required revision (Ref 14). Furthermore, their calculations showed that most of the experimental data given by Wells and Bell were reasonable. Further experimental data, which have been reviewed in Ref 15 and which are at variance with the Nauman and Langerscheid diagram, include the existence of α+ ε+ cementite around 570 °C (1060 °F) as observed in a number of studies (Ref 13, 16, 17, 18). In addition, during nitriding it has been observed that the pearlitic cementite in low-alloy steels transforms to ε(Ref 16, 17, 18). Thus, at the transformation front, α, ε, and cementite can be in contact with each other, indicating the existence of an α+ ε+ Fe_3C three-phase field. On the basis of such new experimental data, Slycke *et al.* (Ref 15) have proposed a new ternary phase diagram for the iron Fe-N-C system at temperatures around 570 °C (1060 °F). This new diagram, which is shown in Fig. 3, allows for the direct contact between the ferrite and ε phase which, as described above, is frequently observed during nitrocarburizing. Use of this diagram has been shown to eliminate all ambiguity regarding the interpretation of how the compound layer structure evolves under a wide variety of steel processing conditions (Ref 8).

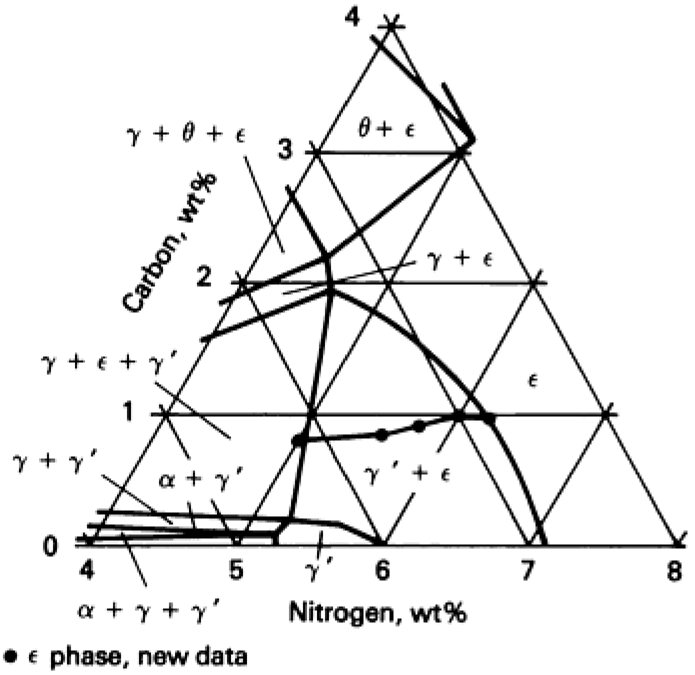

Fig. 2 Auger electron spectroscopy carbon and nitrogen concentration data for ε monophase compound layer produced using methanol/ammonia mixtures superimposed on the Fe-C-N phase diagram according to Ref 12. The five data points of the ε phase derived in Ref 13 are clearly in disagreement with ε phase limits depicted by the ternary diagram.

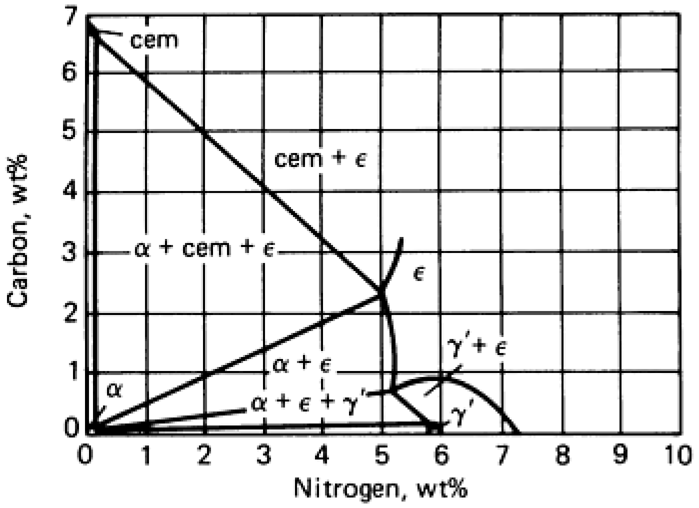

Fig. 3 Tentative Fe-N-C phase diagram at 570 to 580 °C (1060 to 1075 °F). Sizes of α , γ', and cementite (cem) fields are not in scale. Source: Ref 15

By way of example of the use of the new Fe-C-N phase diagram, consider the series of micrographs in Fig. 4, which show the compound layers formed on pure iron (99.9%) after nitrocarburizing in various methanol ammonia mixtures. The structure typical of compound layers formed at low methanol/ammonia ratios is illustrated in Fig. 4(a). X-ray structural analysis demonstrated that the layer is composed predominantly of the ε iron-carbonitride phase. The darker band structure seen in the compound layer was found to consist of the γ' iron nitride phase, which has very restricted carbon solubility. As the methanol/ammonia ratio in the treatment atmosphere was increased, the position of the γ' phase band structure in the compound layer was increasingly displaced away from the layer/matrix interface, as can be seen in Fig. 4(b) to 4(d). At an atmosphere composition of 45-60% methanol/55-40% ammonia, a layer was formed which is free of the γ' phase, or any other detectable secondary phase, and may be described as an ε carbonitride monophase layer (Fig. 4e). The compound layers which were formed in atmospheres with a methanol content in excess of 60% are typified by the structure shown in Fig. 4(f). The layer is thin, duplex in character, and contains a phase identified by x-ray structural analysis as cementite. Schematic representations of the surface compositions from each sample in the series and the resulting gradients from their trails are superimposed in the new Fe-C-N phase diagram in Fig. 5, where it can be seen that there is good agreement with the corresponding phase analysis description outlined above.

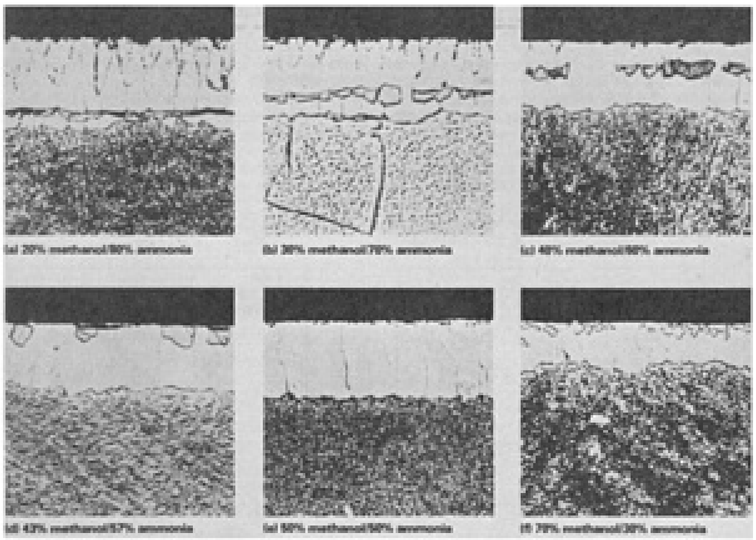

Fig. 4 Compound layers formed on iron by gaseous nitrocarburizing in various methanol/ammonia ratios. Quenched samples, all shown at 80× (a, c, d, e, and f etched in alcoholic ferric chloride and hydrochloric acid with iodine; b, etched in nital with ferric chloride). Source: Ref 13

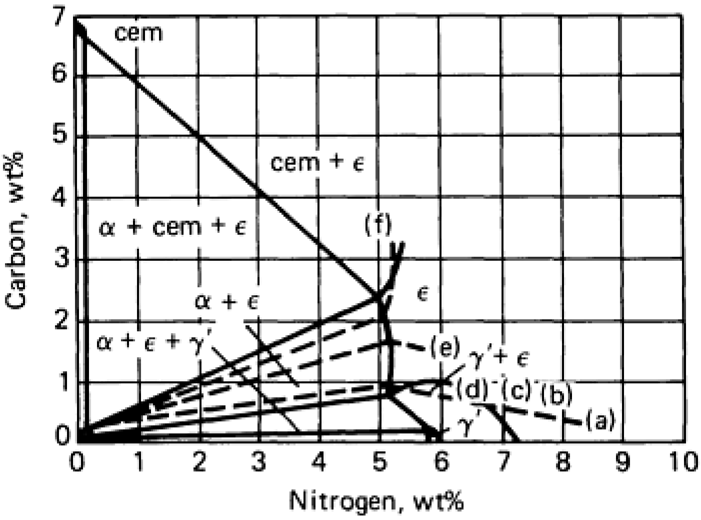

Fig. 5 Schematic representation of the surface composition of the micrographs shown in Fig. 4 superimposed on the revised ternary Fe-N-C phase diagram

Similarly, it has been demonstrated that if a high-carbon steel is treated in atmospheres over a wide range of carbon activities, the following sequence of events may occur (Ref 8):

- Ferrite and cementite dissolve nitrogen
- Cementite transforms into ε phase via ferrite + cementite → ferrite + ε
- Epsilon phase grows at the expense of ferrite until a covering compound layer is formed
- Continued growth of the monophase compound layer is controlled by nitrogen diffusion

A schematic representation of compound layer formation on a high-carbon steel is illustrated in Fig. 6; a corresponding micrograph is shown in Fig. 7.

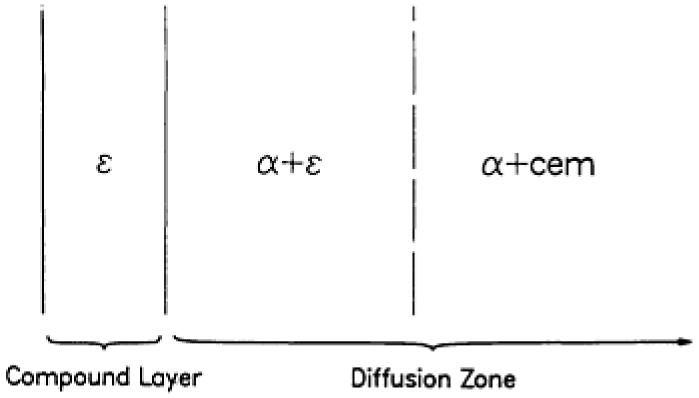

Fig. 6 Schematic sequence of phase development during nitrocarburizing of high-carbon steel. Source: Ref 8

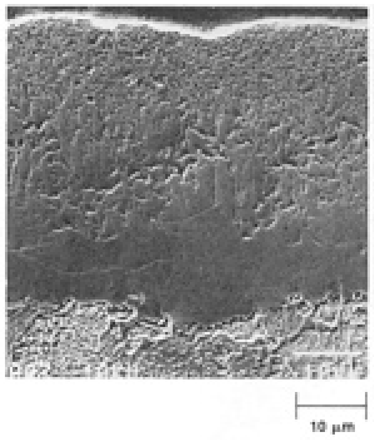

Fig. 7 Compound layer structure of high-carbon steel nitrocarburized in N_2 + 35% NH_3 + 5% CO_2 atmosphere at 580 °C (1075 °F) for 2 h. SEM backscatter mode. Corresponds to the schematic shown in Fig. 6

Diffusion Zone Characteristics and Fatigue Properties

The diffusion zone characteristics are essentially independent of the type of nitrocarburizing media used (Ref 7). During the treatment of plain carbon steels with a large proportion of ferrite, only nitrogen diffuses in from the carbonitride layer, since the ferrite is normally already at its equilibrium concentration with respect to carbon. However, some outward carbon diffusion from high-carbon concentration regions of the matrix into the compound layer can be experienced with most grades of steel and cast iron (Ref 2). While contributing to the quality of the compound layer, this loss of carbon is thought to have no effect on the fatigue properties resulting from the diffusion zone. Using optical (light) metallography, the diffusion zone beneath the compound layer for oil-quenched samples is indistinguishable from the original matrix material (Fig. 1). However, fine scale precipitation of nitrides can be observed by transmission electron microscopy (TEM) following oil quenching (Ref 19). By rapid cooling it is possible to retain most of the nitrogen in supersaturated solid solution and, in this condition, it increases both the yield strength of the base material and its fatigue strength. Indeed, both the bending fatigue strength (Ref 19) and rotating bend strength (Ref 7) of low-carbon steels can be increased by more than 120% (Fig. 8). However, aging, such as atmosphere cooling from the treatment temperature, substantially decreases the fatigue strength (Ref 19). The improvement in fatigue properties is directly related to the depth of nitrogen diffusion, as can be seen in Fig. 9. By using a sufficiently long nitrocarburizing time, it is possible to achieve this fatigue improvement throughout the component section. This is in contrast to conventional surface-hardening processes such as carburizing and carbonitriding of plain carbon steels and the nitriding of alloy steels, where a fatigue strength improvement is obtained as a result of a combination of surface strengthening and by the introduction of a surface compressive macrostress. It has been suggested that for nitrocarburized plain carbon steel, the residual microstresses can have a decisive influence on the endurance limit, even for notched components, since clearly for through hardened nitrocarburized materials there must be zero macroresidual stress effects (Ref 21).

Industrial Gaseous Ferritic Nitrocarburizing

In 1961, before the availability of detailed structural and chemical analyses of the compound layer on salt bath nitrocarburized materials, a patent had been applied for by Joseph Lucas (Industries) Ltd. for a type of gaseous nitrocarburizing (Ref 22). This treatment produced, on mild steel, a porous layer which was claimed to have good anti-frictional properties. The complete patent, when published, revealed that the gaseous atmosphere consisted of ammonia and hydrocarbon or other carbon-containing gases of unspecified proportions and that the treatment was undertaken in the temperature range 450 to 590 °C (840 to 1095 °F). At that time, however, no detailed technical information on the property improvements achieved, or of the structures which were responsible, was published. During the 1960s, further research led to consideration of a large range of gaseous nitrocarburizing processes throughout the world. A wide variety of atmospheres were proposed and, indeed, employed in these processes. These included triethanolamine (Ref 23), ammonia/kerosene (Ref 24), and isopropanol/water/urea/ammonia (Ref 25). However, it was only in the early 1970s that gaseous nitrocarburizing received serious industrial attention with the introduction of a variety of gaseous techniques.

The Nitemper process is usually carried out in sealed quench furnaces and uses an inert atmosphere consisting of 50% ammonia and 50% endogas (Ref 26). The treatment temperature is 570 °C (1060 °F) and treatment times usually between 1 and 3 h are used, after which the components are either quenched into oil or cooled under recirculated protective gas (Ref 26). By 1975, the Nitemper process had been in use for several years and furnaces performing the treatment were in operation in Germany, Sweden, the United States, Japan, and the United Kingdom for improving the scuffing and fatigue resistance of ferrous engineering components. The treatment is now used extensively throughout the world, and the possibility of a two-stage Nitemper process is being developed (Ref 27). This involves the use of an atmosphere with a high carbon dioxide level in the initial stage to promote rapid compound layer formation. The influence of controlled additions of carbon dioxide to ammonia-based nitrocarburizing atmospheres under industrial conditions has recently been investigated by Vogel for a wide range of alloy steels (Ref 28). He demonstrated that the proportion of the ε phase in the compound layer increased with increasing carbon dioxide content, that is, lower carbon activities, and that the ε phase more readily formed on alloy steels than on pure iron or plain carbon steels (Fig. 10). In the

second stage of the modified Nitemper process, an atmosphere with a high carbon monoxide content is employed to increase the carbon content of the compound layer for enhanced wear resistance. In essence, therefore, the process involves a combination of the Nitroc process (Ref 29), which utilizes unpurified exothermic gas as the carburizing medium (see description below), and the Nitemper technology. A similar duplex treatment called Deganit has also been proposed (Ref 30)

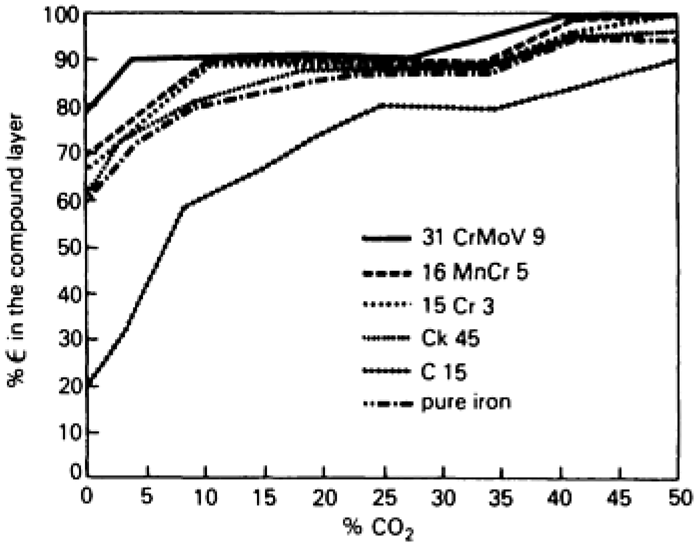

Fig. 10 The influence of CO_2 addition to ammonia on the structure of the compound layer, formed by nitrocarburizing at 580 °C (1075 °F) on pure iron, plain carbon steels, and low-alloy steels. Source: Ref 28

The Alnat-N process is a patented approach to nitrocarburizing whereby nitrous oxide is incorporated in the atmosphere to enhance, through the indirect presence of oxygen, the rate of formation of the compound layer (Ref 31, 32, 33). A further feature of the Alnat-N process is that the addition of a carburizing gas to the basic ammonia/ nitrous oxide/nitrogen mixture is claimed to be unnecessary. Thus, the incorporation of carbon into the compound layer must be via diffusion from the matrix materials.

Control of Gaseous Nitrocarburizing Atmospheres. A possible limitation on the gaseous nitrocarburizing processes developed in the mid-1970s was that optimum processing conditions for all classes of material, including cast irons, tool steels, and stainless steels, could not be assured. A further and perhaps more serious limitation was that reproducibility could be impaired with variable loads and from furnace to furnace. These difficulties were in part overcome through the use of infrared monitoring and control systems (Ref 7). However, gas analysis of atmospheres containing both ammonia and carbon dioxide can be problematic, especially when high ammonia contents and high dew points are concerned. If water is condensed in the sample gas piping, high amounts of ammonia will dissolve and the resulting strong solution can dissolve large amounts of carbon dioxide. If this solution becomes supersaturated a mixture of ammonium carbonate and bicarbonate will precipitate out in the form of a white powder (Ref 8). Experience has shown that when such precipitation has occurred, further measurement of ammonia and carbon dioxide is in error and there is a distinct likelihood that the pipeline of the measurement system will be blocked. Slycke and Sproge have shown that this problem can be largely overcome by suitable heating of the measurement instrumentation and the gas sampling pipeline (Ref 8).

Because of the limitations of the infrared gas analysis approach to the control of gaseous nitrocarburizing atmospheres, attention has been focused recently on the development of solid electrolyte gas sensors for the measurement and control of the nitrogen and oxygen potentials of nitriding and nitrocarburizing atmospheres (Ref 34). Such instruments are, in principle, similar to those widely used for carbon potential control of carburizing gas atmospheres.

Black Nitrocarburizing. Post nitrocarburizing oxidation treatments have been used on a commercial basis since 1976 to enhance the aesthetic properties of gaseous nitrocarburized components for the hydraulics industry (Ref 35). However, in 1982 Dawes and Tranter showed how such black nitrocarburizing treatments, including the Nitrotech process, could be used for the combined enhanced fatigue, wear, and corrosion resistance of mild steels (Ref 20). They showed that this could be achieved by specifically designing a range of cost effective, aesthetically pleasing black oxidized electrical components for use in automobile manufacture.

Particular success has been achieved with vacuum degassed ultra-low carbon deep-drawing steels that have been stabilized with niobium and/or titanium additions. Such steels facilitate many complex thin-sectioned components to be manufactured by single-stage press operations. These steels have very low yield strengths of about 155 MPa (23 ksi) with elongation values of approximately 45%. To achieve optimum engineering properties in the final component, nitrocarburizing can be used. The influence of quenching temperature on the yield strength of these nitrocarburized special steels is shown in Fig. 11. It is clear that low-temperature quenching has resulted in nitride precipitation and loss of strength, and that if a high strength is to be achieved a quenching temperature not less than 550 °C (1020 °F) is necessary. As discussed earlier in the section of this article on diffusion zone characteristics and fatigue properties, this is also the condition for optimum enhancement of the fatigue strength. Another essential feature of this treatment is that distortion of thin sectioned material can be kept to a minimum by controlled quenching into an oil/water emulsion at a temperature of 70 to 80 °C (160 to 175 °F) and that the quench time involved is sufficient to produce an aesthetically pleasing black oxide film of Fe_3O_4 which needs to be less than 1.0 μm in thickness if exfoliation is to be avoided (Fig. 12).

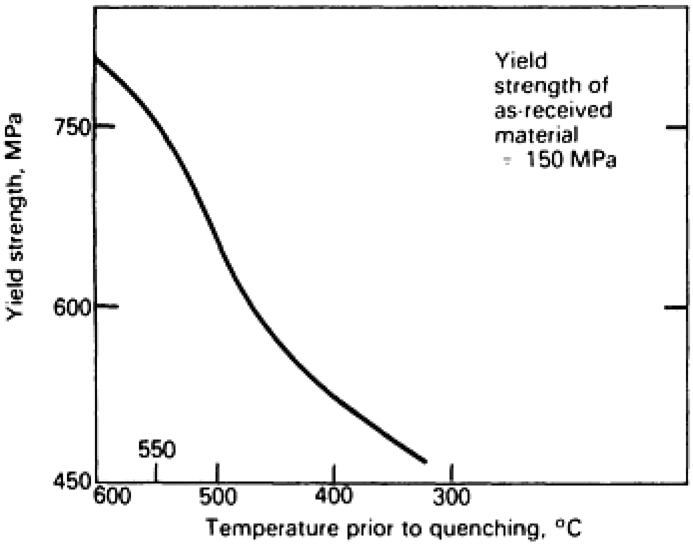

Fig. 11 The influence of quenching temperature on the yield strength of nitrocarburized deep-drawing steels. Source: Ref 20

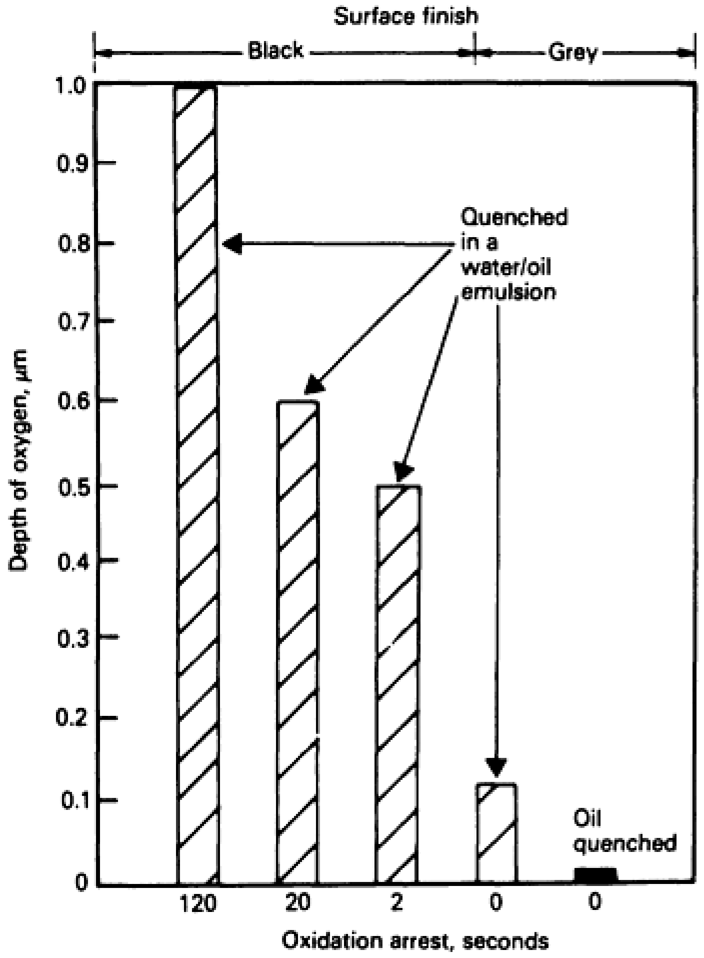

Fig. 12 Influence of depth of oxygen on surface coloration and corresponding oxidation arrest time for various quench media. Source: Ref 20

The flash oxidation parameters of the basic Nitrotec process are designed to produce an oxide structure capable of both conferring a degree of corrosion resistance and acting as a carrier for an organic sealant. Investigations into the composition of organic sealants has resulted in the development of specific formulations which are based on either hydrocarbon-solvent-borne mixtures of metal soaps produced from rosin acids and oxidized petrolatums, or water-based mixtures of emulsified microcrystalline and synthetic hydrocarbon waxes with corrosion inhibitors (Ref 36).

The relative contributions of post-nitro-carburizing oxidation and organic sealing to the overall corrosion resistance resulting from the Nitrotec process is shown in Fig. 13. It can be seen that the degreased nitro-carburized surface itself imparts little inherent corrosion resistance. An example of an automotive fan motor treated by the Nitrotec process and tested relative to zinc plating is illustrated in Fig. 14. Other components now in service using the Nitrotec black nitrocarburizing process include windshield wiper linkage assemblies which have been fitted since 1985 to Austin Rover's Metro, Maestro, and Montego models (Ref 37). The Austin Rover 800 series also uses Nitrotec-treated bumper armatures, while the Renault 25 series has the seat sliders treated. Another application of the process is in the cost-effective manufacture of the viscous slip differential used on Ford Sierra and BMW cars (Ref 38).

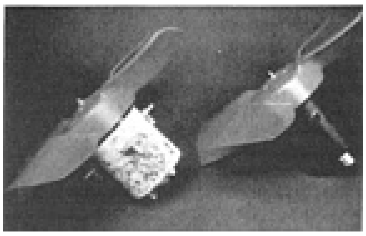

Fig. 14 Electric fan motor treated by Nitrotec process (right side) and neutral salt spray tested for 250 h compared to a zinc-plated component (left side). Source: Ref 20

An alternative black nitrocarburizing finish is the Ashland Nitro Black, which is a patented process utilizing fluidized bed technology (Ref 39). The atmosphere used for the nitrocarburizing stage comprises a mixture of ammonia, natural gas, and nitrogen. After nitrocarburizing, the fluidized bed is purged with nitrogen for 2 min prior to the oxidation step during which steam and air are injected via an integral coil system to impart a thin Fe_2O_3 layer on treated components. Fluidized bed quenching is then followed by coating with a proprietary polymeric emulsion sealant.

Austenitic Nitrocarburizing (Ref 40)

Nitrocarburizing has been defined by the Terminology Committee of the International Federation for Heat Treatment and Surface Engineering as a "thermochemical treatment which is applied to a ferrous object in order to produce surface enrichment in nitrogen and carbon which forms a compound layer. Beneath the compound layer there is a diffusion zone enriched in nitrogen" (Ref 41). When the treatment temperature is such that partial transformation of the matrix to austenite occurs through enrichment with nitrogen, then the treatment is referred to as austenitic nitrocarburizing.

Austenitic nitrocarburizing was first developed as a cyanide salt bath process, under the trade name Noskuff (Ref 42); an equivalent gaseous treatment was patented in 1977 (Ref 43). The primary objective of the austenitic treatment is to overcome the principal disadvantage of ferritic nitrocarburizing, namely, that with plain carbon steel components there is no significant hardened case below the compound layer and, accordingly, the ability of components to withstand high Hertzian stresses is restricted. With austenitic nitrocarburizing, the subsurface (but not the complete cross section) is transformed to iron-carbon-nitrogen austenite, which is subsequently transformed to tempered martensite and bainite, with a hardness in the range of 750 to 900 HV. This high hardness level provides a means of extending the range of applications of nitrocarburizing treatments.

Physical Metallurgy of Gaseous Austenitic Nitrocarburizing

On the basis of extensive physical metallurgy studies at the Wolfson Institute for Surface Engineering, together with work by the Swedish Institute for Metal Research, it has been shown that gaseous austenitic nitrocarburizing treatments can be carried out successfully in sealed quench furnaces using mixtures of endothermic and ammonia gases (Ref 44, 45). Additional detailed laboratory studies have been conducted into the growth kinetics and characterization of compound layers formed by the action of methyl-alcohol saturated ammonia (Ref 46).

As with the ferritic nitrocarburizing treatment, the compound layer should consist mainly of the ε carbonitride phase, which is predominantly responsible for significant improvements in tribological properties. Experimentally, this can be achieved quite readily in the temperature range 675 to 775 °C (1250 to 1425 °F). The 700 °C (1290 °F) isothermal section of the Fe-C-N phase diagram shown in Fig. 15 describes the phase structures produced at this temperature.

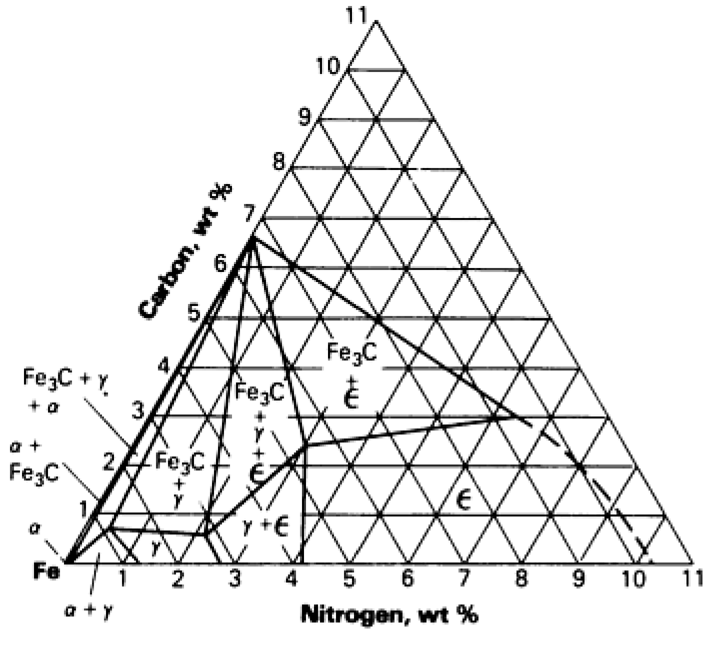

Fig. 15 Isothermal section of the Fe-C-N phase diagram at 700 °C (1290 °F). Source: Ref 12

By way of illustration of the structure and properties resulting from austenitic nitrocarburizing, consider EN32 (BS 080 M 15) steel (0.12 to 0.18% C, 0.10 to 0.40% Si, 0.60 to 1.00% Mn) subjected to an austenitic nitrocarburizing treatment at 700 °C (1290 °F) with a 15% residual ammonia level in the exhaust gas atmosphere of a sealed quench furnace. The appropriate microstructure after 1 h treatment is shown in Fig. 16(a). X-ray diffraction analysis has revealed that the 50 μm thick compound layer consists predominantly of the ε phase. The corresponding interstitial profile analysis as performed with a calibrated electron probe microanalyzer (Ref 47) are shown in Fig. 16(b). It can be seen by reference to Fig. 16(b) that at least the outermost portion of the compound layer falls within the desired monophase ε carbonitride

region. The kinetics of growth of the compound layer obey a parabolic law, as shown in Fig. 17, thus illustrating the diffusion-controlled nature of compound layer formation. The hardness profile of the as-quenched nitrocarburized layer is plotted in Fig. 18. It can be seen clearly that there is a dip in the hardness value at the compound layer/austenite interface associated with the high contents of nitrogen and carbon in solution which depresses the M_S temperature to below ambient. As a result of aging, this hardness dip is removed due to the fine-scale formation of iron-nitrogen bainite.

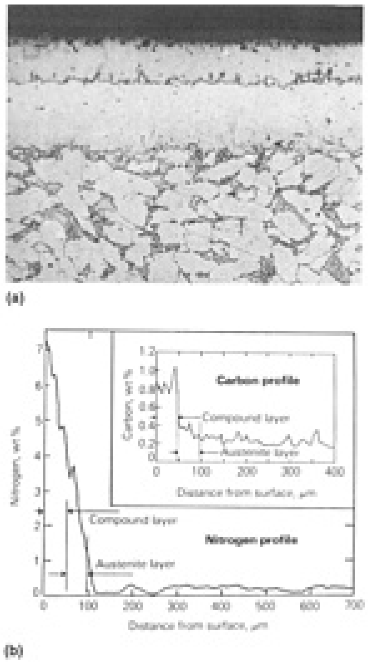

Fig. 16 Structural characteristics of an austenitic nitrocarburized material. (a) Micrograph of EN32 steel nitrocarburized for 1 h at 700 °C (1290 °F) in ammonia/endothermic gas with 15% residual ammonia and oil quenched. (b) Carbon and nitrogen profiles for EN32 nitrocarburized for 1 h at 700 °C (1290 °F) in ammonia/endothermic gas with 15% residual NH_3. Source: Ref 40

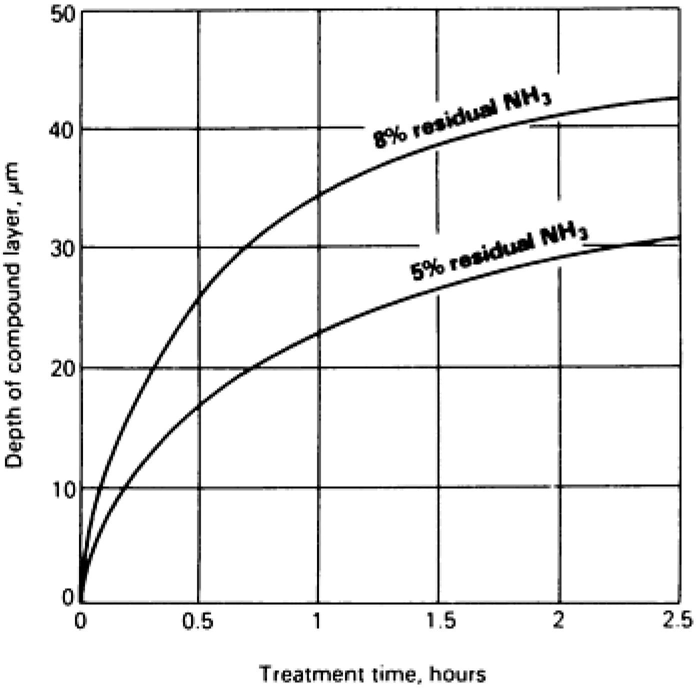

Fig. 17 Growth kinetics of the compound layer at 700 °C (1290 °F) in ammonia/endothermic gas with different residual ammonia levels. Source: Ref 40

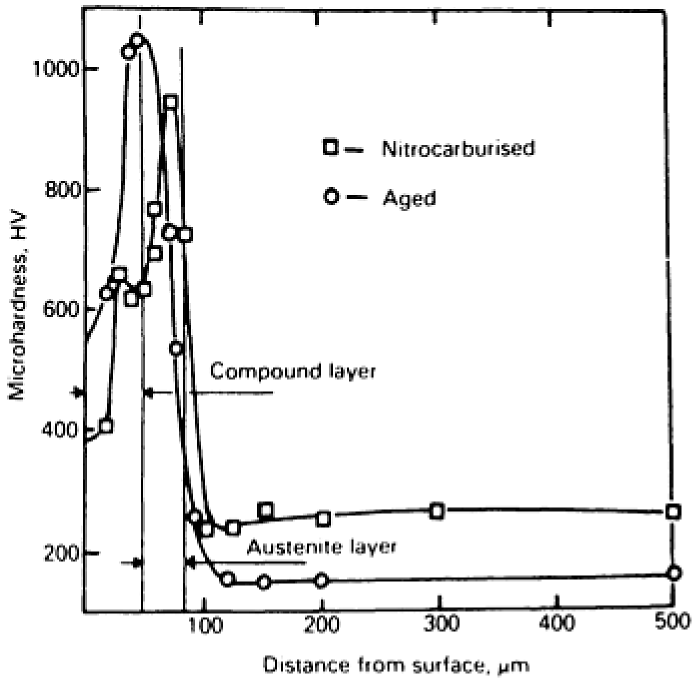

Fig. 18 Microhardness profiles for austenitic nitrocarburized mild steel before and after aging at 250 °C (480 °F) for 2 h. Nitrocarburized for 1 h at 700 °C (1290 °F) in ammonia/endothermic gas with 15% residual NH_3 and oil quenched. Source: Ref 40

As with ferritic nitrocarburizing, the presence of the compound layer significantly enhances the wear resistance (Fig. 19). Similarly, there is a major enhancement in the fatigue strength (approximately 100%) both directly after quenching and after quenching and aging (Ref 40).

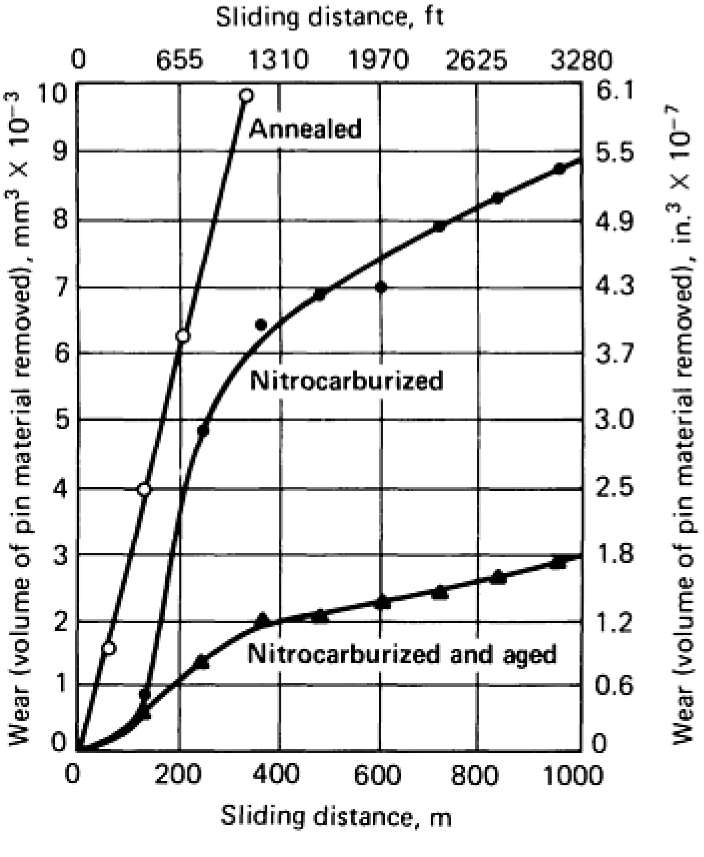

Fig. 19 Wear rates of mild steel in the annealed austenitic nitrocarburized and aged conditions. Nitrocarburized at 700 °C (1290 °F) for 1 h in ammonia/endothermic gas with 15% residual ammonia, oil quenched. Aged at 250 °C (480 °F) for 2 h. Pin-on-disk test with a treated mild steel pin and carbonitrided EN8 disk

Industrial Gaseous Austenitic Nitrocarburizing

It has been illustrated above that in order to obtain maximum subsurface strength, it is necessary to transform the austenitic zone beneath the compound layer into iron-nitrogen-carbon bainite. Typical transformed austenite case thicknesses are in the range 50 to 200 μm, with a hardness of between 750 and 900 HV. However, much deeper cases can be achieved by employing a precarburizing treatment prior to nitrocarburizing (Ref 43). These variants of the austenitic nitrocarburizing process have been exploited commercially with the Alpha Plus and Beta industrial processes (Ref 19). Typical hardness profiles resulting from these treatments using a carrier gas of nitrogen/methanol enriched with ammonia and natural gas are illustrated in Fig. 20; typical industrial applications are summarized in Table 2. Benefits from such treatments include:

- Resistance to wear, scuffing, and seizure
- Predictable growth and low shape distortion
- Increased core strength
- Corrosion resistance
- Indentation resistance

Table 2 Production applications of austenitic nitrocarburizing

Austenitic nitrocarburizing treatment type	Applications
Alpha Plus (0.125 mm, or 0.005 in., underlying case)	**Clutch plates, levers, gears, bushes, thin pressings**
Alpha Plus (0.25 mm, or 0.010 in., underlying case)	**Gears, levers, pulleys, liners**
Beta (0.60 mm, or 0.025 in., underlying case)	**Machine slideways, guide bars, gears, sprockets, pins, bushes, water-pump parts, liners, jigs/fixtures, bearings**

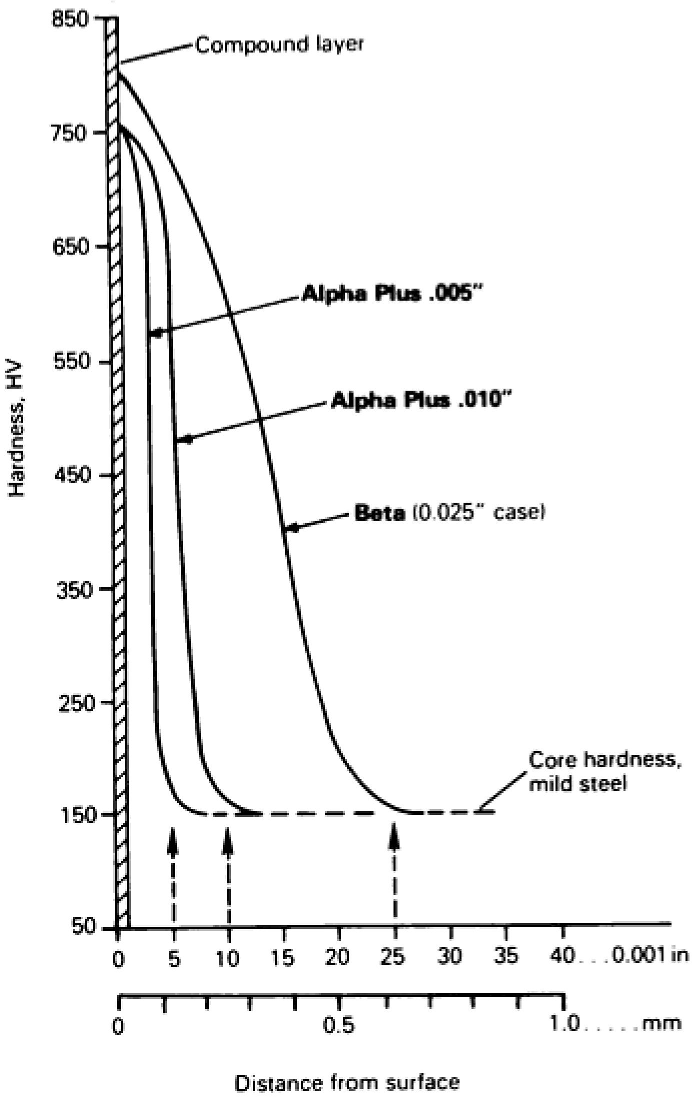

Fig. 20 Hardness profiles resulting from three austenitic nitrocarburizing treatments applied to mild steel. Source: Ref 48

Recently, a deep case variant of the Nitrotec process has been introduced, known as Nitrotec C (Ref 49). This is a black austenitic nitrocarburizing process in which a precarburized substrate is subsequently processed to produce the surface ε compound layer at a temperature that allows for hardening of the carburized zone during quenching.

Plasma Nitrocarburizing

Plasma nitrocarburizing is in essence a variant of the now well-established glow-discharge plasma nitriding method (see the article "Plasma (Ion) Nitriding" in this Volume), the physical metallurgy of which has been reviewed recently by Sun and Bell (Ref 50). The origins of the plasma thermochemical process lie in the patents filed by Bernhard Berghaus in the 1930s. Over the period 1957 to 1967, the German company Gesellschaft zur Förderung der Glimmentledungforschung, funded by the Regional Government of Norderhein-Westfalen, undertook research into the physics, chemistry, and metallurgy of glow-discharge plasmas. IONON, a private company owned by Berghaus in Köln was responsible for the industrial exploitation of the technology generated. Following the death of Berghaus in 1965, Klockner Ionon was formed in 1967 and thus gained access to this technology which formed the basis of the international commercialization of this environmentally friendly surface heat-treatment technique (Ref 51). Emphasis has recently been placed on the requirement of the production engineer to meet surface engineering specifications in a manner increasingly influenced by environmental considerations. Advantages associated with plasma heat-treatment technology include:

- No toxic fumes or waste produced
- No risks of explosion
- No significant dirt, noise, or heat pollution
- Reduced processing times
- Reduced energy consumption
- Reduced treatment gas consumption

Physical Metallurgy of Plasma Nitrocarburizing

In respect to the tribological properties of nitrocarburized steels, evidence from gaseous and salt bath nitrocarburizing research indicates that the monophase ε structure is strongly preferred. However, plasma nitrocarburizing still faces the problem of controlling the quality and character of the compound layer structure to achieve the monophase ε carbonitride on a regular basis (Ref 52). Accordingly, with plasma nitrocarburizing the compound layer usually consists of ε and γ' phases for low-carbon level atmospheres. Equilibrium thermodynamic considerations, as discussed earlier in this article, would indicate that increasing the carbon level in the atmosphere should produce the monophase ε structure. However, under the nonequilibrium thermodynamic conditions prevailing in the glow-discharge plasma, an increase in the carbon level does not automatically produce a 100% ε structure, and yet cementite does appear above a certain limit of the carbon level (Ref 53). Laboratory studies using methane as the source of carbon in the gaseous plasma, have shown that some stabilization of the ε phase is possible, but above a certain limit (depending on the substrate materials) the cementite always appears and soot formation is difficult to prevent. The use of controlled additions of oxygen-bearing gases to reduce the activity of carbon has shown some promise in stabilizing the ε phase and the kinetics of compound layer growth are increased.

Recent laboratory experiments using 90% nitrogen/hydrogen atmospheres with controlled additions of carbon dioxide (up to 2.5%) have been carried out at 570 °C (1060 °F) for 2 h (Ref 54). It was found that:

- With pure iron, increasing the carbon dioxide stabilized the ε phase and an essentially monophase εstructure was formed at 1% carbon dioxide level (Fig. 21a and b). A further increase in carbon dioxide level to 2% led to the formation of surface oxides
- With plain carbon steel, increasing the carbon dioxide level again stabilized the ε phase, but a mixture of the ε and γ' phases was invariably present (Fig. 22a and b)
- With a low-alloy chromium-bearing steel, EN40B (0.20-0.28% C, 0.10-0.35% Si, 0.45-0.70% Mn, 3.0-3.5% Cr, 0.45-0.65% Mo), the γ' phase was suppressed by even 0.5% carbon dioxide, but cementite compounds

were invariably formed (Fig. 23a and b)

These controlled laboratory experiments clearly illustrate the lack of tolerance of the plasma nitrocarburizing process to minor variations in atmosphere condition. Accordingly, current industrial plasma nitrocarburizing practice, although meeting engineering mechanical property specifications, can be anticipated to show variations in microstructural characteristics.

Industrial Plasma Nitrocarburizing

The maturity of plasma nitriding and nitrocarburizing equipment is reflected by the ability of suppliers to respond to the high reliability requirements of the automotive sector through the introduction of microprocessor-controlled modular units, such as that shown schematically in Fig. 24. As can be seen, the plasma-processing equipment has the following modules:

- Vacuum furnace
- Vacuum system
- Gas supply with gas mixing and pressure control system
- Electric power supply unit
- Microprocessor control unit

The total engineering and design of such equipment and the wide range of functions available in the microprocessor software gives high production reliability and makes it very easy for the operator to set the processing conditions. In a typical plasma nitrocarburizing unit, up to 24 programs can be stored for different applications and the equipment can be integrated in series in a manufacturing production line. In the equipment illustrated in Fig. 25, loads of 3000 automotive seat slider rails have been nitrocarburized automatically for more than 5 yr without any significant technical or metallurgical problems. Mixtures of hydrogen, nitrogen, and a carbon-bearing gas, such as methane or carbon dioxide are used for the nitrocarburizing process, which is carried out at 570 °C (1060 °F) to produce a compound layer of >5 μm and a surface hardness of ≥ 350 HV (Ref 56). The micro-processor-controlled unit ensures that the treatment schedules are undertaken in the correct sequence. Following nitrocarburizing, the workpieces are allowed to cool under controlled vacuum conditions.

As a direct consequence of increased legislation designed to protect the environment, there is significantly growing interest in the plasma nitrocarburizing of sintered powder metallurgy (P/M) components. Traditionally, P/M components have been nitrocarburized using salt bath technology. This technique usually results in salt entrapment within the pores of the metallic structure. Frequently, these salts are highly toxic, and consequently there are handling problems and safe working procedures have to be employed.

A technical argument against the use of plasma nitrocarburizing has been the effect of retained lubricant on the character and stability of the glow-discharge plasma, thus effecting the reliability of the plasma technology when applied to sintered parts. Lubricants are added to powdered products in order to achieve optimum pressing conditions by the final forming operation after sintering. A method by which the lubricant can be satisfactorily removed prior to the P/M parts entering the vacuum chamber of the plasma unit is described in Ref 56. Using this method, it is now routinely possible to plasma nitrocarburize in one batch up to 4500 components, such as chain gear wheels, that have been manufactured by P/M (Ref 57). The microstructure of such a plasma nitrocarburized component is shown in Fig. 26. It is interesting to note that detailed examination shows that pores within the material, but close to the surface, also show the presence of the compound layer. The extent of the depth of such nitrocarburized pores is a function of the degree of interconnected porosity of the component, which is, in turn, a function of the pressing conditions. Such interconnected pores are capable of retaining lubricant and thus considerably enhance the reduction in wear rate of the treated components. Chain gear wheels have been plasma nitrocarburized to produce a compound layer with a typical thickness of 6 μm in a bell-type plasma furnace like that shown in Fig. 27. The chain gear wheels are stacked one on top of each other along an internal pipe that acts as an easy-to-handle jigging system (Fig. 28). Just the teeth area needs to be plasma nitrocarburized, and a simple masking arrangement ensures that the internal part of the gears remains untreated, as is required in the design specification.

Boriding (Boronizing) of Steels

Anil Kumar Sinha, Bohn Piston Division

Introduction

BORIDING, or boronizing, is a thermo-chemical surface hardening process that can be applied to a wide variety of ferrous, nonferrous, and cermet materials. The process involves heating well-cleaned material in the range of 700 to 1000 °C (1300 to 1830 °F), preferably for 1 to 12 h, in contact with a boronaceous solid powder (boronizing compound), paste, liquid, or gaseous medium. Other developments in thermochemical boriding include gas boriding techniques such as plasma boriding and fluidized bed boriding. There is a current trend toward the use of multicomponent boriding.

This article presents mainly the various media used for thermochemical boriding, their advantages, limitations, and applications. Physical and chemical vapor deposition (PVD and CVD), plasma spraying, and ion implantation are alternative nonthermo-chemical surface-coating processes for the deposition of boron or codeposition of boron and metallic element(s) onto a suitable metallic or nonmetallic substrate material. This article briefly describes the CVD process, which has emerged to be dominant among the metal boride deposition processes.

Characteristic Features of Boride Layers

During boriding, the diffusion and subsequent absorption of boron atoms into the metallic lattice of the component surface form interstitial boron compounds (Ref 1, 2, 3, 4, 5). The resulting layer may consist of either a single-phase boride or a polyphase boride layer. The morphology (Fig. 1), growth, and phase composition of the boride layer can be influenced by the alloying elements in the base material. The microhardness of the borided layer also depends strongly on the composition and structure of the boride layer and the composition of the base material (Table 1).

Table 1 Melting point and microhardness of different boride phases formed during boriding of different substrate materials

Substrate	Constituent phases in the boride layer	Microhardness of layer, HV or kg/mm^2	Melting point

Advantages. Boride layers possess a number of characteristic features with special advantages over conventional case-hardened layers. One basic advantage is that boride layers have extremely high hardness values (between 1450 and 5000 HV) with high melting points of the constituent phases (Table 1). The typical surface hardness values of borided steels compared with other treatments and other hard materials are listed in Table 2. This clearly illustrates that the hardness of boride layers produced on carbon steels is much greater than that produced by any other conventional surface (hardening) treatments; it exceeds that of the hardened tool steel, hard chrome electroplate, and is equivalent to that of tungsten carbide.

Table 2 Typical surface hardness of borided steels compared with other treatments and hard materials

Material	Microhardness kg/mm^2 or HV
Boride mild steel	1600
Borided AISI H13 die steel	1800
Borided AISI A2 steel	1900
Quenched steel	900
Hardened and tempered H13 die steel	540-600
Hardened and tempered A2 die steel	630-700
High-speed steel BM42	900-9l0
Nitrided steels	650-1700
Carburized low-alloy steels	650-950

The combination of a high surface hardness and a low surface coefficient of friction of the borided layer also makes a significant contribution in combating the main wear mechanisms: adhesion, tribooxidation, abrasion, and surface fatigue (Ref 4, 9). This fact has enabled the mold makers to substitute easier-to-machine steels for the base metal and to still obtain wear resistance and antigalling properties superior to those of the original material (Ref 10). Figure 2 shows the effect of boriding on abrasive wear resistance of borided C45 steel, titanium, and tantalum as a function of number of revolutions (or stressing period) based on Faville test. Figure 3 shows the influence of steel composition on abrasive wear resistance.

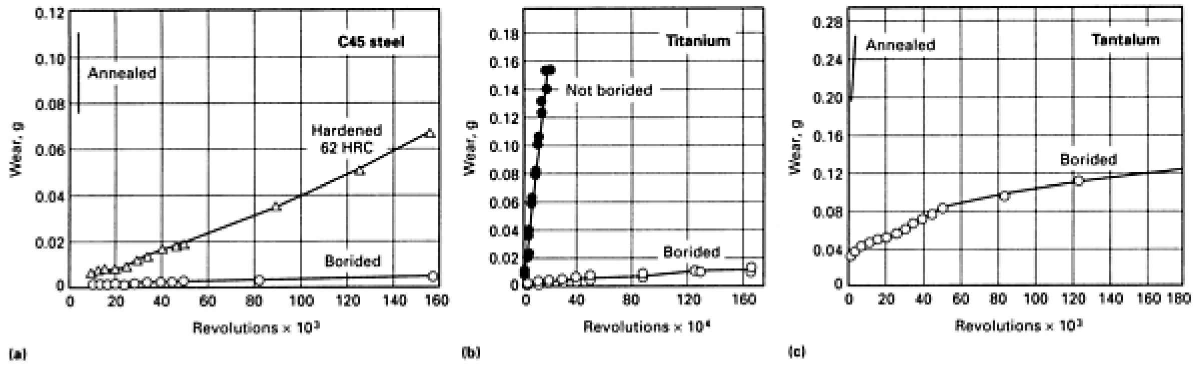

Fig. 2 Effect of boriding on the wear resistance (Faville test). (a) 0.45% C (C45) steel borided at 900 °C (1650 °F) for 3 h. (b) Titanium borided at 1000 °C (1830 °F) for 24 h. (c) Tantalum borided at 1000 °C (1830 °F) for 8 h. Source: Ref 11

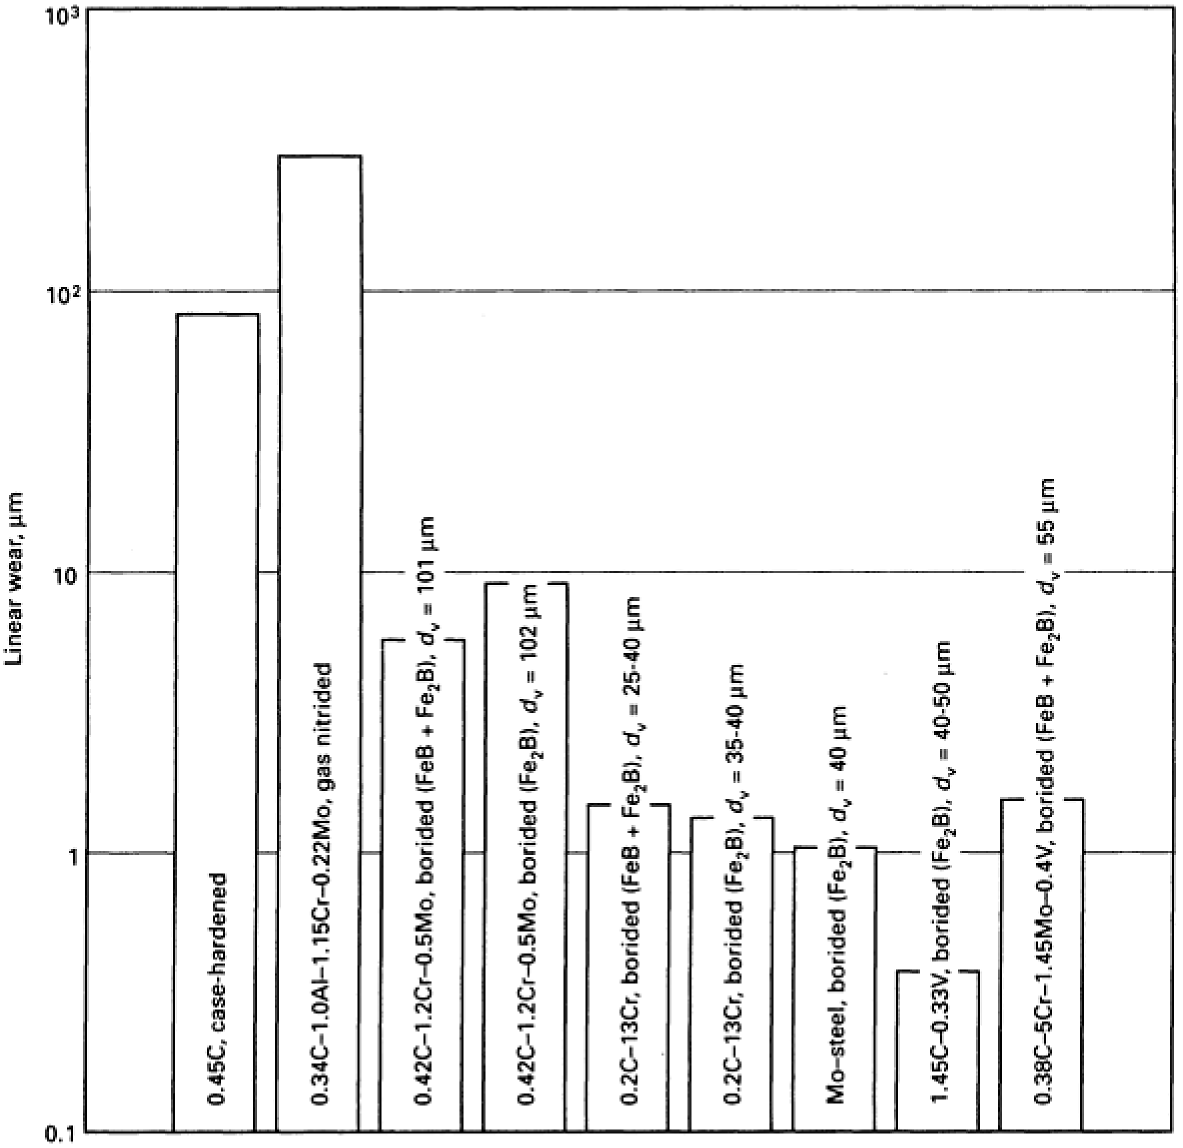

Fig. 3 Effect of steel composition (nominal values in wt%) on wear resistance under abrasive wear (d_v = thickness of the boride layer). Test conditions: DP-U grinding tester, SiC paper 220, testing time 6 min. Source: Ref 6, 9

Other advantages of boriding include:

- Hardness of the boride layer can be retained at higher temperatures than, for example, that of nitrided cases

- A wide variety of steels, including through-hardenable steels, are compatible with the processes (Ref 12)
- Boriding, which can considerably enhance the corrosion-erosion resistance of ferrous materials in nonoxidizing dilute acids (Fig. 4) and alkali media, is increasingly used to this advantage in many industrial applications (Ref 4)
- Borided surfaces have moderate oxidation resistance (up to 850 °C, or 1550 °F) and are quite resistant to attack by molten metals
- Borided parts have an increased fatigue life and service performance under oxidizing and corrosive environments

Disadvantages of boronizing treatments are:

- The techniques are inflexible and rather labor intensive, making the process less cost effective than other thermochemical surface hardening treatments such as gas carburizing and plasma nitriding. Both gas carburizing and plasma nitriding have the advantage over boronizing because those two processes are flexible systems, offer reduced operating and maintenance costs, require shorter processing times, and are relatively easy to operate. It is, therefore, suited to engineering components that need high hardness and outstanding wear and corrosion resistance of the boride layers, and/or where cheaper labor is available (Ref 3)
- The growth (that is, the increase in volume) resulting from boronizing is 5 to 25% of the layer thickness (for example, a 25 μm, or 1000 μin., layer would have a growth of 1.25 to 6.25 μm, or 50 to 250 μin.); its magnitude depends on the base material composition but remains consistent for a given combination of material and treatment cycle. However, it can be predicted for a given part geometry and boronizing treatment. For treatment of precision parts, where little stock removal is permitted, an allowance of ~20 to 25% dimensional increase of the final boride layer thickness must be provided
- Partial removal of the boride layer for closer tolerance requirements is made possible only by a subsequent diamond lapping because conventional grinding causes fracture of the layer. Thus, precise boronizing is mostly practiced for components with a large cross-sectional area (Ref 3)
- Boriding of most steels provides a marginal increase, if any, in the bending fatigue endurance limit, although some improvement in the corrosion-fatigue strength has been noticed
- In general, the rolling contact fatigue properties of borided alloy steel parts are very poor compared to carburized and nitrided steels at high contact loads (2000 N, or 450 lbf). This is why boronizing treatments of gears are limited to those screw designs where transverse loading of gear teeth is minimized (Ref 3)
- There is frequently a need to harden and temper the tool after boriding (Ref 14), which requires a vacuum or inert atmosphere to preserve the integrity of the boride layer

Boriding of Ferrous Materials

Unlike carburizing treatment on ferrous materials, where there is a gradual decrease in composition from the carbon-rich surface to the substrate, the boriding of ferrous materials results in the formation of either a single-phase or double-phase layer of borides with definite compositions. The single-phase boride layer consists of Fe_2B, while the double-phase layer consists of an outer dark-etching phase of FeB and an inner bright-etching phase of Fe_2B. The formation of either a single or double phase depends on the availability of boron (Ref 15).

Characteristics of FeB and Fe_2B Layers. The formation of a single Fe_2B phase (with a sawtooth morphology due to preferred diffusion direction) is more desirable than a double-phase layer with FeB. The boron-rich FeB phase is considered undesirable, in part, because FeB is more brittle than the iron subboride Fe_2B layer. Also, because FeB and Fe_2B are formed under tensile and compressive residual stresses, respectively, crack formation is often observed at or in the neighborhood of the FeB/Fe_2B interface of a double-phase layer. These cracks may lead to flaking and spalling when a mechanical strain is applied (Ref 5) or even separation (Fig. 5) when a component is undergoing a thermal and/or mechanical shock. Therefore, the boron-rich FeB phase should be avoided or minimized in the boride layer (Ref 5).

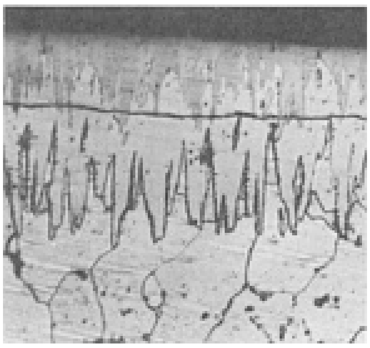

Fig. 5 Separation of two-phase boride layer on a low-carbon (St 37) steel (borided at 900 °C, or 1650 °F, for 4 h) caused by grinding with a cutting-off disk. 200×. Source: Ref 13

It has also been reported that the tribological properties depend on the microstructure of the boride layer. The dual-phase FeB-Fe_2B layers are not inferior to those of monophase Fe_2B layers, provided that the porous surface zone directly beneath the surface is removed (Ref 16). Alternatively, a thinner layer is favored because of less development of brittle and porous surface-zone formation and flaking.

Typical properties of the FeB phase are:

- Microhardness of about 19 to 21 GPa (2.7×10^6 to 3.0×10^6 psi)
- Modulus of elasticity of 590 GPa (85×10^6 psi)
- Density of 6.75 g/cm^3 (0.244 lb/in.^{3})
- Thermal expansion coefficient of 23 ppm/°C (13 ppm/°F) between 200 and 600 °C (400 and 1100 °F) (Ref 6 and 17)
- Composition with 16.23 wt% boron
- Orthorhombic crystal structure with 4 iron and 4 boron atoms per unit cell
- Lattice parameters: a = 4.053 Å, b = 5.495 Å, and c = 2.946 Å

Layers of Fe_2B. The formation of single-phase Fe_2B layers with a sawtooth morphology is desirable in the boriding of ferrous materials (Ref 18). A single Fe_2B phase can be obtained from a double FeB-Fe_2B phase by a subsequent vacuum or salt bath treatment for several hours above 800 °C (1470 °F), which may be followed by oil quenching to increase substrate properties (Ref 19).

Typical properties of Fe_2B are:

- Microhardness of about 18 to 20 GPa (2.6×10^6 to 2.9×10^6 psi)
- Modulus of elasticity of 285 to 295 GPa (41×10^6 to 43×10^6 psi)
- Thermal expansion coefficient of 7.65 ppm/°C (4.25 ppm/°F) and 9.2 ppm/°C (5.1 ppm/°F) in the range of 200 to 600 °C (400 to 1100 °F) and 100 to 800 °C (200 to 1500 °F), respectively (Ref 6 and 17)
- Density of 7.43 g/cm^3 (0.268 lb/in.^{3})

- Composition with 8.83 wt% boron
- Body-centered tetragonal structure with 12 atoms per unit cell
- Lattice parameters: a = 5.078 Å and c = 4.249 Å

The solubility of boron in ferrite and austenite is very small (<0.008% at 900 °C, or 1650 °F) according to the Fe-B phase diagram (Ref 20). According to Brown *et al.* (Ref 21) and Nicholson (Ref 22), the phase diagram exhibits an $\alpha/\gamma/Fe_2B$ peritectoid reaction at about 912 °C (1674 °F), based on their findings of higher solubility of boron in ferrite than in austenite at the reaction temperature. However, later work revealed a higher solubility of boron in austenite compared to that in ferrite, thereby suggesting the reaction is eutectoid in nature (Ref 23).

The boriding process consists of two types of reaction (Ref 6). The first reaction takes place between the boron-yielding substance and the component surface. The nucleation rate of the particles at the surface is a function of the boriding time and temperature. This produces a thin, compact boride layer.

The subsequent second reaction is diffusion controlled, and the total thickness of the boride layer growth at a particular temperature can be calculated by the simple formula:

$$d=k\sqrt{t} \qquad \textbf{(Eq 1)}$$

where d is the boride layer thickness in centimeters; k is a constant, depending on the temperature; and t is the time in seconds at a given temperature. The diffusivity of boron at 950 °C (1740 °F) is 1.82×10^{-8} cm^2/s for the boride layer and 1.53×10^{-7} cm^2/s for the diffusion zone. As a result, the boron-containing diffusion zone extends more than 7 times the depth of boride layer thickness into the substrate (Ref 24). It has been proposed that a concentration gradient provides the driving force for diffusion-controlled boride laver growth (Ref 25).

Diffusion case thicknesses range to approximately 0.13 mm (0.005 in.) for ferrous alloys, depending on alloy compositions and configurations. A lower case depth is required for the high-carbon and/or high-alloy tool steels, whereas higher case depths may be needed for the low- or medium-carbon steels. When case depth is about 320 to 350 μm, subsequent heat treatment is not performed.

Ferrous Materials for Boriding. With the exception of aluminum- and silicon-bearing steels, industrial boriding can be carried out on most ferrous materials such as structural steels; case-hardened, tempered, tool, and stainless steels; cast steels; Armco (commercially pure) iron; gray and ductile cast irons; and sintered iron and steel (Ref 26). Because boriding is conducted in the austenitic range, air-hardening steels can be simultaneously hardened and borided. Water-hardening grades are not borided because of the susceptibility of the boride layer to thermal shock. Similarly, resulfurized and leaded steels should not be used because they have a tendency toward case spalling and case cracking. Nitrided steels should not be used because of their sensitivity to cracking (Ref 27).

Influence of Alloying Elements. The mechanical properties of the borided alloys depend strongly on the composition and structure of the boride layers. The characteristic sawtooth configuration of the boride layer is dominant with pure iron, unalloyed low-carbon steels, and low-alloy steels. As the alloying element and/or carbon content of the substrate steel is increased, the development of a jagged boride/substrate interface is suppressed, and for high-alloy steels a smooth interface is formed (Ref 28 and Fig. 1). Alloying elements mainly retard the boride layer thickness (or growth) caused by restricted diffusion of boron into the steel because of the formation of a diffusion barrier. Figure 6 shows the effect of alloying additions in steel on boride layer thickness (Ref 29, 30).

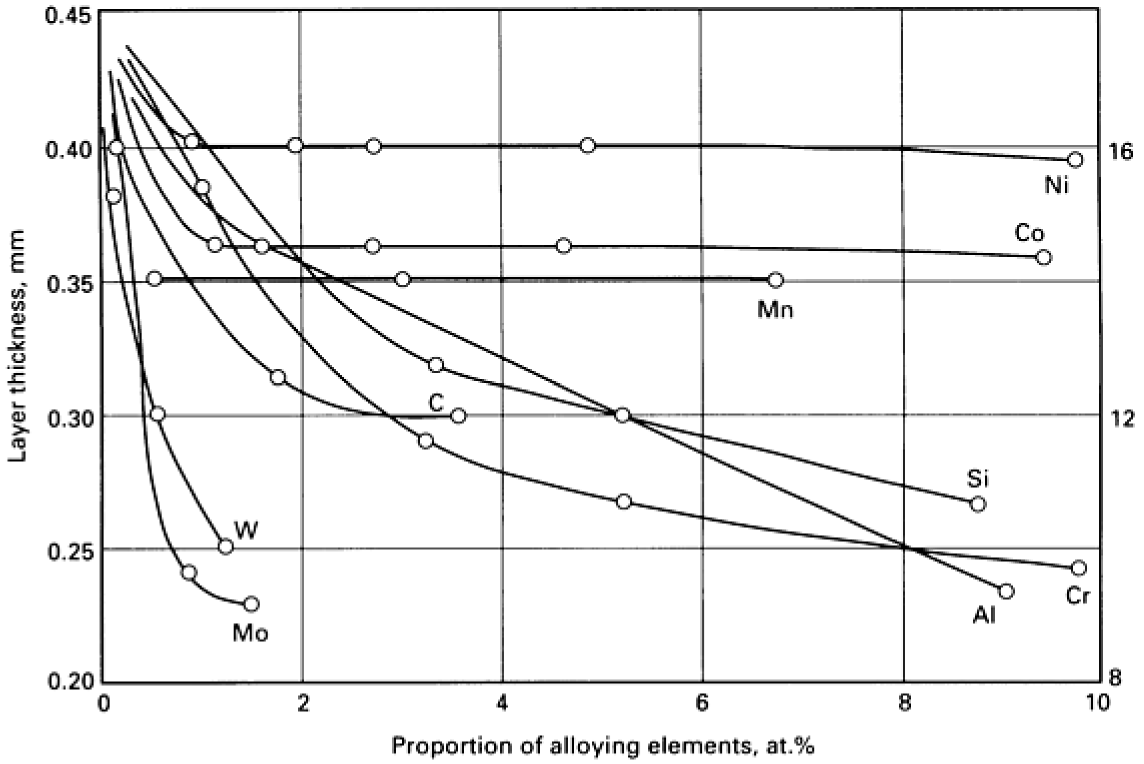

Fig. 6 Effect of alloying elements in steel on boride layer thickness. Source: Ref 29, 30

Carbon does not dissolve significantly in the boride layer and does not diffuse through the boride layer. During boriding carbon is driven (or diffused away) from the boride layer to the matrix and forms, together with boron, borocementite $Fe_3(B,C)$ [or more appropriately, $Fe_3(B_{0.67}\ C_{0.33})$ in the case of Fe-0.08% C steel] as a separate layer between Fe_2B and the matrix (Ref 31, 32).

Like carbon, silicon and aluminum are not soluble in the boride layer, and these elements are pushed from the surface by boron and are displaced ahead of the boride layer into the substrate, forming iron silicoborides--$FeSi_{0.4}B_{0.6}$ and Fe_5SiB_2--underneath the Fe_2B layer. Steels containing high contents of these ferrite-forming elements should not be used for boriding because they reduce the wear resistance of normal boride layer (Ref 1); they produce a substantially softer ferrite zone beneath the boride layer than that of the core (Ref 33). At higher surface pressure, this type of layer buildup results in the so-called egg shell effect, that is, at greater thicknesses extremely hard and brittle boride layer penetrates into the softer intermediate layer and is consequently destroyed (Ref 34).

A reduction in both the degree of interlocking tooth structure and of boride depth can occur with high-nickel-containing steels. Nickel has been found to concentrate below the boride layer; it enters the Fe_2B layer and in some instances promotes the precipitation of Ni_3B from the FeB layer (Ref 9, 35, 36, 37). It also segregates strongly to the surface from the underlying zone corresponding to the Fe_2B layer. This is quite pronounced in both Fe-14Ni and austenitic stainless steels. Consequently, gas boronizing of austenitic stainless steels appears to be a more appropriate treatment for producing a low-porosity, homogeneous, single-phase Fe_2B layer because of the lower boron activity of the gaseous mixture (Ref 37).

Chromium considerably modifies the structure and properties of iron borides. As the chromium content in the base material increases, progressive improvements in the following effects are observed: formation of boron-rich reaction products, decrease in boride depth, and flattening or smoothening of the coating/substrate interface (Ref 38). A reduction of boride thickness has also been noticed in ternary Fe-l2Cr-C steels with increasing carbon content (Ref 37). Manganese, tungsten, molybdenum, and vanadium also reduce the boride layer thickness and flatten out the tooth-shaped morphology in carbon steel. The distribution of titanium, cobalt, sulfur, and phosphorus in the boride layer has not been well established.

Heat Treatment after Boriding. Borided parts can be quench hardened in air, oil, salt bath, or polymer quenchant and subsequently tempered. Heating to the hardening temperature should be carried out in an oxygen-free protective atmosphere or in a neutral salt bath (Ref 6).

Boriding of Nonferrous Materials

Nonferrous materials such as nickel-, cobalt-, and molybdenum-base alloys, as well as refractory metals and their alloys and cemented carbides can be borided. Copper cannot; therefore, it provides a good stopping-off material. Of special interest is the boriding of nickel alloys and titanium and its alloys. Usually, boriding of nickel plate is done in gaseous BCl_3-H_2-Ar mixture in the temperature range of 500 to 1000 °C (930 to 1830 °F) (Ref 7), whereas Permalloy is pack

borided with 85% B_4C and 15% Na_2CO_3, or 95% B_4C and 5% $Na_2B_4O_7$ powder mixture at 1000 °C (1830 °F) for 6 h in H_2 atmosphere.

Boriding of titanium and its alloys is carried out preferably between 1000 and 1200 °C (1830 and 2200 °F) Here pack boriding in oxygen-free amorphous boron in combination with high-vacuum (0.0013 Pa, or 10^{-5} torr) and high-purity argon atmosphere or gas boriding with H_2-BCl_3-Ar gas mixture is preferred. The microhardness readings of boride layers formed on titanium and refractory metals are very high compared to those formed on cobalt and nickel (see Table 1). The wear properties of sintered carbides can be increased by boriding because of the acceptance of boron by soft cobalt and nickel binders (Ref 27).

Boride layers formed on tantalum, niobium, tungsten, molybdenum, and nickel do not exhibit tooth-shaped morphology as with titanium. When cemented carbides (such as WC-Co wire-drawing dies) are commercially pack borided with a powder mixture containing 40% B_4C, 45% SiC, and 5% KBF_4, three distinct zones are found to be formed in the boride layer comprising the exterior (zone I), intermediate (zone II), and interior (zone III) regions (Table 3).

Table 3 Three distinct zones formed in borided cemented carbide materials

Zone	Reference 38	Reference 7
I	CoB, W_2B_5, WC	CoB, WC
II	W_2CoB_2, WCoB, WC	Co_2B, WC
III	$W_2Co_2B_6$, WC, Co	Co_3B, WC

(a) Sources: Ref 3, 8, 39

Effects of Alloying Elements. As in iron and steel, suitable alloying additions raise the hardness of the boride layer formed on these metals; this is presumably caused by the formation of solid-solution borides.

Additions of alloying elements in nickel, cobalt, and titanium retard the rate of boride layer growth, and in the case of multiphase layers, the proportion of boride layer with high boron content (for example, TiB_2 in titanium) increases. The tooth-shaped morphologies in the cases of cobalt and titanium are also retarded with alloying addition, and the layers appear more uniform (Ref 11).

Thermochemical Boriding Techniques

Because extensive investigations have been carried out on boriding of ferrous materials, the techniques described below focus mainly on the boriding of ferrous materials.

Pack boriding (Ref 40, 41, 42) is the most widely used boriding process because of its relative ease of handling, safety, and the possibility of changing the composition of the powder mix, the need for limited equipment, and the resultant economic Savings (Ref 1). The process involves packing the annealed, cleaned, smooth parts in a boriding powder mixture contained in a 3 to 5 mm (0.1 to 0.2 in.) thick, heat-resistant steel box so that surfaces to be borided are covered with an approximately 10 to 20 mm (0.4 to 0.8 in.) thick layer. Many different boriding compounds have been used for pack boriding. They include solid boron-yielding substances, diluents, and activators.

The common boron-yielding substances are boron carbide (B_4C), ferroboron, and amorphous boron; the last two have greater boron potential, provide a thicker layer, and are more expensive than B_4C (Ref 42). Silicon carbide (SiC) and alumina (Al_2O_3) serve as diluents, and they do not take part in the reaction. However, SIC controls the amount of boron and prevents caking of the boronizing agent. $NaBF_4$, KBF_4, $(NH_4)_3BF_4$, NH_4Cl, Na_2CO_3, BaF_2, and $Na_2B_4O_7$ are the boriding activators. There are special proprietary brands of boriding compounds, such as different grades of Ekabor, available on the market that can be used with confidence.

Typical compositions of commercial solid boriding powder mixtures are:

- 5% B_4C, 90% SiC, 5% KBF_4
- 50% B_4C, 45% SiC, 5% KBF_4
- 85% B_4C, 15% Na_2CO_3
- 95% B_4C, 5% $Na_2B_4O_7$
- 84% B_4C, 16% $Na_2B_4O_7$
- Amorphous boron (containing 95 to 97% B)
- 95% amorphous boron, 5% KBF_4

The parts conforming to the shape of the container are packed (Fig. 7), covered with a lid, which rests inside the container and is weighted with an iron slug or stone to ensure an even trickling of the boriding agent during the boriding treatment. It is then heated to the boriding temperature in an electrically heated box or pit furnace with open or covered heating coils or a muffle furnace for a specified time. The container should not exceed 60% of the furnace chamber volume. In principle, boriding should be accomplished in such a way that high internal stresses are relieved, which in turn, eliminates cracks or spalling. With the packing process, the powder may be reused by blending with 20 to 50 wt% of fresh powder mixture. In this case, the powder should be discarded after 5 or 6 cycles.

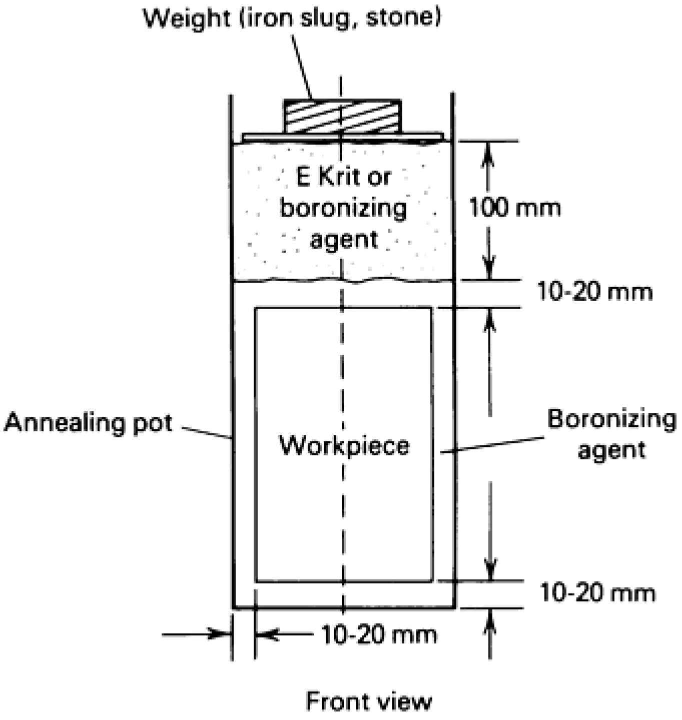

Fig. 7 Diagram of the packing of a single geometrical part in a pack boriding box. Source: Ref 1

Case Depth. The thickness of the boride layer depends on the substrate material being processed, boron potential of the boronizing compound (Fig. 8), boronizing temperature, and time (Fig. 9). In ferrous materials, the heating rate especially between 700 °C (1300 °F) and the boriding temperature (800 to 1000 °C, or 1470 to 1830 °F) should be high in order to minimize the formation of FeB (Ref 6).

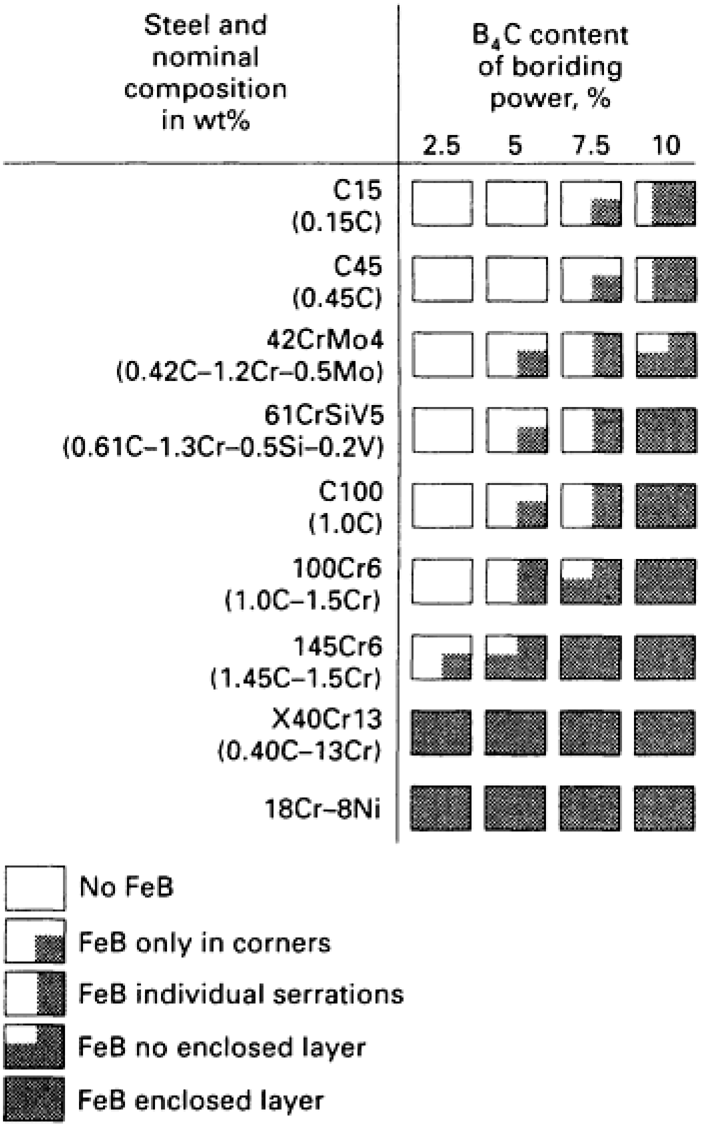

Fig. 8 Diagram showing the influence of the B_4C content of the boriding powder on the proportion of FeB phase in the boride layer of various steels borided with pack powder at 900n °C (1650 °F) for 5 h. Source: Ref 11

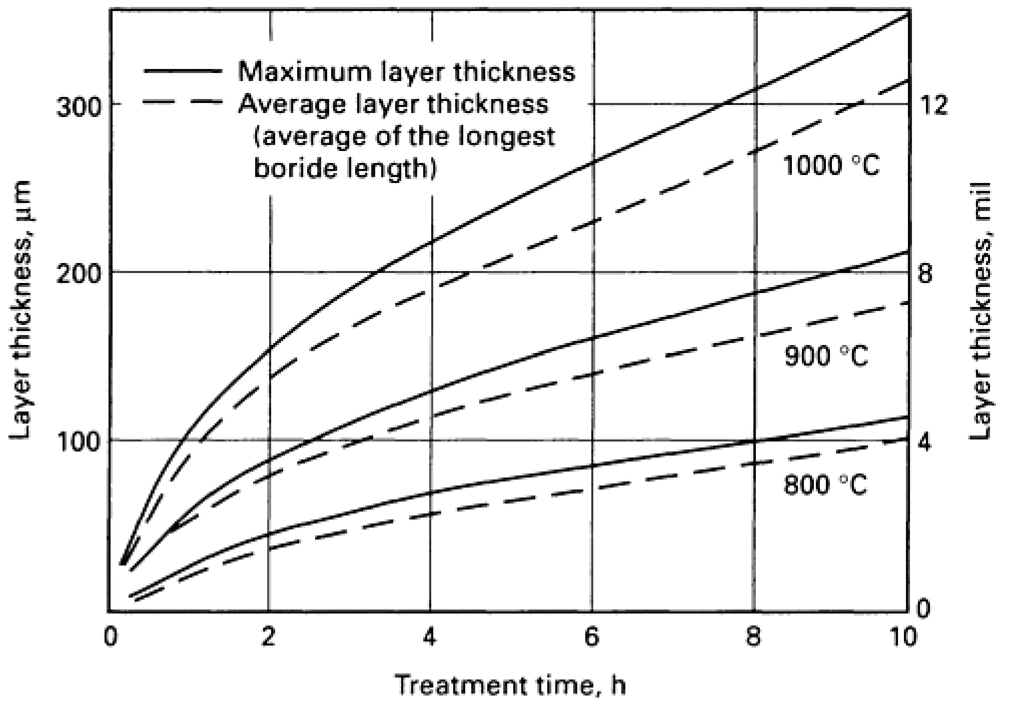

Fig. 9 Effect of pack boriding temperature and time on the boride layer thickness in a low-carbon (Ck 45) steel.

Source: Ref 26

It is usual practice to match the case depth with the intended application and base material. As a rule, thin layers (for example, 15 to 20 μm) are used for protection against adhesive wear (such as chipless shaping and metal-stamping dies and tools), whereas thick layers are recommended to combat erosive wear (for example, extrusion tooling for plastics with abrasive fillers and pressing tools for the ceramic industry). The commonly produced case depths are 0.05 to 0.25 mm (0.002 to 0.01 in.) for low-alloy and low-carbon steels and 0.025 to 0.076 mm (0.001 to 0.003 in.) for high-alloy steels. However, case depths >0.089 mm (>0.0035 in.) are uneconomical for highly alloyed materials such as stainless steels and some tool steels (Ref 27).

Borudif Process. In another modified pack boriding treatment, called the Borudif process, steel parts are packed in a 1:4 mixture of B_4C-SiC, and the moderate activator, BF_3 plus $(BOF)_3$ gas (formed by passing BF_3 through silica heated to above 450 °C, or 840 °F), is passed through the pack at 850 to 1100 °C (1560 to 2000 °F) for 4 h (Ref 43). The process offers a wide range of boriding potential because of the easy control of $(BOF)_3$ gas concentration that facilitates the treatment of a wide variety of substrate materials (Ref 43).

Paste boriding is used commercially when pack boronizing is difficult, more expensive, or time consuming. In this process, a paste of 45% B_4C (grain size 200 to 240 μm) and 55% cryolite (Na_3AlF_6, flux additive, Ref 5), or conventional boronizing powder mixture (B_4C-SiC-KBF_4) in a good binding agent (such as nitrocellulose dissolved in butyl acetate, aqueous solution of methyl cellulose, or hydrolyzed ethyl silicate) is repeatedly applied (that is, brushed or sprayed) at intervals over the entire or selected portion of parts until, after drying, a layer about 1 to 2 mm (0.04 to 0.08 in.) thick is obtained. Subsequently, the ferrous materials are heated (say at 900 °C, or 1650 °F, for 4 h) inductively, resistively, or in a conventional furnace to 800 to 1000 °C (1470 to 1830 °F) for 5 h. In this process, a protective atmosphere (for example, argon, cracked NH_3, or N_2) is necessary. A layer in excess of 50 μm thickness may be obtained after inductively or resistively heating to 1000 °C (1830 °F) for 20 min (Fig. 10). This process is of special interest for large components or for those requiring partial (or selective) boriding (Ref 6).

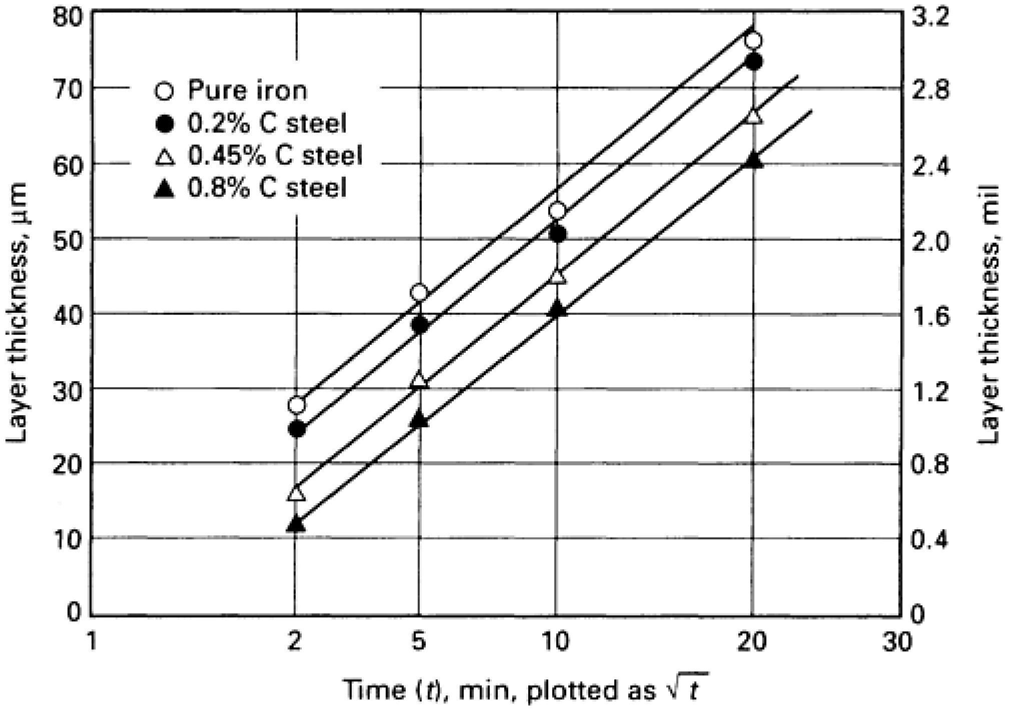

Fig. 10 A linear relationship between boride layer thickness and $\sqrt{time}$ for iron and steel boronized with B_4C-$Na_2B_4O_7$-Na_3AlF_6-based paste at 1000 °C (1830 °F). Source: Ref 40

Liquid boriding is grouped into electroless and electrolytic salt bath processes. These processes have several disadvantages:

- Removal of excess salt and unreacted boron is essential after the treatment; this step may prove to be expensive and time consuming
- To achieve boronizing reproducibility, bath viscosity is not allowed to increase. This is done by

recharging with salt, which involves high maintenance costs

- In some situations protection from corrosive fumes may be required

Electroless salt bath boriding of ferrous materials is carried out in a borax-based melt at about 900 to 950 °C (1650 to 1750 °F), to which about 30 wt% B_4C is added (Ref 44). The boronizing action can be further improved by replacing up to 20 wt% B_4C with ferroaluminum because it is a more effective reductant. However, superior results have been found by using a salt bath mixture containing 55% borax, 40 to 50% ferroboron, and 4 to 5% ferroaluminum (Ref 45). It has also been shown that 75:25 KBF_4-KF salt bath can be used at temperature below 670 °C (1240 °F) for boronizing nickel alloys, and at higher temperatures for ferrous alloys, to develop the desired boride layer thickness.

Electrolytic Salt Bath Boriding. In this process, the ferrous part acting as the cathode and a graphite anode are immersed in the electrolytic molten borax at 940 °C (1720 °F) for 4 h using a current density of about 0.15 A/cm^2 (Ref 46). The parts are then air cooled. In general, the parts are rotated during the treatment to obtain a uniform layer. A high current density produces a thin coating on low-alloy steels in a short time. For high-alloy steels of greater thickness, lower current densities are required for a longer time (Ref 47).

In the fused state tetraborate decomposes into boric acid and nascent oxygen.

$$B_4O_7 + 2e = 2B_2O_3 + O \qquad \textbf{(Eq 2)}$$

Simultaneously, sodium ions, after being neutralized in the vicinity of cathode, react with boric acid to liberate boron.

$$6\ Na + B_2O_3 = 3\ Na_2O + 2B \qquad \textbf{(Eq 3)}$$

In this manner, a high boriding potential is established near the cathode region. Other satisfactory electrolytic salt bath compositions include:

- KBF_4-LiF-NaF-KF mixture for parts to be treated at 600 to 900 °C (1100 to 1650 °F) (Ref 47)
- 20KF-30NaF-50LiF-0.7BF_2 mixture (by mole %) at 800 to 900 °C (1470 to 1650 °F) in 90N_2-10H_2 atmosphere
- 9:1 (KF-LiF)-KBF_4 mixture under argon atmosphere (Ref 48)
- KBF_4-NaCl mixture at 650 °C (1200 °F) (Ref 49)
- 90(30LiF + 70KF)-10KBF_4 mixture at 700 to 850 °C (1300 to 1560 °F)
- 80$Na_2B_4O_7$-20NaCl at 800 to 900 °C (1470 to 1650 °F) (Ref 50)

Gas boriding may be accomplished with:

- Diborane (B_2H_6)-H_2 mixture
- Boron halide-H_2/or (75:25 N_2-H_2) gas mixture
- Organic boron compounds such as $(CH_3)_3B$ and $(C_2H_5)_3B$

Boronizing with B_2H_6-H_2 mixture is not commercially viable due to the high toxic and explosive nature of diborane (Ref 1, 3). When organic boron compounds are used, carbide and boride layers form simultaneously. Because BBr_3 is expensive and is difficult to handle (with violent reactions with water), and because BF_3 requires high reduction temperature (due to its greater stability) and produces HF fumes, BCl_3 remains the attractive choice for gas boriding.

When parts are gas borided in a dilute (1:15) BCl_3-H_2 gas mixture at a temperature of 700 to 950 °C (1300 to 1740 °F) and a pressure up to 67 kPa (0.67 bar), a boride layer 120 to 150 μm thick is reported to be produced at 920 °C (1690 °F) in 2 h (Ref 51). Recent work has suggested the use of 75:25 N_2-H_2 gas mixture instead of H_2 gas for its better performance because of the production of boride layers with minimum FeB content. The latter phase can be easily

eliminated during the subsequent diffusion treatment before hardening (Ref 52). This process can be applied to titanium and its alloys as well.

Plasma Boriding. Both mixtures of B_2H_6-H_2 and BCl_3-H_2-Ar may be used successfully in plasma boronizing (Ref 53, 54). However, the former gas mixture can be applied to produce boride layer on various steels at relatively low temperatures such as 600 °C (1100 °F), which is impossible with a pack or liquid boronizing process (Ref 55). It has been claimed that plasma boriding in a mixture of BCl_3-H_2-Ar gases shows good features such as better control of BCl_3 concentration, reduction of the discharge voltage, and higher microhardness of the boride films (Ref 56). Figure 11 shows a schematic layout of a plasma boriding facility.

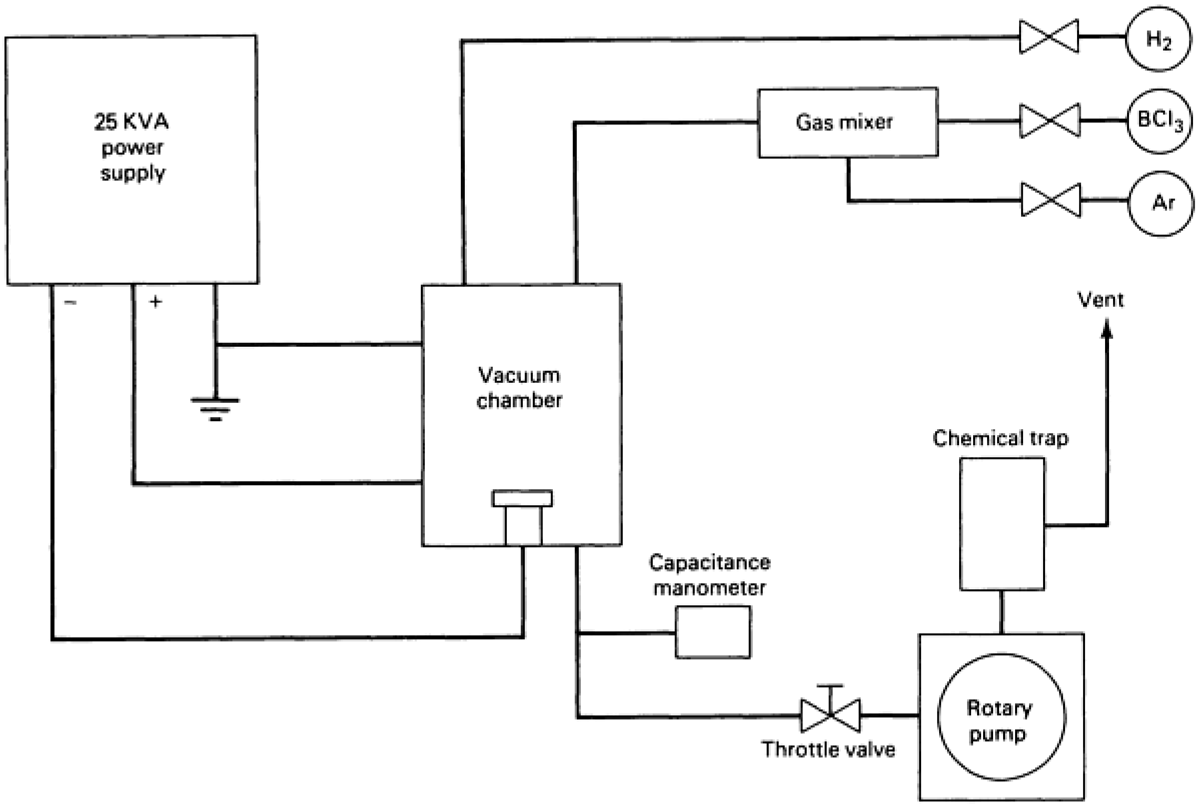

Fig. 11 Layout of plasma boronizing facility. Source: Ref 19

The dual-phase layer is characterized by visible porosity, occasionally associated with a black boron deposit. This porosity, however, can be minimized by increasing the BCl_3 concentration. Boride layers up to 200 μm in thickness can be produced in steels after 6 h treatment at a temperature of 700 to 850 °C (1300 to 1560 °F) and a pressure of 270 to 800 Pa (2 to 6 torr) (Ref 57).

Advantages of this process are:

- Control of composition and depth of the borided layer
- Increased boron potential compared to conventional pack boronizing
- Finer plasma-treated boride layers
- Reduction in temperature and duration of treatment
- Elimination of high-temperature furnaces and their accessories
- Savings in energy and gas consumption

The only disadvantage of the process is the extreme toxicity of the atmosphere employed. As a result, this process has not gained commercial acceptance. To avoid the above shortcoming, boriding from paste (containing a mixture of 60% amorphous boron and 40% liquid borax) in a glow discharge at the impregnating temperature has been recently developed, which is found to greatly increase the formation of the surface boride layer (Ref 58).

Fluidized Bed Boriding A recent innovation is boriding in fluidized beds (Fig. 12), which involves bed material of coarse-grained silicon carbide particles, a special boriding powder such as Ekabor WB, and an oxygen-free gas such as N_2-H_2 mixture (Ref 59). When electricity is used as the heat source, the bed serves as a faster heat-transfer medium. This is usually equipped with quench and tempering furnaces.

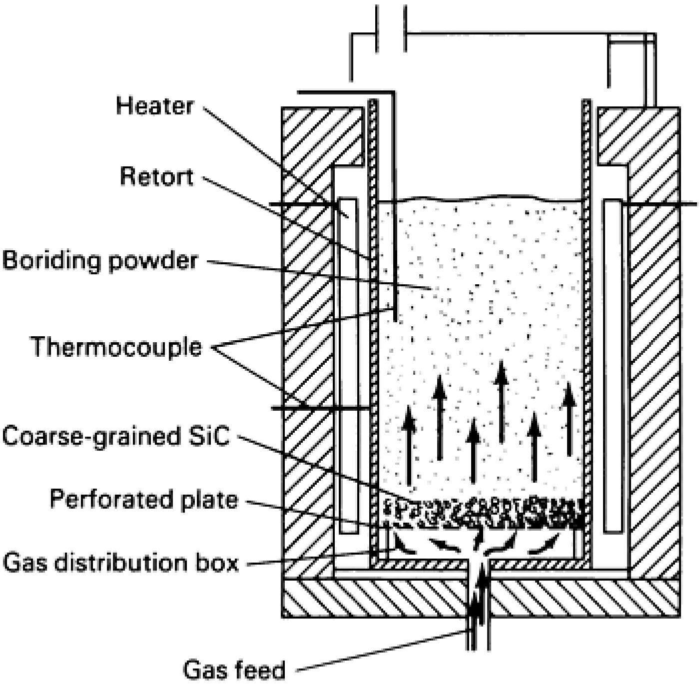

Fig. 12 Diagram of a fluidized bed for boriding. Source: Ref 4

This process offers such advantages as:

- High rates of heating and flow, as well as direct withdrawal of the parts, provide shorter operating cycle times (that is, rapid boronizing)
- Temperature uniformity with low capital cost and flexibility is ensured
- A fluidized furnace is very tight because of upward pressure of the gas
- This process produces reproducibility, close tolerances, and a very uniform finish on mass-produced parts
- This process can be adaptable to continuous production and can lend itself to automation as the parts are charged and withdrawn intermittently
- Quenching (and subsequent tempering) of the parts directly after this treatment is possible
- Low operating cost (due to reduced processing time and energy consumption) for mass production of boronized parts

An important disadvantage lies in the continuous flushing of the boriding agent within the retort by the inert gas. The exhaust gases containing enriched fluorine compounds must be cleaned absolutely, for example, in an absorber filled with dry $CaCO_3$ chips to avoid environmental problems (Ref 34). Alternatively pulsed fluidizing process can considerably decrease the amount of exhaust gases (Ref 34).

Multicomponent boriding is a thermochemical treatment involving consecutive diffusion of boron and one or more metallic elements such as aluminum, silicon, chromium, vanadium, and titanium into the component surface. This process is carried out at 850 to 1050 °C (1560 to 1920 °F) and involves two steps:

1. Boriding by conventional methods--notably pack, paste, and electrolytic salt bath methods (Ref 60). Here, the presence of FeB is tolerated, and, in some cases, may prove beneficial. Among these methods, much work has been done on pack method (Table 4 and Ref 2, 60, 61, 62), which produces a compact layer at least 30 μm (1 mil) thick
2. Diffusing metallic elements through the powder mixture or borax-based melt into the borided surface. If

the pack method is used, Sintering of particles can be avoided by passing argon or H_2 gas into the reaction chamber

There are six multicomponent boronizing methods (Ref 3, 60): boroaluminizing, boro-siliconizing, borochromizing, borochromtitanizing, borochromvanadizing, and borovanadizing.

Table 4 Multicomponent boriding treatments

Reference	Multicomponent boriding technique	Media type	Media composition[(a)], wt%	Process steps investigated[(a)]	Substrate(s) treated	Temperature, °C (°F)
61	Boroaluminizing	Electrolytic salt bath	3-20% Al_2O_3 in borax	S	Plain carbon steels	900 (1650)
62	Boroaluminizing	Pack	84% B_4C + 16% borax 97% ferroaluminium + 3% NH_4Cl	S B-Al Al-B	Plain carbon steels	1050 (1920)
2	Borochromizing	Pack	5% B_4C + 5% KBF_4 + 90% SiC (Ekabor II) 78% ferrochrome + 20% Al_2O_3 + 2% NH_4Cl	S B-Cr Cr-B	Plain carbon steels	Borided at 900 (1650) Chromized at 1000 (1830)
2	Borosiliconizing	Pack	5% B_4C + 5% KBF_4 + 90% SiC (Ekabor II) 100% Si	B-Si Si-B	0.4% C steel	900-1000 (1650-1830)
2	Borovanadizing	Pack	5% B_4C + 5% KBF_4 + 90% SIC (Ekabor II) 60% ferrovanadium + 37% Al_2O_3 + 3% NH_4Cl	B-V	1.0% C steel	Borided at 900 (1650) Vanadized at 1000 (1830)

Source: Ref 3

(a) S, simultaneous boriding and metallizing; B-Si, borided and then siliconized; Al-B, aluminized and then borided

Boroaluminizing. When boroaluminizing involves boriding followed by aluminizing, the compact layer formed in steel parts provides good wear and corrosion resistance, especially in humid environments (Ref 6, 30, 60).

Borosiliconizing results in the formation of FeSi in the surface layer, which enhances the corrosion-fatigue strength of treated parts (Ref 62).

Borochromizing (involving chromizing after boriding) provides better oxidation resistance than boroaluminizing, the most uniform layer (probably comprising a solid-solution boride containing iron and chromium), improved wear resistance compared with traditionally borided steel, and enhanced corrosion-fatigue strength. In this case, a post-heat-treatment operation can be safely accomplished without a protective atmosphere (Ref 2, 63, 64).

Borochromtitanized structural alloy steel provides high resistance to abrasive wear and corrosion as well as extremely high surface hardness 5000 HV (15 g load) (Ref 60). Figure 13 shows the microstructure of the case of a borochromtitanized constructional alloy steel part exhibiting titanium boride in the outer layer and iron-chromium boride beneath it.

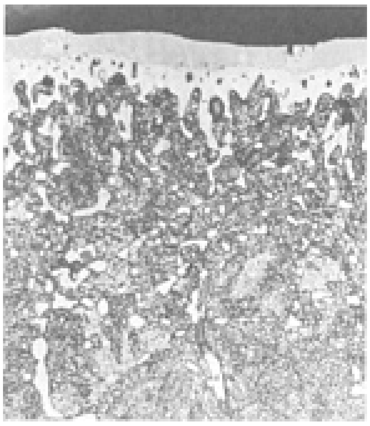

Fig. 13 Microstructure of the case of a borochromtitanized construction alloy steel. Source: Ref 6, 60

Borovanadized and borochromvanadized layers are quite ductile with their hardnesses exceeding 3000 HV (15 g load). This reduces drastically the danger of spalling under impact loading conditions (Ref 60).

Applications of Thermochemical Boriding. Presently borided parts have been used in a wide variety of industrial applications (Table 5) because of the numerous advantageous properties of boride layers. In sliding and adhesive wear situations, boriding is applied to:

- Spinning steel rings, steel rope, and steel thread guide bushings (made of DIN St 37 steel)
- Grooved gray cast iron drums (thread guides) for textile machinery
- Four-holed feed Water regulating valves (made from DIN 1.4571, or AISI 316 Ti steel)
- Burner nozzles, swirl elements, and injector tops for steel oil burners in the chemical industry (Ref 4)
- Drive, worm, and helically toothed steel gears in various high-performance vehicle and stationary engines (Ref 3)

(a) Sources: Ref 4, 26

As abrasive Wear-resistance materials, borided stainless steels are used for parts such as screw cases and bushings, perforated and slotted hole screens, rollers, valve components, fittings, guides, shafts, and spindles, and borided Ti-6Al-4V for parts such as leading edge rotor blade cladding for helicopter applications. Other applications in this category include:

- Nozzles of bag filling equipment
- Extrusion screws, cylinders, nozzles, and reverse-current blocks in plastic production machinery (extruder and injection molding machinery) (Ref 1)
- Bends and baffle plates for conveying equipment for mineral-filled plastic granules in the plastics industry
- Punching dies (for making perforations in accessory parts for cars), press and drawing matrices, and necking rings (made from S1 tool steel)
- Press dies, cutting templates, punched plate screens (made of DIN St 37 steel)
- Screw and wheel gears, bevel gears (from AISI 4317 steel)
- Steel molds (for the manufacture of ceramic bricks and crucibles in the ceramics industry), extruder barrels, plungers and rings (from 4140 steel)
- Extruder tips, nonreturn valves and cylinders (for extrusion of abrasive minerals or glass fiber-filled plastics, from 4150 steel)
- Casting fillers for processing nonferrous metals (from AISI H11 steel)
- Transport belts for lignite coal briquettes

Borided parts also find applications in die-casting molds; bending blocks; wire draw blocks; pipe clips; pressing and shaping rollers, straightening rollers, engraving rollers, rollers for cold mills; mandrels; press tools; bushings; guide bars; discs; casting inserts; various types of dies including cold heading, bending, extrusion, stamping, pressing, punching, thread rolling, hot forming, injection molding, hot forging, drawing, embossing, and so on in A2, A6, D2, D6, H10, H11, 02, and other tool steels (Ref 42).

Borided steel parts have also been used as transport pipe for molten nonferrous metals such as aluminum, zinc, and tin alloys (made from DIN St 37), corrosion-resistant transport pipe elbows for vinyl chloride monomer, grinding discs (made from DIN Ck 45), die-casting components, air foil erosion-resistant cladding, data printout components (for example, magnetic hammers, wire printers), and engine tappets (Ref 12).

Boronized Permalloy is used for magnetic head applications. Boronized cemented carbides are used as drawing dies, guiding parts, and dimensional measurement parts. Some examples of multicomponent boriding include: improving the wear resistance of austenitic steels (borochromizing), of parts for plastics processing machines (borochromtitanizing), and of dies used in the ceramics industry (borochromizing) (Ref 60).

Chemical Vapor Deposition

Metal boride coatings or deposition via chemical vapor deposition (CVD) of TiB_2, ZrB_2, rare earth borides, and so forth on steel, refractory metals, and alloys have been made using the following chloride reaction:

$$MCl_4\ (g) + 2BCl_3\ (g) + 5H_2\ (g) = MB_2\ (s) + 10\ HCl\ (g) \qquad \textbf{(Eq 4)}$$

Good deposition of some borides is obtained under the conditions listed in Table 6. Among these boride coatings, much research work has been directed toward the deposition of TiB_2.

Table 6 Chemical vapor deposition (CVD) conditions for some borides

Boride	Precursors	Temperature		Pressure		After

SiB_x	$SiBr_4$-BBr_3	975-1375	1790-2500	0.007	0.05	Armas and Combescure (1977)
TaB_2	$TaBr_5$-BBr_3	850-1750	1560-3180	0.003-0.025	0.025-0.2	Armas *et al.* (1976)
	$TaCl_5$-B_2H_6	500-1025	930-1875	100	760	Randich (1980)
TiB_2	$TiCl_4$-BCl_3-H_2	1200-1415	2200-2580	0.4-2	3-15	Gebhardt and Cree (1965)
	$TiCl_4$-B_2H_6	600-900	1100-1650	100	760	Pierson and Mullendore (1980)
	$TiCl_4$-BCl_3-H_2	750-1050	1380-1920	100	760	Caputo *et al.* (1985)
	$TiCl_4$-BCl_3-H_2	1200	2200	6.5	50	Desmaison *et al.* (1987)
ZrB_2	$ZrCl_4$-BCl_3-H_2	1400	2550	0.4-0.8	3-6	Gebhardt and Cree (1965)

The CVD process for the deposition of TiB_2 or ZrB_2 coatings on various substrate materials is carried out by passing a mixture of $TiCl_4$ (or $ZrCl_4$) and BCl_3-H_2 gas mixture over a heated part placed in a vacuum chamber where the gas decomposition into atomic boron and titanium (or zirconium) and subsequent deposition of TiB_2 (or ZrB_2) occurs at the component surface when the appropriate deposition temperature and gas pressure are maintained (Table 6). It is necessary to adjust the gas flow so that the atomic ratios are:

- B/Ti = 1 to 2 and H/Cl = 6 to 10 for TiB_2
- B/Zr = 1.0, and H/Cl = 20.0 for ZrB_2

It is further noticed that when B/(B + Cl) = ~0.4, the TiB_2 deposit becomes dense with a {1010} or {1120} preferred orientation, which is often associated with a columnar appearance (Ref 66) and microhardness values of about 3300 to 4500 HV (50 g load).For a good adherent deposit of TiB_2 on steel and cemented carbides, it is desirable to precoat the substrate with corrosion-resistant layers of cobalt and TIC, respectively (Ref 66, 67, 68).

Advantages and Applications. This process has several advantages such as the high purity of the deposit, a relatively high rate of deposition; close chemical composition control; high resistance to thermal shock, erosion, and/or corrosion at elevated temperatures; and large economic savings for the mass production of small parts. As a result, TiB_2 coatings are variously used on cemented carbide cutting inserts (Ref 68), on graphite electrodes in aluminum reduction cells, and on letdown valves in coal conversion reactors (Ref 69, 70). $ZrBr_2$ coatings on graphite are sometimes used as a spectrally selective surface at elevated temperatures (Ref 71).

Thermoreactive Deposition/Diffusion Process for Surface Hardening of Steels

Tohru Arai, Toyota Central Research and Development Laboratories, Inc.; Steven Harper, Arvin TD Center, Arvin Industries

Introduction

THE THERMOREACTIVE DEPOSITION/DIFFUSION PROCESS (TRD) is a method of coating steels with a hard, wear-resistant layer of carbides, nitrides, or carbonitrides. In the TRD process, the carbon and nitrogen in the steel substrate diffuse into a deposited layer with a carbide-forming or nitride-forming element such as vanadium, niobium, tantalum, chromium, molybdenum, or tungsten. The diffused carbon or nitrogen reacts with the carbide- and nitride-forming elements in the deposited coating so as to form a dense and metallurgically bonded carbide or nitride coating at the substrate surface.

The TRD process is unlike conventional case-hardening methods, where the specific elements (carbon and nitrogen) in a treating agent diffuse into the substrate for hardening. Unlike conventional diffusion methods, the TRD method also results in an intentional buildup of a coating at the substrate surface. These TRD coatings, which have thicknesses of about 5 to 15 μm (0.2 to 0.6 mil), have applications similar to those of coatings produced by chemical vapor deposition (CVD) or physical vapor deposition (PVD). In comparison, the thickness of typical CVD coatings (usually less than 25 μm, or 1 mil) has about the same range as TRD coatings.

Process Characteristics

The hard alloy carbide, nitride, and carbonitride coatings in the TRD method can be applied to steels by means of salt bath processing (Ref 1, 2, 3, 4) or fluidized beds (Ref 5). The carbide coating by salt bath immersion was first developed in Japan and used industrially almost 20 years ago under the name of the Toyota Diffusion (TD) coating process (Ref 1, 2). The TD method uses molten borax with additions of carbide-forming elements such as vanadium, niobium, titanium, or chromium, which combine with carbon from the substrate steel to produce alloy carbide layers. Because the growth of the layers is dependent on carbon diffusion, the process requires a relatively high temperature, from 800 to 1250 °C (1470 to 2280 °F), to maintain adequate coating rates. Carbide coating thicknesses of 4 to 7 μm are produced in 10 min to 8 h, depending on bath temperature and type of steel. The coated steels may be cooled and reheated for hardening, or the bath temperature may be selected to correspond to the steel austenitizing temperature, permitting the steel to be quenched directly after coating.

Salt bath temperatures can also be lowered to the tempering range of steel (Ref 3). In order to lower salt bath deposition temperatures, techniques to produce alloy carbonitride coatings are used. Such coatings are applied to hardened and nitrided steels in vanadium-containing chloride baths at temperatures of 550 to 600 °C (1020 to 1110 °F). This section deals exclusively with coating at a high temperature.

Coating Procedure and Mechanism of Coating Formation. The high-temperature salt bath TRD process is performed in a molten borax bath at 850 to 1050 °C (1560 to 1920 °F). Immersion time ranges from 0.5 to 10 h to obtain an optimum carbide layer thickness of 5 to 15 μm (0.2 to 0.6 mil) for most applications. This temperature range is suitable for quench hardening many grades of low-alloy steels, carburized steels, and tool steels.

Before parts are TRD processed they are first preheated to minimize distortion and to lower the TRD processing time. They are then TRD processed at the austenitizing temperature for the particular grade of steel. After TRD processing, the parts are quenched in air, salt, or oil to produce a hardened substrate. After quenching, tempering is carried out. Figure 1 shows a schematic of a typical cycle. High-speed steels and other steels that have austenitizing temperatures greater than 1050 °C (1920 °F) may be post-TRD heat treated in vacuum, gas, or protective salt to achieve full substrate hardness.

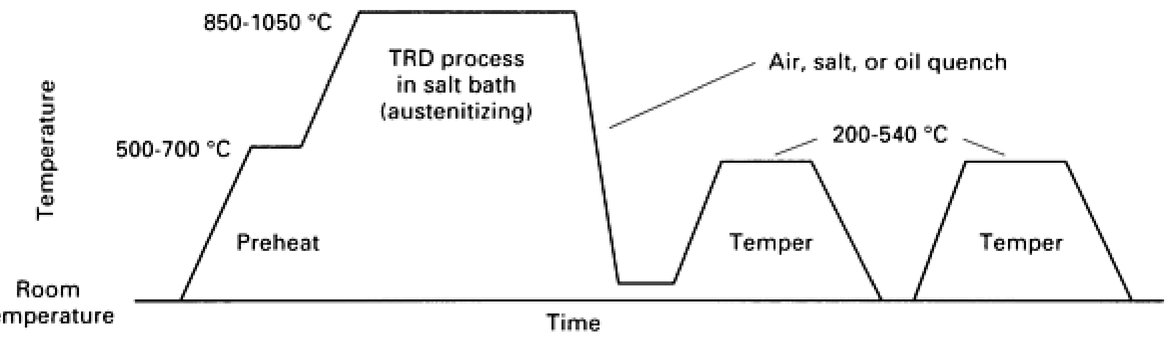

Fig. 1 Schematic of typical TRD processing cycle

When substrate materials containing carbon and nitrogen are kept in contact with treating agents at appropriately elevated temperatures, carbon and nitrogen chemically combine with the carbide- and nitride-forming elements of the treating agent due to their small free energies for carbide and nitride formation. This formation of carbides, carbonitrides, and nitrides on the substrate results in the growth of a layer, as shown in Fig. 2 for vanadium carbide and chromium carbide coatings. Carbide layers are formed in the following steps:

- Carbide-forming elements dissolve into borax from added powders
- Carbon in steel combines with the carbide-forming elements to produce a carbide layer on the surface
- The carbide layer grows at the surface front through reaction between carbide-forming elements and carbon atoms successively supplied from the substrate

Vanadium and chromium diffuse into the steel substrate to form iron-chromium or iron-vanadium solid-solution layers beneath the carbide layer. The solid-solution layers were formed on low-carbon steel at high treating temperature.

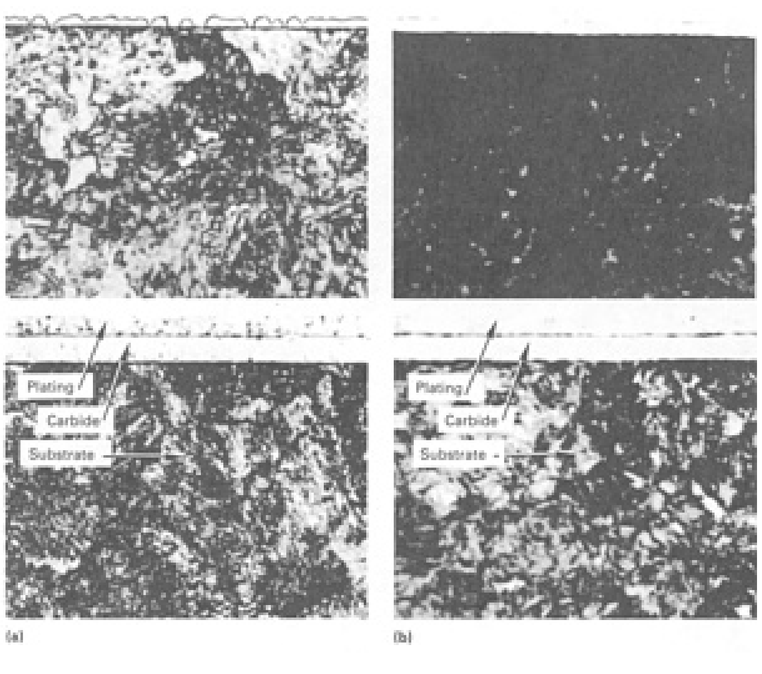

Fig. 2 Carbide coating grown during TRD process. Substrate, W1 steel; temperature, 900 °C (1650 °F). Salt: borax, V_2O_5 and B_4C borax and chromium. (a) Vanadium carbide coating. Upper, 5 min; lower, 30 min. (b) Chromium carbide coating. Upper, 5 min; lower, 30 min

Reagents Used. The carbide-forming elements (CFE) and the nitride-forming elements (NFE) must be in an active state to combine with carbon and nitrogen. Typical reagents have the CFE and NFE dissolved into molten salt in the salt bath immersion method and those in halide vapor produced through reaction between CFE- and NFE-containing powders and halide at elevated temperatures in the powder-pack and fluidized-bed methods. Therefore, borax with additions of CFE and NFE contained in ferroalloy powder or with oxides of CFE and NFE and their reducing agents, such as boron carbide and aluminum, are successfully used as bath agents. Mixtures of ferroalloy powder containing CFE and NFE and halide powder, such as ammonium chloride, often added with alumina powder, are used in packed boxes (Ref 6 and 7) or in a fluidized bed (Ref 5).

Substrate Materials. Most carbon-containing materials such as steels, cast iron, cobalt alloys, cemented carbides, carbide-metal cermets, carbide ceramics (Ref 8), and carbon may be used as the substrates for carbide coating. Carbon-deficient metals, for example, iron and nickel alloys, can be used after carburization prior to application of the carbide coating. Carbonitride coating is applicable to preliminarily nitrided steel. A nitride coating can be formed on nitride ceramics (Ref 8).

Various tool steels are most frequently used for tooling. Low- or medium-carbon constructural steels are used for machine components. The composition and properties of the coatings are almost independent of the substrate materials. Therefore, inexpensive and easily machinable materials should be used.

Effect of Treating Parameters. The coating growth rate is determined by the number of carbon atoms and nitrogen atoms that can be supplied to the coating from the substrate by diffusion, if the treating reagents can supply CFE and NFE in excess of the critical amount required to combine with the carbon and nitrogen supply from the substrate. Excess amounts of material containing CFE and NFE (for example, more than 10 wt% Fe-V, or 20 wt% V_2O_5 and 5 wt% B_4C in molten borax for vanadium carbide coating, or more than 10 wt% Cr and 1 wt% NH_4Cl in a fluidized bed for chromium carbide coating) are usually added to maintain this requirement. Therefore, the coating growth rate is determined by factors that affect only the amount of CFE and NFE required for coating: temperature, time, type of substrate, and type of coating.

As in many diffusion treatments, the effect of temperature and time on coating thickness (d) is expressed by the following equation:

$$d^2/t = K = K_o \exp(-Q/RT) \qquad \textbf{(Eq 1)}$$

where d is the thickness of coating (cm), t is time (s), K is the growth rate constant (cm^2/s), K_o is the constant term of K (cm^2/s), Q is the activation energy (KJ/mol), T is absolute temperature (K), and R is the gas constant. Figure 3 shows the relation between the thickness of the vanadium carbide layer formed on W1 steel versus salt bath temperature and immersion time in the molten salt bath immersion method. The temperature is usually selected around the hardening temperature of steels, that is, 800 to 1250 °C (1475 to 2285 °F).

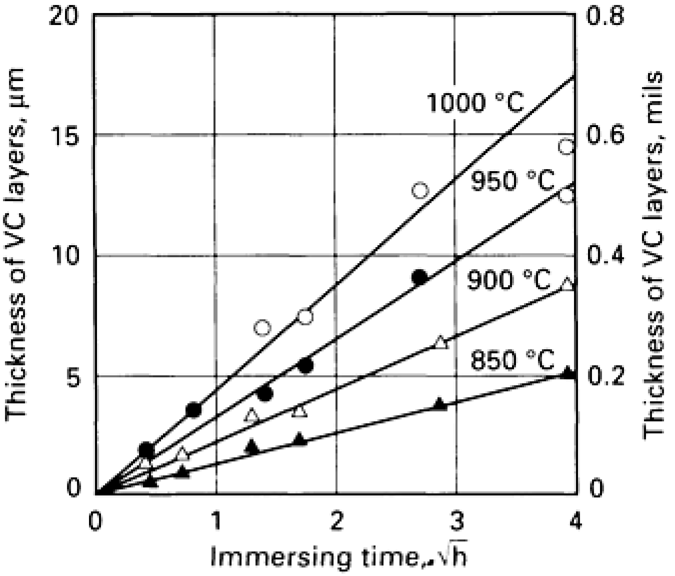

Fig. 3 Effect of temperature and time on thickness of vanadium carbide layer in a borax bath containing 20 wt% Fe-V powder

The carbon and nitrogen content in the substrate has a positive effect on the growth rate. However, the total content in the substrate does not have a direct effect. For example, in steels the carbon content in the austenite matrix, not the total carbon content, is nearly linear in relation to the thickness of the carbide coating. This is shown in Fig. 4 for the salt bath immersion process (Ref 1, 2). In the case of alloyed steels, an increase of temperature increases the carbon content in the matrix phase, as well as the diffusion rate of carbon in the carbide layer and in the substrate, resulting in a considerable increase of coating thickness. Figure 5 exemplifies the relation between bath temperature and immersion time needed for producing a 4 μm and 7 μm thick VC coating on four types of steel. In the case of cemented carbides, not only the carbon content but also the amount of cobalt matrix has a large effect on the thickness. The diffusion rate and its temperature dependence in relation to the carbon and nitrogen content are different between coatings. However, the difference in thickness among vanadium carbide (VC), niobium carbide (NbC), chromium carbide (Cr_7C_3, $Cr_{23}C_6$), and titanium carbide (TiC) is negligibly small.

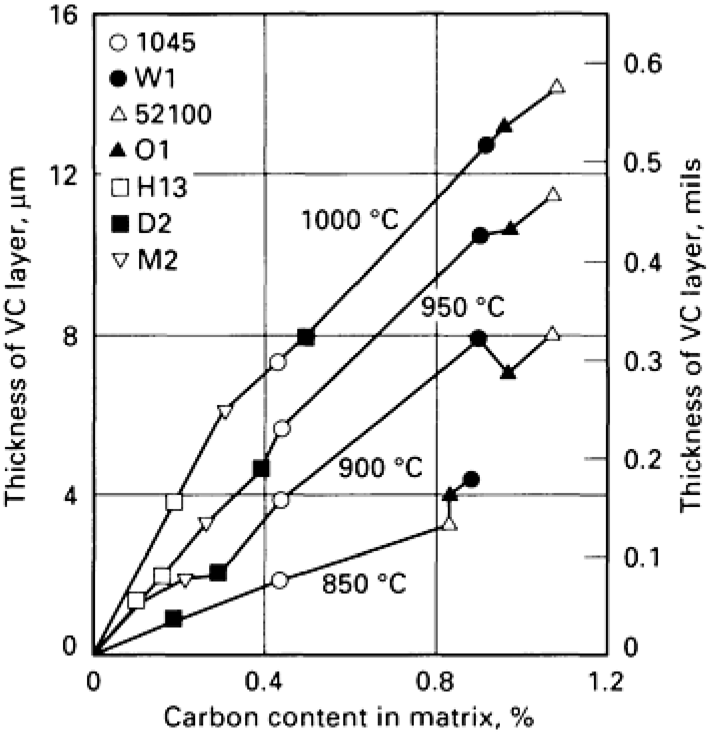

Fig. 4 Effect of carbon content in matrix phase on thickness of vanadium carbide layer in a borax bath containing 20 wt% Fe-V powder. Immersion time, 4 h

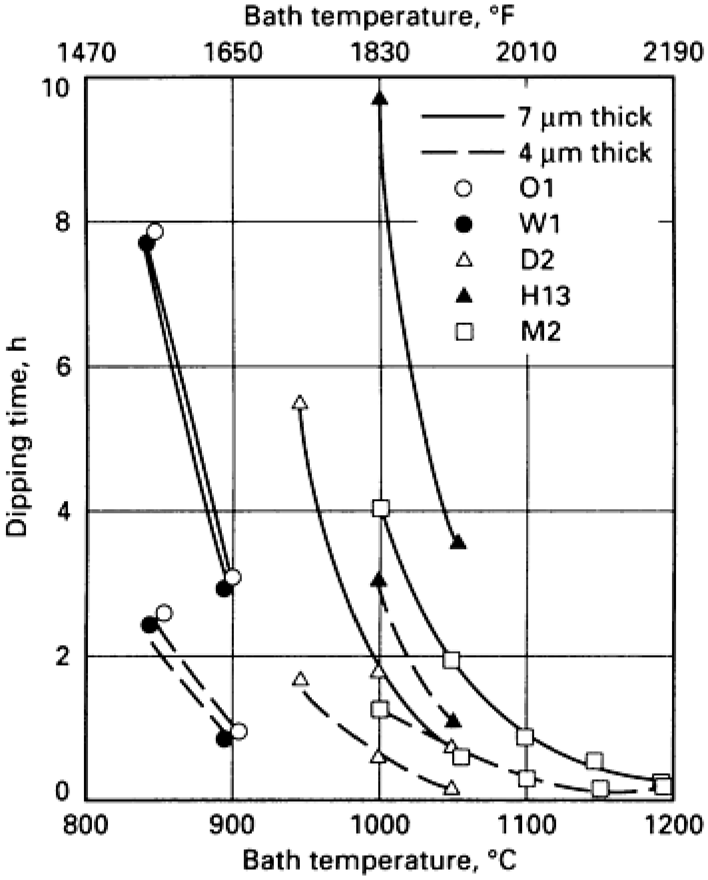

Fig. 5 Effect of bath temperature and substrate steel on the immersion time required to form a 7 μm and 4 μm thick vanadium carbide layer in a borax bath

Control of Distortion. The possibility of distortion is present with the high-temperature process. Distortion entails dimensional change and deformation. Dimensional change is due to phase transitions in heat treatment of the base steel and to formation of the carbide layer. Deformation is a change in shape.

TRD processing usually hardens a material. Therefore, to minimize dimensional change, it is best to start with a part that has been hardened and finish ground. Even then, there will be some dimensional change due to differences in the amount of retained austenite. Cemented carbide is not hardened in the process, therefore it has very little dimensional change.

The amount of retained austenite before TRD processing should equal the amount after processing. The easiest method of controlling retained austenite is to reduce it to 0% before and after the TRD process. This can be achieved in D2 tool steel by tempering at 520 to 535 °C (975 to 1000 °F) to decompose the retained austenite. Sub-zero treatment is another method of decomposing retained austenite.

Deformation is caused by thermal stresses, transformation stresses, creep during heating, anisotropy of the substrate structure, and residual stresses. The following are steps that can be taken to minimize deformation:

- Minimize variations in cross-sectional area
- Use air-hardening grades of tool steel, which can be slow cooled
- Machine tools so that critical dimensions are transverse of the rolling direction of the raw material
- Use powder metal steels
- Relieve residual stresses caused by machining and grinding

In making new tooling, it is recommended to leave stock on nonworking surfaces and finish only the working surfaces. The non-working surfaces may then be finished after TRD processing.

TRD Carbide Coatings

General Characteristics. Carbide coatings that are available with the high-temperature salt bath process include vanadium carbide, niobium carbide, and chromium carbide. Vanadium carbide and niobium carbide have high surface hardness and resistance to wear, seizure, and corrosion. Chromium carbide has light wear resistance and high resistance to oxidation. The surface hardness and wear, seizure, corrosion, and oxidation resistance in relation to other surface-hardening processes is shown in Fig. 6, 7, 8, 9, and 10.

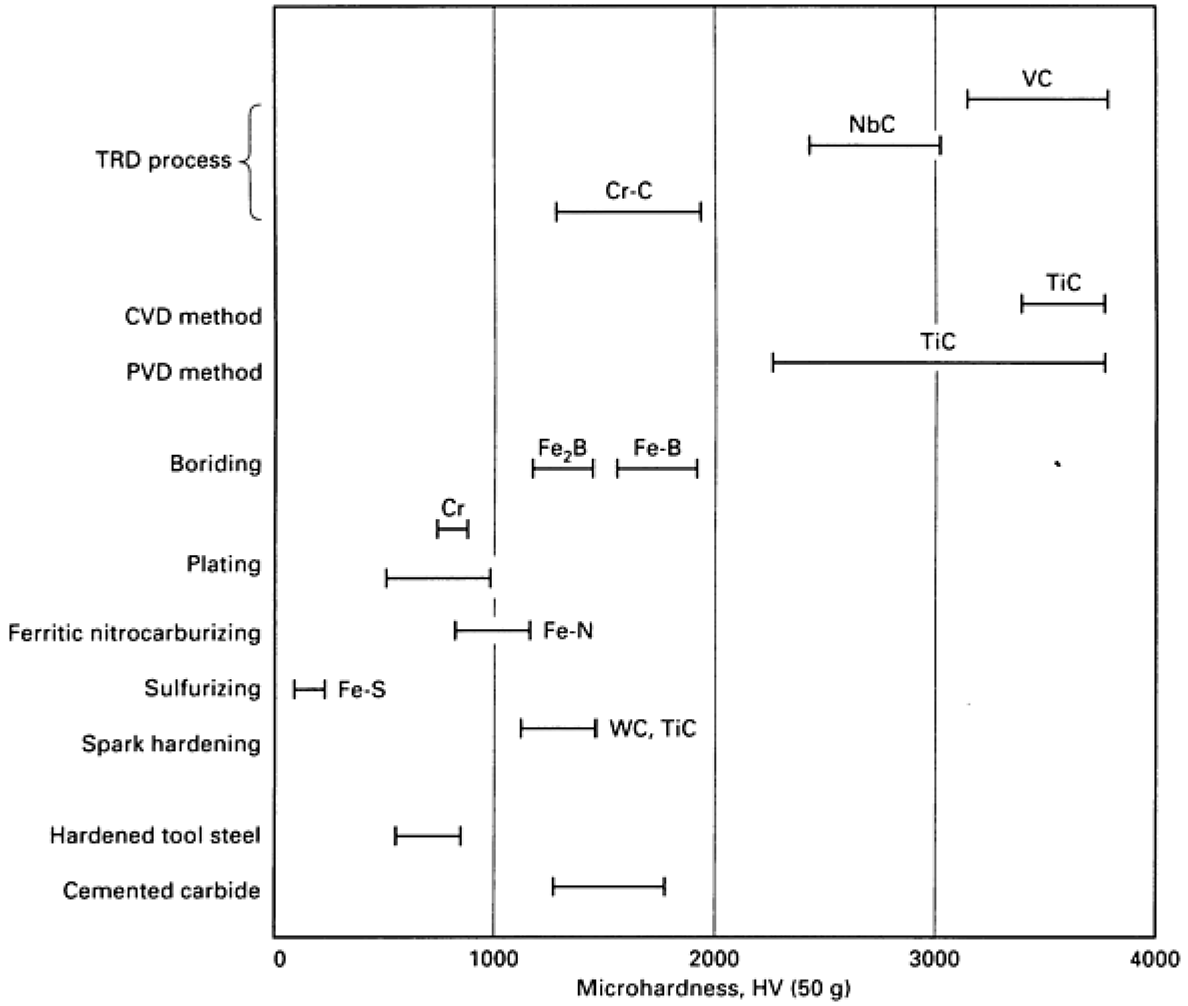

Fig. 6 Surface hardness of carbide layers by TRD process in relation to other surface-hardening processes

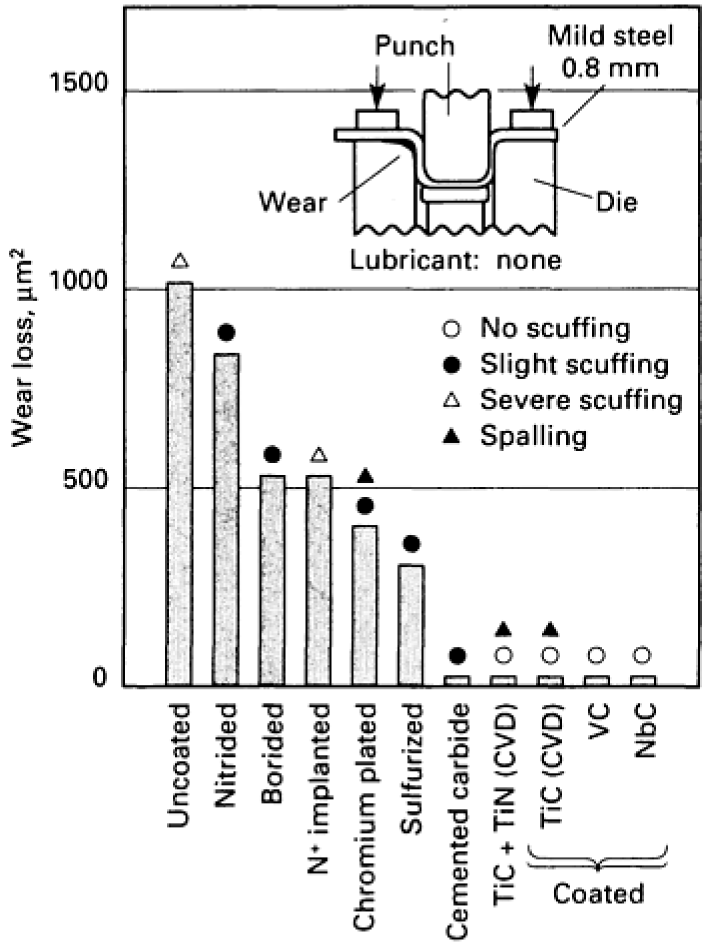

Fig. 7 Comparative cross-sectional area of wear, scuffing, and spalling on a die radius in a sheet steel-bending test

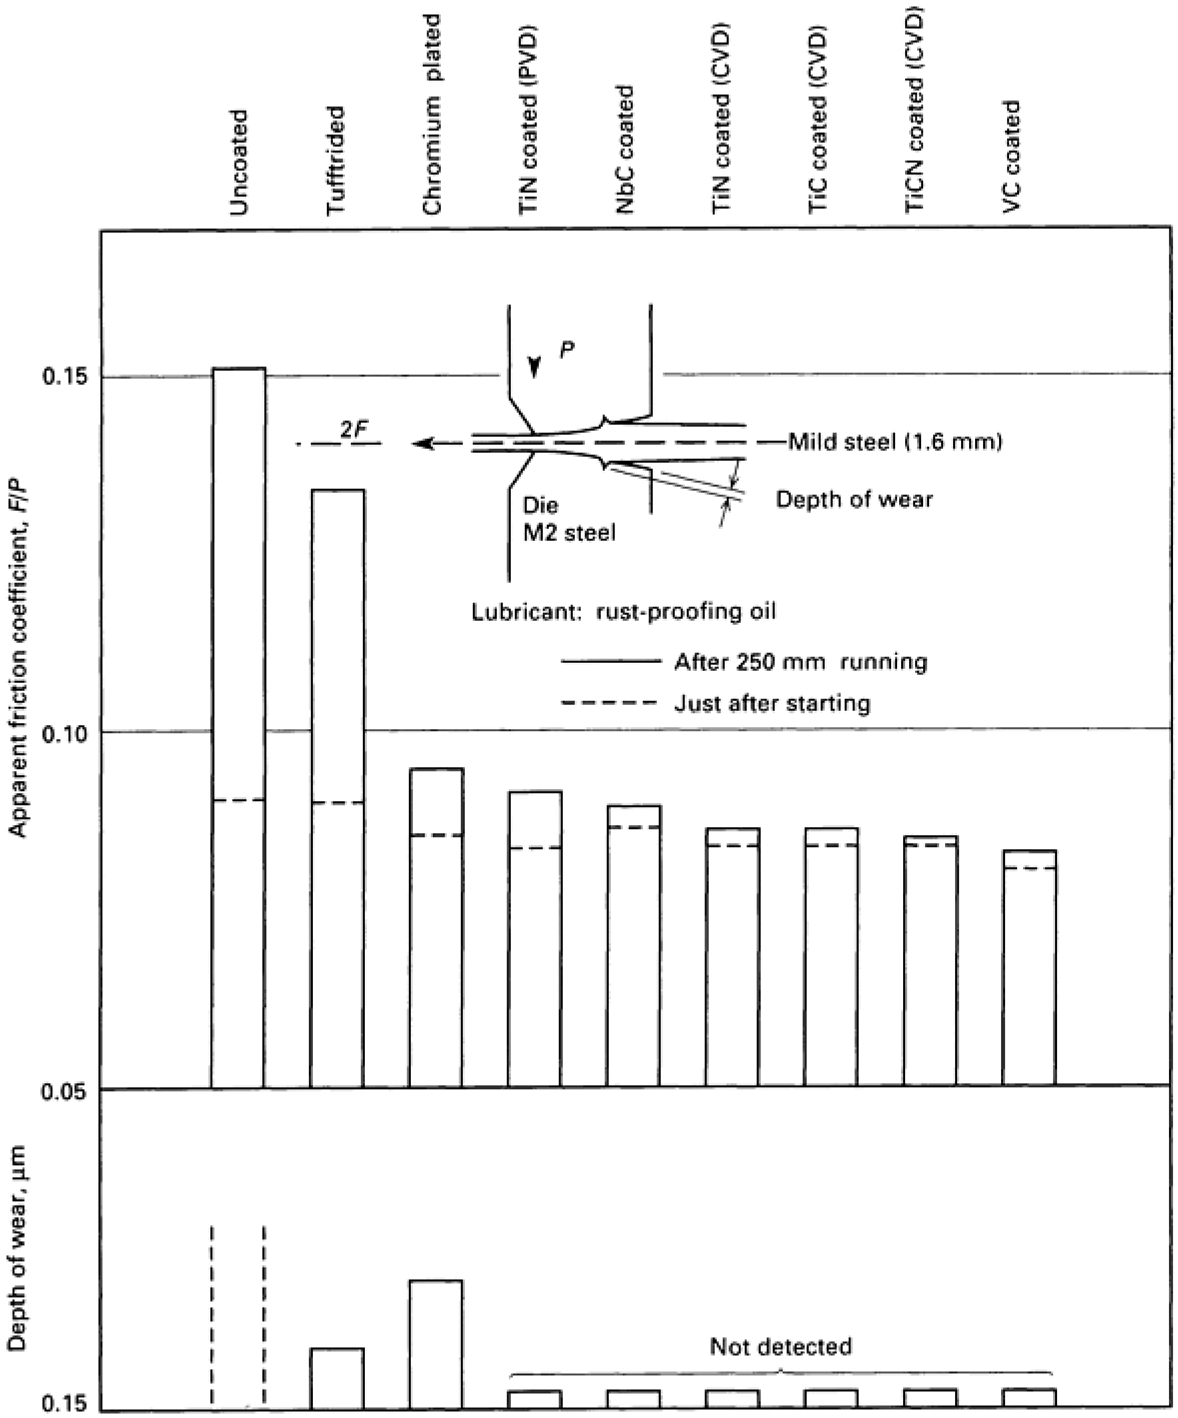

Fig. 8 Comparative friction coefficient and depth of wear on dies in a sheet steel-ironing test

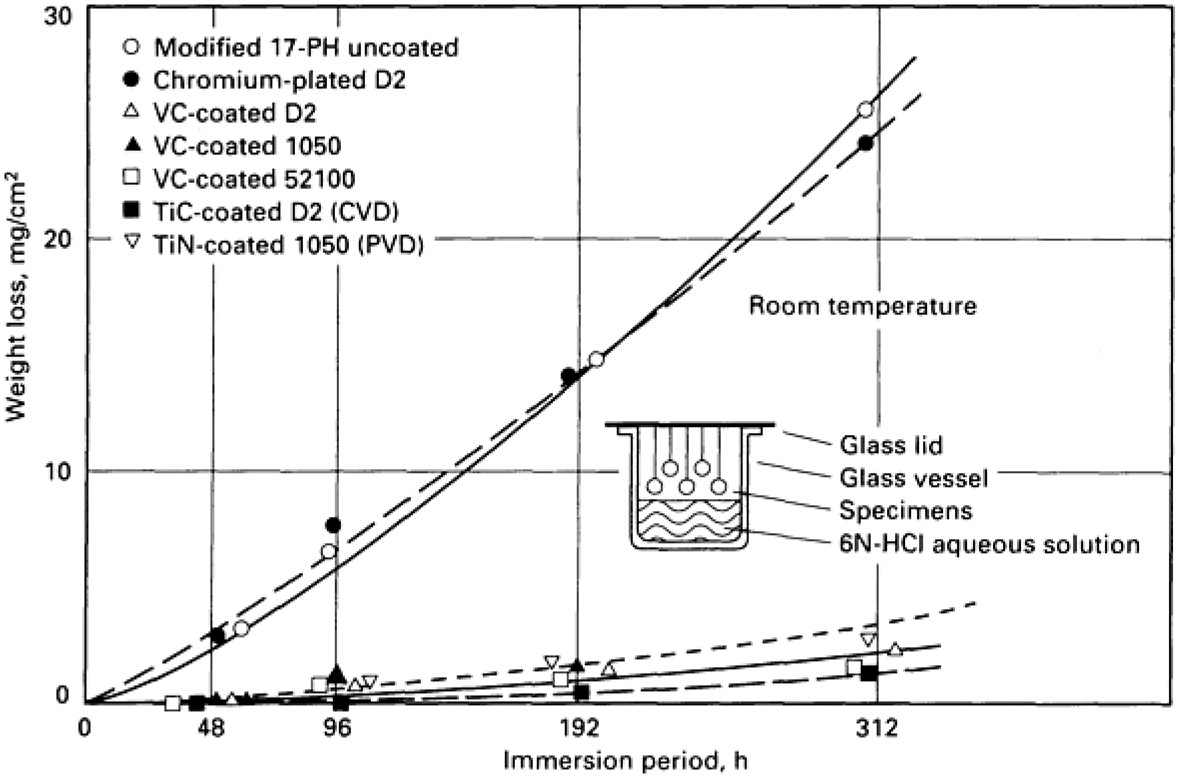

Fig. 9 Comparative weight loss by corrosion in hydrochloric acid vapor

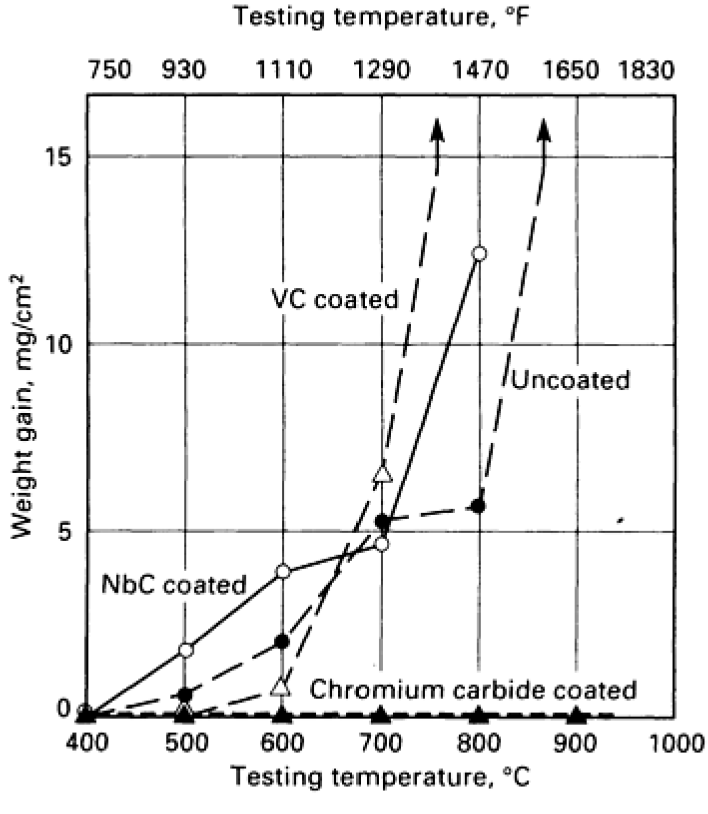

Fig. 10 Comparative weight gain in a high-temperature oxidation test. Substrate, D2; testing period, 40 h

The spalling resistance of the carbide layers is very good. Figure 11 shows the spalling resistance of vanadium carbide in relation to other coating processes. In applications with cyclic stresses, the fatigue resistance of steels is often slightly deteriorated by tensile residual stress induced on the base metal, as shown in Fig. 12. The residual stress initiates cracks in the base metal. The problem can be solved by proper TRD processing and soaking after TRD treatment to decrease the tensile stress, if necessary. The toughness is usually not affected by the process, as shown in Fig. 13.

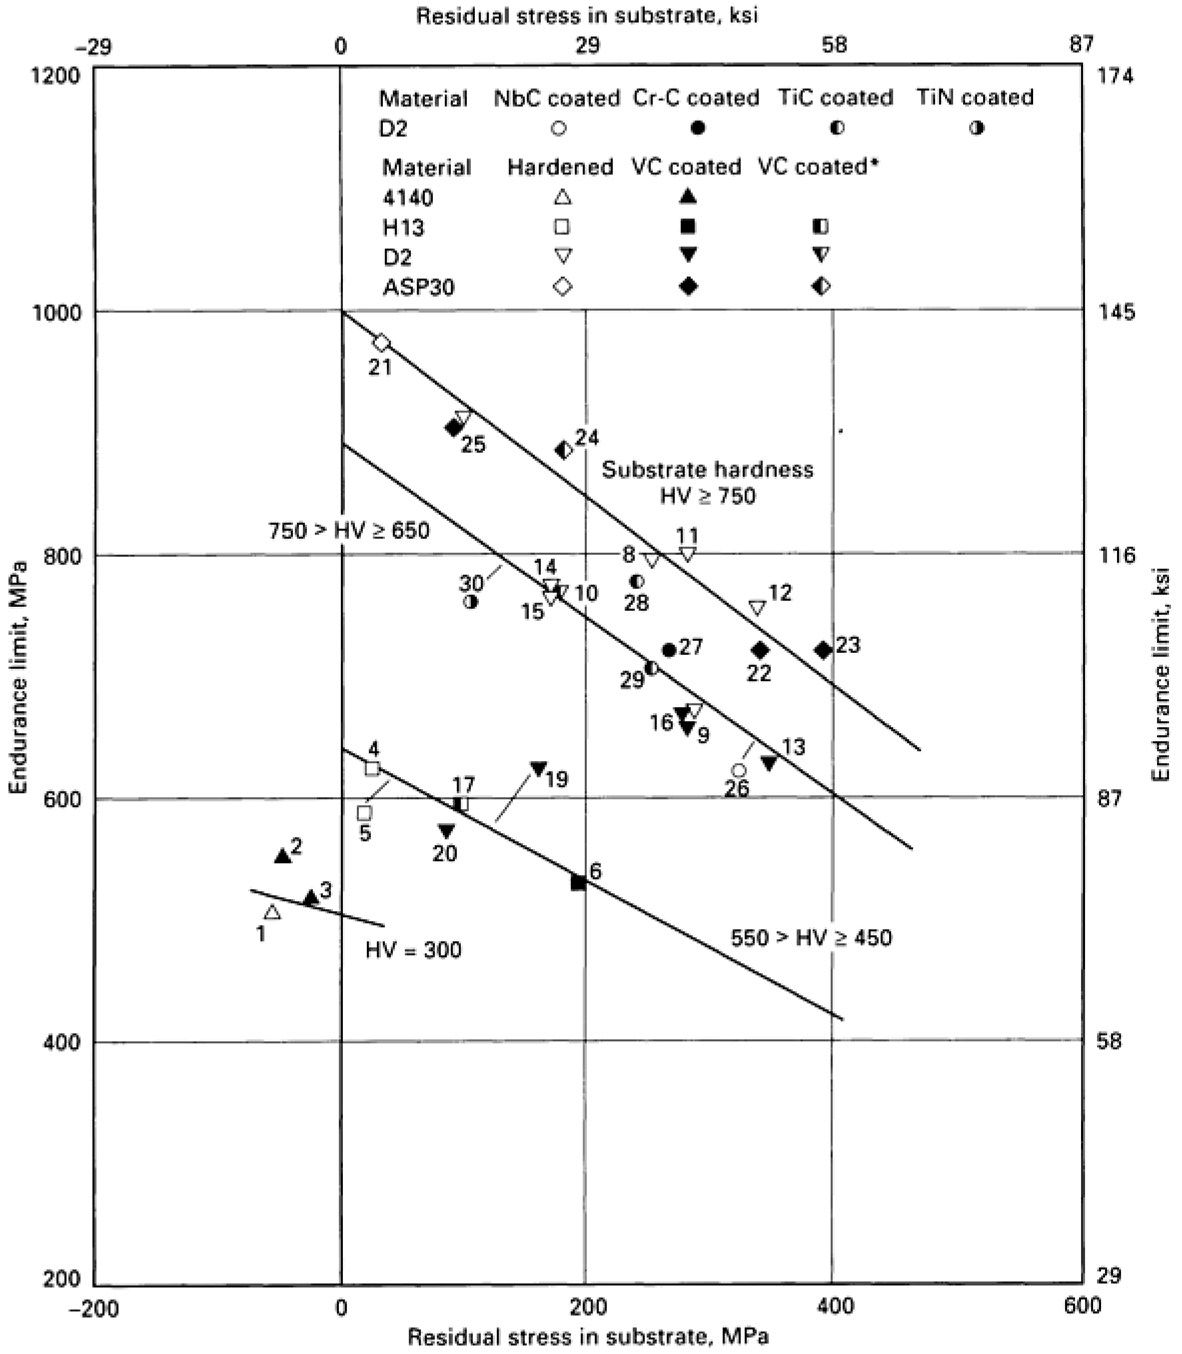

Fig. 12 Relation between endurance limit in fatigue test and residual stress in substrate and substrate hardness (in HV). Sample numbers for data included in figure

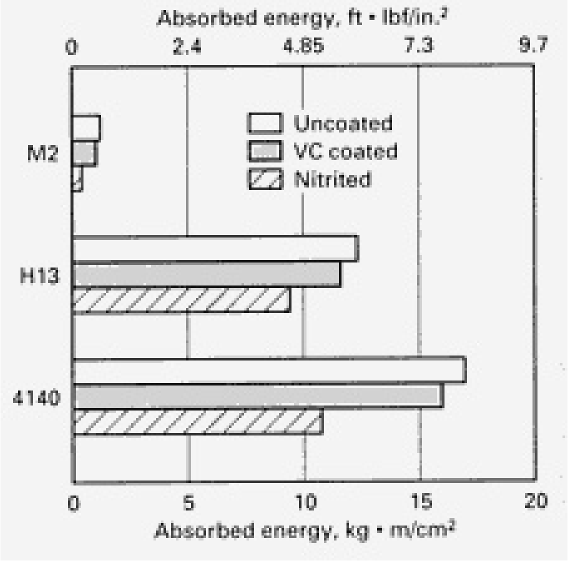

Fig. 13 Comparative absorbed energy in a dynamic bending toughness test

Tooling Applications. Tool steels that contain 0.3% or greater carbon may be TRD processed. This includes most cold- and hot-work steels, high-speed steels, and some martensitic stainless steels. To achieve full substrate hardness in high-speed steel, it must be rehardened after TRD processing. Cemented carbide is frequently used as the substrate for tooling.

The best applications for TRD are tools that have high wear and galling problems. This includes many types of forming and cutting tools, and die components, as shown in Table 1. Mild steel, high-strength steel, plated steel, stainless steel, nonferrous metal, plastics, and rubber are some of the materials that can be worked.

Table 1 Applications of TRD-processed tooling

Application	Tool
Sheet metal working	Draw die, bending die, pierce punch, form roll, embossing punch, coining punch, shave punch, seam roll, shear blade, stripper guide pin and bushing, pilot pin, and so on
Pipe and tube manufacturing	Draw die, squeeze roll, breakdown roll, idler roll, guide roll, and so on
Pipe and tube working	Bending die, pressure die, mandrel, expand punch, swaging die, shear blade, feed guide, and so on
Wire manufacturing	Draw die, straightening roll, descaling roll, feed roll, guide roll, cutting blade
Wire working	Bending die, guide plate, guide roll, feed roll, shear blade
Cold forging and warm forging	Extrusion punch and die, draw die, upsetting punch and die, coining punch and die, rolling die, quill cutter, and so on
Hot forging	Press-forging die, rolling die, upsetting die, rotary swaging die, closed-forging die, and so on
Casting (aluminum, zinc)	Gravity-casting core pin, die-casting core pin, core, sleeve, and so on
Rubber forming	Form die, extrusion die, extrusion screw, torpedo, cylinder sleeve, piston, nozzle, and so on
Plastic forming	Form die, injection screw, sleeve, plunger, cylinder, nozzle, gate, and so on
Glass forming	Form die, plunger, blast nozzle, machine parts, and so on
Powder compacting	Form die, core rod, extrusion die, screw, and so on
Cutting and grinding	Cutting tool, cutting knife, drill, tap, gage pin, tool holder, guide plate, and so on

The substrate hardness may be the same or lower than normal in some applications. In applications where tool chipping or breakage is the problem, a lower substrate hardness with increased toughness can be used. The hard carbide coating provides the surface wear resistance. Underhardened high-speed steel could be used to provide needed substrate toughness.

In applications with high surface pressures, such as extrude dies and cold-forging dies, the carbide layer has to be supported by a hard substrate. High-speed steels should be post-TRD hardened. Some powdered high-speed steels that contain cobalt can be treated at the maximum TRD processing temperature of 1050 °C (1920 °F) to give hardnesses of 60 to 65 HRC. The hardest substrate available is cemented carbide, which can be TRD treated very successfully.

Edge preparation of cutting and piercing tools is important. An edge that is too sharp or that contains burrs will break. The cutting edge should be rounded to a radius of 0.05 to 0.25 mm (0.002 to 0.010 in.) with a stone or emery paper. A worn cutting edge may be resharpened. This is not detrimental because performance is governed by the carbide layer on the side surface of the cutting edge.

The surface finish and polishing direction of a forming die prior to TRD processing is very important. Due to the high-hardness carbide layer, a TRD processed tool that has a rough surface finish will perform worse than a regular uncoated tool. This is shown in Fig. 14. The surface should be finished to a maximum peak-to-valley roughness height (R_{max}) of 3 μm (120 μin.). All large scratches and machining marks should be removed. When plated steel, stainless steel, high-strength steels, and aluminum are the materials being processed, a finish of 0.5 to 1 μm (20 to 40 μin.) for R_{max} is recommended on the tool being used. The polishing lines should be parallel to the metal flow. The characteristic white layer that is produced in electrical discharge machining should be removed before TRD processing.

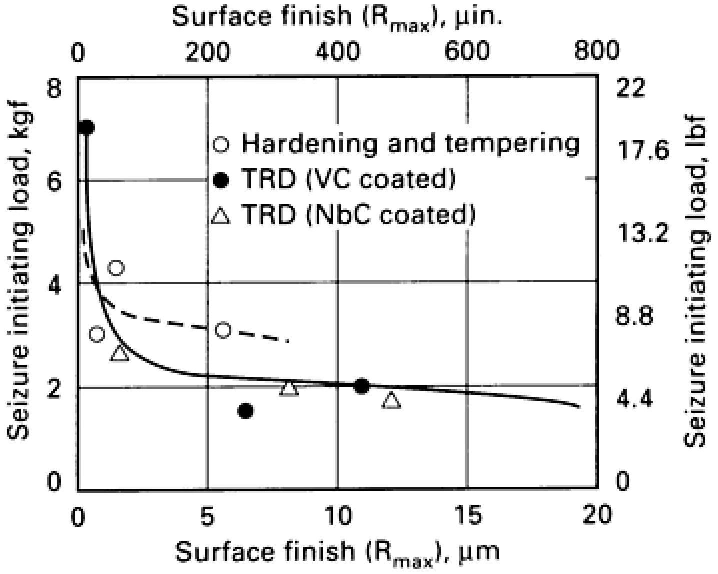

Fig. 14 Influence of tool surface finish on seizure-initiating load for a TRD-coated tool and uncoated tool. Mating material, SUS304; speed, 2.6 m/s (8.5 ft/s); lubricant, none

Tools processed by TRD may be re-treated by TRD. Some tools have been re-treated eight times. After the worn areas are refinished, tools can be re-treated without removing the sound carbide. The difference in layer thicknesses will be insignificant, due to the slower growth rate of the carbide layer on the previously coated areas.

Other TRD Product Applications. The TRD process is very useful for products as well as for tools because the carbide coating formed provides high resistance to abrasive wear, adhesive wear, fretting wear, corrosion, and oxidation, which cannot be provided by other conventional surface treatments. The following are examples of application:

- *Components used in high-performance machines:* roller chain for racing bicycles, motorcycles, and automobiles; traveller rings used under extremely high-velocity spinning; and pump plungers used under extremely high pressure
- *Components used in corrosive or adverse operating conditions:* vanes in vane pumps, spraying nozzles that work with corrosive liquids, and liquids in which abrasive particles exist; link components in glass-molding machines; and automobile components that are susceptible to oxidation and corrosion by exhaust gas

Structural steels such as 10*xx* series carbon steel, and 41*xx* series low-alloyed steel are widely used for these applications. Low-carbon steels are often carburized prior to TRD processing. Substrate hardening is done during cooling in TRD treatment or by reaustenitizing hardening, if it is necessary. Attention should be paid to surface finishing and edge preparation for components used in severe conditions. Barrel finishing is often used for surface finishing of small components in large volume.

Methods of Measuring Case Depth in Steels

Revised by Christopher M. Klaren, John Deere, Waterloo Works; and James Nelson, Buehler Ltd.

Introduction

CASE HARDENING may be defined as a process by which a ferrous material is hardened so that the surface layer, known as the case, becomes substantially harder than the remaining material, known as the core. Case-hardening processes include carburizing, nitriding, carbonitriding, cyaniding, and induction and flame hardening. Each of these methods increases the surface hardness of ferrous materials.

An accurate and repeatable method of measuring case depth is essential for quality control of the case-hardening process and for evaluation of workpieces for conformance with specifications, such as might be done during a failure analysis. This article describes various methods for measuring case depth as outlined in SAE specification J423 (Ref 1). Nondestructive eddy current measurement of case depth is also discussed. Each method has its own area of application established through proven practice, and no single method is recommended for all purposes. The methods employed for measuring case depth are chemical, mechanical, visual with an acid etch, or nondestructive. The mechanical method is the most widely used technique for case depth measurement.

Measurement Specifications

Case depths determined by the different methods can vary extensively, depending on case characteristics, parent-steel composition, and quenching conditions. The various methods also take measurements at different locations in a case, which can result in variations in hardness. For example, typical hardness surveys taken on cross sections at the pitch line, root fillet, and root land of a tooth in a carburized and hardened gear made of 8620H steel are shown in Fig. 1. These data illustrate the importance of well-defined specifications by showing that there are variations in effective case depth even among three areas of the same gear tooth.

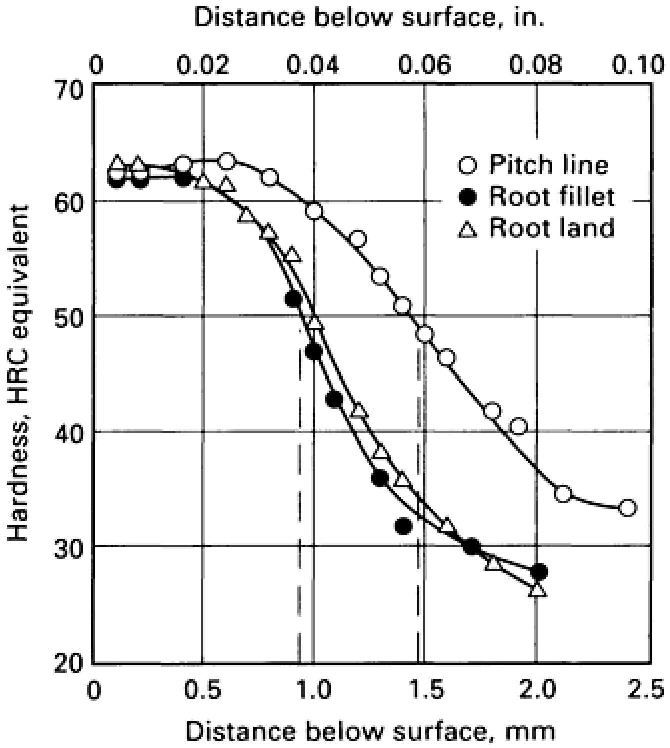

Fig. 1 Variation in hardness with distance below surface for a carburized and hardened 8620H steel gear. Effective case depths to 50 HRC: 0.94 mm (0.037 in.) at root fillet, 1.02 mm (0.040 in.) at root land, 1.45 mm (0.057 in.) at pitch line

It is also important to distinguish between total case depth and effective case depth. Measurements are reported as either effective or total case depth for hardened specimens, and as either total case depth or equivalent effective case depth for unhardened specimens used in the chemical method. Specific descriptions, such as total case depth, effective case depth to 50 HRC, and case depth to 0.40 wt% C will help to avoid misunderstandings.

Effective case depth is the perpendicular distance from the surface of a hardened case to the deepest point at which a specified level of hardness is reached. The hardness criterion, except when otherwise specified, is 50 HRC. The effective case depth is typically about two-thirds to three-fourths the total case depth.

Total case depth may be defined as the perpendicular distance from the surface of a hardened or unhardened case to the point at which differences in chemical or physical properties of the case and core can no longer be distinguished. Total case depth sometimes is considered to be the distance from the surface to the deepest point at which the carbon content is 0.04% higher than the carbon content of the core.

Chemical Method

The chemical method of measuring case depth generally is used only for carburized cases but may be used for cyanided or carbonitrided cases as well. This method consists of determining the carbon content (and, when applicable, the nitrogen content) by chemical analysis at incremental depths below the surface. The chemical method is considered to be the most accurate method of measuring total case depth. Two common methods used for analyzing carbon content are combustion analysis or spectrographic analysis. Combustion carbon analysis is the most widely employed.

Procedure for Carburized Cases. If test specimens are used, they should be of the same grade of steel, but not necessarily the same heat, as that of the parts being carburized. Specimens may be actual parts, rings, or bars, and the carburized surface should be flat or otherwise suitable for accurate machining to obtain chips for subsequent carbon analysis. To ensure maximum uniformity of the carburizing process among various types of furnaces, large heat-treatment facilities often use test specimens. These specimens are often standardized with respect to alloy and configuration to establish carburizing schedules for various case depths and to ensure maximum uniformity among various furnaces. Case depths of actual parts then can be correlated to the standard test specimen.

Test specimens should be carburized with actual parts, but in some cases a simulation procedure is used in a manner representative of the procedure to be used for actual parts. However, simulation is not recommended because the furnace

load containing the test specimens should approximate actual production conditions in terms of load density, configuration, and surface area to be carburized. These three variables affect atmosphere flow, temperature uniformity, and carbon demand. Differences in these conditions between production loads and the load that contains the specimens can lead to errors in the correlation of case depths.

In cooling of test specimens after carburizing, care should be exercised to avoid distortion and decarburization. When parts and test specimens are quenched after being carburized, they should be tempered at approximately 165 to 190 °C (325 to 375 °F). After removal of a sample from the test specimen for case depth determination, the remainder should be tempered at 595 to 650 °C (1100 to 1200 °F). Time at temperature should be minimized to avoid excessive carbon diffusion. The parts and specimens should be straightened to 0.038 mm (0.0015 in.) maximum total indicator reading (TIR) before machining is attempted.

Test specimens must have clean surfaces and should be machined dry, taking the necessary precautions to avoid burning. Predetermined increments of depth from 0.05 to 0.25 mm (0.002 to 0.010 in.) are chosen, depending on desired accuracy and expected case depth. A typical procedure for obtaining specimens for carbon analysis is:

1. Prepare a bar of suitable material in the configuration shown in Fig. 2. Identify the bar in some manner, such as by stamping a number on the end
2. Carburize and then quench or cool the bar as required. If the bar is slowly cooled, steps 3 through 7 can be omitted
3. Wash bar with soap and water. Rinse with methanol, and dry
4. Cut a section from the 25 mm (1 in.) diam end for examination of micro-structure
5. Record the as-quenched surface hardness of the large-diameter end
6. Temper the bar for the time and at the temperature specified for the part with which the test bar was carburized. Record the as-tempered hardness of the large-diameter end
7. Temper for $1\frac{1}{2}$ h at 650 °C (1200 °F)
8. Grit blast lightly, clean centers, and straighten bar to 0.038 mm (0.0015 in.) TIR taken in three places
9. Wash bar with soap and water. Rinse with methanol, and dry
10. For case depths less than 5.10 mm (0.200 in.), machine approximately 3.8 mm (0.15 in.) from the 25 mm (1 in.) diam end to a depth of 5.0 mm (0.20 in.), to ensure that the case on the end does not contaminate the specimens for carbon analysis. An alternative is to just perform a plunge cut in the center section of the turn bar, in order to preclude any machining at the ends of the bar
11. Machine the bar. Before each machining operation, record the diameter of the bar as measured with a micrometer. Maximum allowable taper of machined area is 0.03 mm (0.001 in.) on the radius. Machine a maximum of 0.05 mm (0.002 in.) from the radius to clean the surface. Save the chips for analysis. Next, machine the radius in increments ranging from 0.05 to 0.25 mm (0.002 to 0.010 in.), depending on the desired accuracy and expected case depth. Machine the radius in increments to a depth of 0.25 mm (0.010 in.) below the maximum expected case depth. Take three more increments of 0.25 mm (0.010 in.) from the radius or make three cuts at the expected case-depth break (0.40 wt% C). Save chips from each increment for separate analysis. Take precautions to ensure that chips from each cut are not burned or contaminated by dirt, paper, oil, or chips from preceding cuts
12. Analyze chips or turnings
13. Calculate and plot the carbon-gradient curve. A sample data sheet and a carbon-gradient curve are presented in Table 1 and Fig. 3, respectively

Table 1 Sample data sheet for computing case-depth values for a carbon-gradient plot

Data are for 8620H steel, carburized at 925 °C (1700 °F) in a 19-tray continuous pusher furnace with infrared control of carbon dioxide content in zones 2, 3, and 4. See text for explanation of procedure, and see Fig. 3 for plot of carbon gradient.

(a) D_R, D_L = Diameters of left and right ends of turned bar, respectively. $D_{L, 0}$, $D_{R, 0}$ are diameters before turning; $D_{L, n}$, $D_{R, n}$ are diameters measured after each cut.

(b) A_L, A_R = Material removed from diameter as measured from preceding cut; $A_{L, n} = D_{R, n-1} - D_{L, n}$, $A_{R, n} = D_{R, n-1} - D_{R, n}$, n > 0.

(c) C_L, C_R = Total diametrical depth of material removed, measured from case-hardened bar surface; $C_{L, n} = D_{L, n} - D_{L, 0}$, $C_{R, n} = D_{R, n} - D_{R, 0}$, n > 0.

(d) X = Average total radial depth of material removed from case-hardened bar surface; $X_n = (C_{L, n} + C_{R, n})/4$, n > 0.

(e) M = Average radial midpoint of current depth of cut as measured from preceding depth; $M_n = (X_n - X_{n-1})/2$, n > 0.

(f) P = Plotted depth from surface of bar corresponding to chemical analysis of turnings from this depth; $P_n = X_{n-1} + M_n$, n > 0

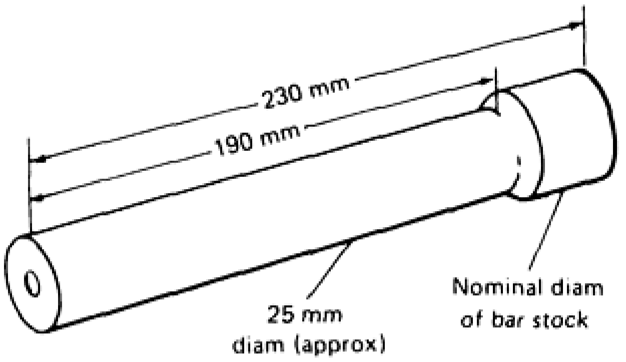

Fig. 2 Nominal configuration of standard test bar used for chemical method of case depth measurement. The 25 mm (1 in.) diam end is finished with 80 grit sandpaper.

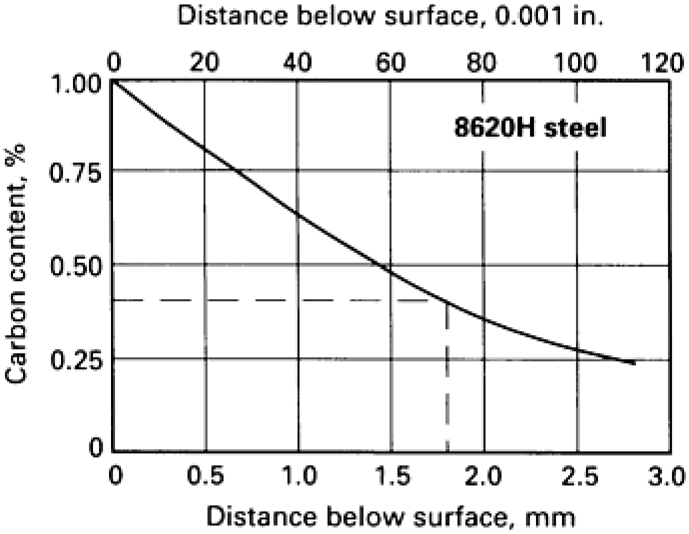

Fig. 3 Carbon gradient for carburized test bar of 8620H steel. A test bar similar to the one shown in Fig. 2 was carburized at 925 °C (1700 °F) in a 19-tray continuous pusher furnace with infrared control of carbon dioxide content in zones 2, 3, and 4. Effective case depth to 0.40% C is 1.82 mm (0.0715 in.) (indicated by broken lines). See text for explanation of procedure for calculating plot points and Table 1 for sample data sheet for this figure.

Spectrographic Analysis. Carbon content may be determined accurately by spectrographic analysis. This method makes use of a vacuum spectrometer, which permits measurement of spectral lines in the ultra-violet region where air would ordinarily absorb much of the emitted radiation.

Many critical items must be assessed for carbon content to ensure uniform properties after heat treatment. The spectrographic carbon method normally uses flat test specimens that can be taper ground, step ground, or reground incrementally after each carbon determination. A very small amount of material is ground from the surface (to remove oxides). Successive cuts are made and analyses are performed after each cut. Each test takes less than 2 min.

Special care must be taken for accurate measurement of the depth corresponding to each carbon determination. Case depth determined on flat or round test specimens will often be different from case depth determined directly on workpieces because of the difference in shape.

Whereas carbon determination by the combustion method provides an average carbon content for the amount of material removed by machining, the spectrograph determines the local carbon content of the specimen to a depth of 0.03 mm (0.001 in.). A comparison of carbon values obtained from five specimens by spectrographic methods is presented in Table 2.

Table 2 Carbon contents of shim stock and of surfaces of workpieces concurrently processed, as determined by spectrographic and combustion analysis

Both shim stock and workpieces were heat treated in a continuous-belt furnace with an endothermic-base atmosphere (class 301; dew point, -9 to -1 °C, or 15 to 30 °F).

Specimen No.	Carbon present, %		
	Shim stock		Workpiece surface (spectrographic analysis)
	Spectrographic analysis	Combustion analysis	
1	0.36	0.36	0.38
2	0.24	0.27	0.25
3	0.22	0.24	0.225
4	0.35	0.35	0.34

Mechanical Method

In the mechanical method of measuring case depth, hardness traverses are taken on the case and core of a specimen that has been prepared by one of three procedures. The mechanical method is the most widely used method and is considered the most accurate method of measuring effective case depth (depth to 50 HRC). This method is also preferred for measuring total depth of thin cases (≤ 0.25 mm, or 0.01 in.).

For measurement of effective case depth, read to the point of specified hardness, which is 50 HRC (or approved equivalent) except for selectively hardened cases, for which the values recommended are:

Carbon content, %	Case hardness, HRC
0.28-0.32	35
0.33-0.42	40
0.43-0.52	45
0.53 and over	50

Microhardness testers that produce small, shallow impressions should be used for all of the following procedures so that the hardness values obtained will be representative of the surface or area being tested. Testers that produce Vickers or Knoop microhardness numbers with loads of 0.2 to 1.0 kg are recommended.

Considerable care should be exercised during the preparation of specimens for case depth determination by the mechanical method to prevent cutting or grinding temper burns. The use of an etchant for burn detection is recommended

as a general precaution because of the serious error that can be introduced by the presence of metal whose metallurgical condition has been altered during specimen preparation by temper burning. However, a heavy application of etchant could affect hardness values and should be avoided.

Cross-Section Procedure. Cut specimens perpendicular to the hardened surface at a near central-length location, being careful to avoid any cutting or grinding practice that would affect the original hardness.

Grind and polish the specimen. The surface of the area to be traversed should be polished finely enough so that hardness impressions are unaffected (the lighter the indenter load, the finer the polish necessary). A 6 μm maximum final polish is recommended.

The procedure illustrated in Fig. 4 is recommended for the measurement of light and medium cases. The alternative procedure shown in Fig. 5 is recommended for the measurement of medium and heavier cases (>0.38 mm, or 0.015 in. case depth).

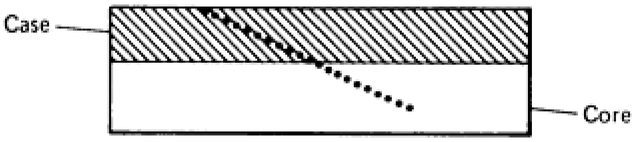

Fig. 4 Cross-sectioned specimen for hardness-traverse method of measuring depth of light and medium cases. Dots show locations of hardness-indenter impressions.

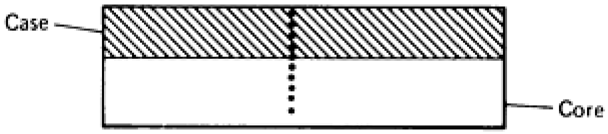

Fig. 5 Cross-sectioned specimen for hardness-traverse method of measuring depth of medium and heavy cases. Dots show locations of hardness-indenter impressions.

The hardness traverse should be started far enough below the surface (0.13 mm, or 0.005 in., with a 500 g load at 58 HRC or greater hardness) to ensure proper support from the metal between the center of the impression and the surface. Subsequent impressions are spaced far enough apart so that the hardness test impressions are not distorted. The distance from the surface to the center of the impression is measured on a calibrated optical instrument, micrometer stage, or other suitable measuring device.

Taper-Grind Procedure. This procedure, illustrated in Fig. 6, sometimes is used for the measurement of light and medium cases. A shallow taper is ground through the case, and hardness measurements are made along the surface thus prepared. The angle is chosen so that equidistant readings will represent the hardnesses at the desired increments below the surface of the case. This procedure is difficult and therefore not recommended.

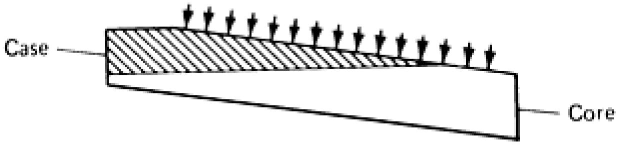

Fig. 6 Taper-ground specimen for hardness-traverse method of measuring depth of light and medium cases. Arrows show locations of hardness-indenter impressions.

Step-Grind Procedure. This procedure, shown in Fig. 7, is recommended for the measurement of medium and heavy cases. It is essentially the same as the taper-grind procedure, with the exception that hardness readings are made on steps that are known distances below the surface. Like the taper-grind procedure, the step-grind procedure is not generally recommended.

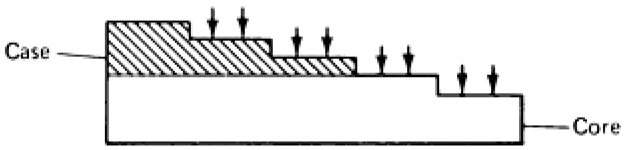

Fig. 7 Step-ground specimen for hardness-traverse method of measuring depth of medium and heavy cases. Arrows show locations of hardness-indenter impressions.

A variation on this procedure is the step-grind method in which two predetermined depths are ground. If the hardness is greater than 50 HRC on the shallow step and less than 50 HRC on the deep step, the effective case depth to 50 HRC lies somewhere between the two steps. This variation frequently is used to ensure that the effective case depth is within specified limits.

Visual Methods

These methods employ any visual procedure, with or without the aid of magnification, for reading the depth of case produced by any of the various processes. Specimens may be prepared by combinations of fracturing, cutting (with water cooling to prevent burning), grinding, and polishing. Etching with a suitable reagent normally is required to produce a contrast between the case and the core. Nital (concentrated nitric acid in alcohol) of various strengths is frequently used as the reagent for producing this contrast.

Visual methods have been classified into two general categories: macroscopic and microscopic. In macroscopic procedures, specimens normally are ground no finer than through No. 000 metallographic emery paper (600 grit silicon carbide paper), and magnifications usually do not exceed 20 diameters. The Brinell microscope, a hand-held optical instrument with retical markings at intervals of 0.1 mm (about 0.004 in.) and 20 diam magnification, is a convenient tool for macroscopic measurement. In microscopic procedures, complete metallographic polishing and etching generally are required, and case depths normally are read at a magnification of 100 diameters.

Macroscopic Visual Procedures

Macroscopic methods for measuring case depth are recommended for routine process control, primarily because of the short time required for determinations and because of the minimum of specialized equipment and trained personnel that are needed. Although these methods normally are applied to hardened specimens, they have the additional advantage of being applicable to the measurement of unhardened cases as well. However, the accuracy of such measurements can be improved by correlation with the results of other methods. A variety of methods may be employed with equal success, but typical and widely used procedures are:

- *Fracture:* Prepare part or specimen by fracturing. Examine at a magnification not exceeding 20 diameters, with no further preparation
- *Fracture and etch:* Water quench part or specimen directly from the carburizing temperature. Fracture, then etch in 20% nitric acid in water for a time established to develop maximum contrast. Rinse in water, and read while wet
- *Fracture or cut, and rough grind:* Prepare specimen by either fracturing or cutting (with water cooling), and then rough grinding. Etch in 10% nital for a time established to provide a sharp line of demarcation between case and core. Examine at a magnification not exceeding 20 diameters (Brinell microscope), and read all of the darkened area for approximate total case depth
- *Fracture or cut, and polish or grind:* Prepare specimen by fracturing or cutting (with water cooling). Polish, or grind through No. 000 or finer metallographic emery paper (600 grit silicon carbide paper), or both. Etch in 5% nital for approximately 1 min. Rinse in two clean alcohol or water rinses. Examine at a magnification not exceeding 20 diameters (Brinell microscope) and read all of the darkened zone. After correlation, effective case depth can be determined by reading from external surface of specimen to a selected line of the darkened zone. An alternative etching procedure is to etch in 25% nital for 30 s, wash in concentrated picral, rinse in alcohol, blow dry, and read as described above
- *M_s method:* This method of case-depth measurement utilizes the fact that the martensite-start temperature (M_s point) varies with carbon content. Quenching and holding the steel for a short time at the M_s point corresponding to a given carbon content tempers the martensite formed at all lower carbon levels. Subsequent water quenching transforms austenite at all higher carbon levels to untempered martensite. Then polishing and etching of the testpiece will reveal a sharp line of demarcation between tempered and untempered martensite; this line is normally read at 20 diam magnification (Brinell microscope) to a precision of ±0.05 mm (±0.002 in.)

The case depth is not sensitive to small temperature changes in the quenching bath. The final selection of quenching temperature is usually done statistically to produce an equal plus-and-minus distribution of error about known carbon curves.

The main factors that affect the accuracy of this method are pearlite formation during quenching to the M_s point and time at M_s temperature. The specimen size should be sufficiently small to ensure that the severity of quench transforms all austenite of lower carbon levels to martensite without any formation of pearlite. (Specimen size may be critical for low-hardenability steels.) The time at M_s temperature should be short enough to preclude the formation of bainite, which interferes with the sharpness of the line of demarcation upon etching and can obliterate it completely. For additional information on the M_s technique, see Ref 2.

Microscopic Visual Procedures

Microscopic methods generally are used for laboratory measurement of case depth and require complete metallographic polishing and etching suitable for the material and the process. Measurements are made using a filar measuring microscope accessory that replaces one of the ocular viewing lenses. The most common magnification used for examination is 100 diameters.

Carburized Cases. Microscopic methods may be used for laboratory determinations of total and effective case depths of material in the hardened condition. When the specimen is annealed properly, the total case depth can be determined quite precisely. For certain applications involving alloy steels of moderate-to-high hardenability that contain 0.4 to 0.8% C, the M_s method of determining case depth to a specific carbon level has been found effective.

Procedure for hardened condition:

1. Fracture or cut specimen (water cool when cutting) at right angles to the surface
2. Prepare specimen for microscopic examination and etch in 2 to 5% nital
3. For approximation of effective case depth, read from surface to metallographic structures that have been shown to be equivalent to 50 HRC. Often, the structure that is nearly equivalent to 50 HRC consists of about 85% tempered martensite and 15% intermediate quench or mixed upper transformation products
4. For approximation of total case depth, read to the line of demarcation between the case and the core. In alloy steels that have been quenched from a high temperature, the line of demarcation is not sharp. Read all of the darkened zone that indicates a difference in carbon content from that of the uniform core structure

See Table 3 and Fig. 8 for Vickers, Brinell, Knoop, and Rockwell hardness conversions.

Table 3 Approximate equivalent hardness numbers for steel

For carbon and alloy steels in the annealed, normalized, and quenched-and-tempered conditions; less accurate for cold-worked condition and for austenitic steels. The values in **boldface type** correspond to the values in the joint SAE-ASM-ASTM hardness conversions as printed in ASTM E140, Table 1. The values in parentheses are beyond normal range and are given for information only.

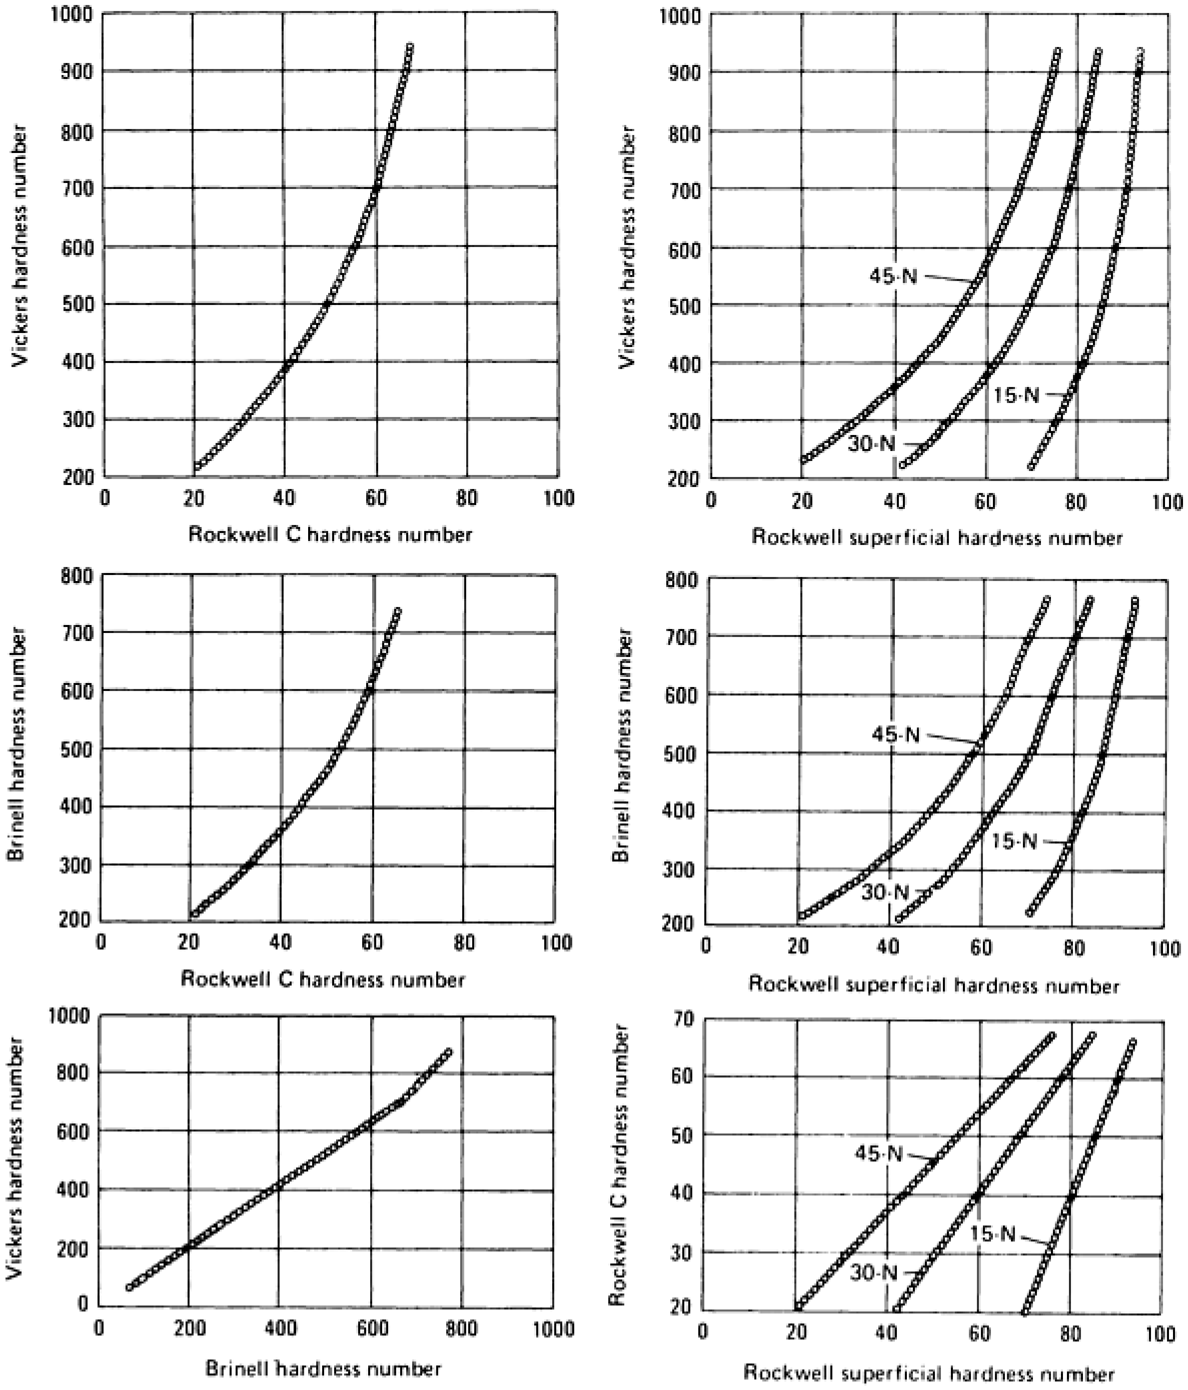

Fig. 8 Approximate equivalent hardness numbers for steel

Procedure for annealed condition (for specimens previously hardened or not cooled under controlled conditions):

1. The specimen to be annealed may be protected by copper plating or by masking with other suitable compounds for preventing carbon loss
2. Anneal specimens in a protective atmosphere (or use the outdated practice of packing specimens in a thin-walled container with a suitable material such as charcoal, spent chips, or pitch coke)
3. Heat specimens to a temperature about 30 to 55 °C (about 50 to 100 °F) above the upper critical temperature (Ac_3) for the core. (Generally, an annealing temperature of 870 to 925 °C, or 1600 to 1700 °F, is

satisfactory.) Hold specimen at temperature only long enough to transform completely to austenite; otherwise, excessive diffusion of carbon may lead to inordinately high estimates of actual total case depth
4. Cool from the annealing temperature at the following rates for carbon and alloy steels: a normally satisfactory cooling rate for most plain carbon steels such as 1010, 1015, and 1018 is 150 °C/h (270 °F/h) from the annealing temperature to 425 °C (800 °F). For high-manganese steels (1500 series), boron steels, and steels with high residual alloy contents, cooling may have to be slower. Cool as desired below 425 °C (800 °F). For most alloy steels, the best results are obtained from isothermal transformation. For some steels, however, a low cooling rate, such as 75 °C/h (135 °F/h) from the annealing temperature to 425 °C (800 °F), is satisfactory. If martensite is retained in the structure, better contrast after etching may be obtained by tempering the specimen at 540 to 595 °C (1000 to 1100 °F). Cool as desired after tempering
5. Section, prepare, and etch specimen as described under "Procedure for hardened condition"
6. For total case depth, read the depth at which no further change in microstructure occurs

Production carburizing schedules often have cooling rates similar to those described above under "Procedure for annealed condition." Specimens treated in this manner may be prepared and examined without being reheated after carburizing, and the results can be accurately correlated to a standard specimen.

Additional information is available in the articles "Gas Carburizing," "Pack Carburizing," "Vacuum Carburizing," "Plasma (Ion) Carburizing," and "Microstructures and Properties of Carburized Steels" in this Volume.

Carbonitrided cases are measured for total case depth in the hardened condition. High quenching temperatures, high alloy content of the steel, and high carbon content of the core decrease the accuracy of readings obtained by this method.

Procedure: Section, prepare, etch, and read as described above for carburized cases, under "Procedure for hardened condition" in this section.

Cyanided cases are thin, and only the microscopic method is recommended for accurate case depth measurement. The usual cyanided case contains a light-etching layer followed by a totally martensitic constituent, which in turn is followed by martensite accompanied by increasingly extensive networks of other constituents, depending on the type of steel. Cyanided cases are read in the hardened condition only, and results are reported as total case depth. Additional information is available in the article "Liquid Carburizing and Cyaniding" in this Volume.

Procedure:

1. Section, prepare, and etch specimen as already described for carburized cases under "Procedure for hardened condition"
2. Read to the line of demarcation between the case and the core. Often, optical case depth greatly exceeds effective case depth. (When a sharp line of demarcation does not exist, a hardness traverse such as that described in the section "Mechanical Method" in this article is recommended)

Nitrided Cases. For measuring the depths of nitrided cases, the microscopic method is used chiefly in those situations in which the available sample cannot readily be prepared for the more desirable hardness-traverse method.

Procedure:

1. Section and prepare specimen as described above for carburized cases under "Procedure for hardened condition"
2. Etch specimen in less than 10% nital
3. Read all of the darkened zone for total case depth

Additional information is available in the articles "Carbonitriding," "Gas Nitriding," "Liquid Nitriding," and "Plasma (Ion) Nitriding" in this Volume.

Selectively Hardened Cases. Because no compositional change occurs in selective hardening (induction hardening, for example), readings must be taken on material in the hardened or the hardened-and-tempered condition only. A procedure for reading effective case depth may be established by correlating microstructures with a hardness-traverse method. A minimum hardness of 50 HRC is commonly used, but some other value may be selected or required, for example, in lower-carbon steels that do not reach 50 HRC when fully hardened (see the in-text table correlating carbon content with effective case depth hardness under the section "Mechanical Method"). The microstructure at the selected location will vary depending on steel composition, prior treatment, and hardness level chosen.

Procedure:

1. Section, prepare, and etch specimen as described above for carburized cases under "Procedure for hardened condition"
2. For total case depth, read the entire zone containing structures hardened by the process
3. For effective case depth, read to selected microstructure correlated with specified hardness

Microhardness Testing. The most precise means of measuring effective case depth is the microhardness test. This consists of making light load indentations at specified linear intervals from a point near the edge of the surface to a point well within the core area, as shown in Fig. 9. For case depth measurements, the selection of a Knoop indenter is recommended so that the highest density of indentations may be obtained.

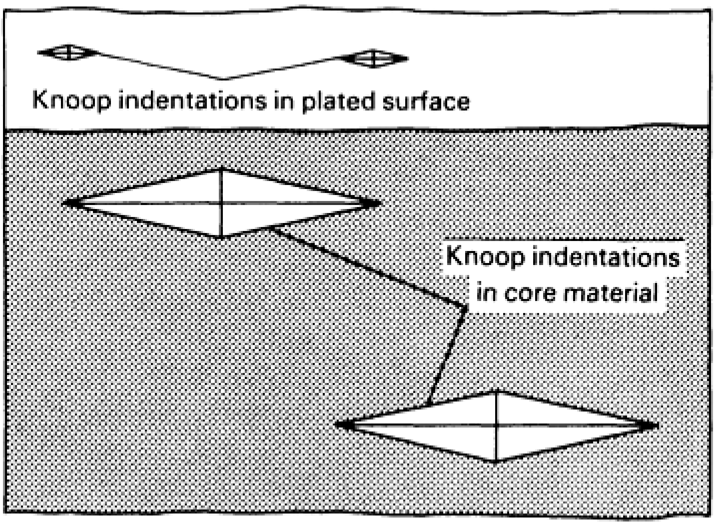

Fig. 9 Comparison of Knoop indentation using the same load in both the hardened case and soft core of a workpiece

The Knoop indenter shown in Fig. 10 uses a spheroconical diamond that produces an elongated indentation. This is especially important when measuring thin cases.

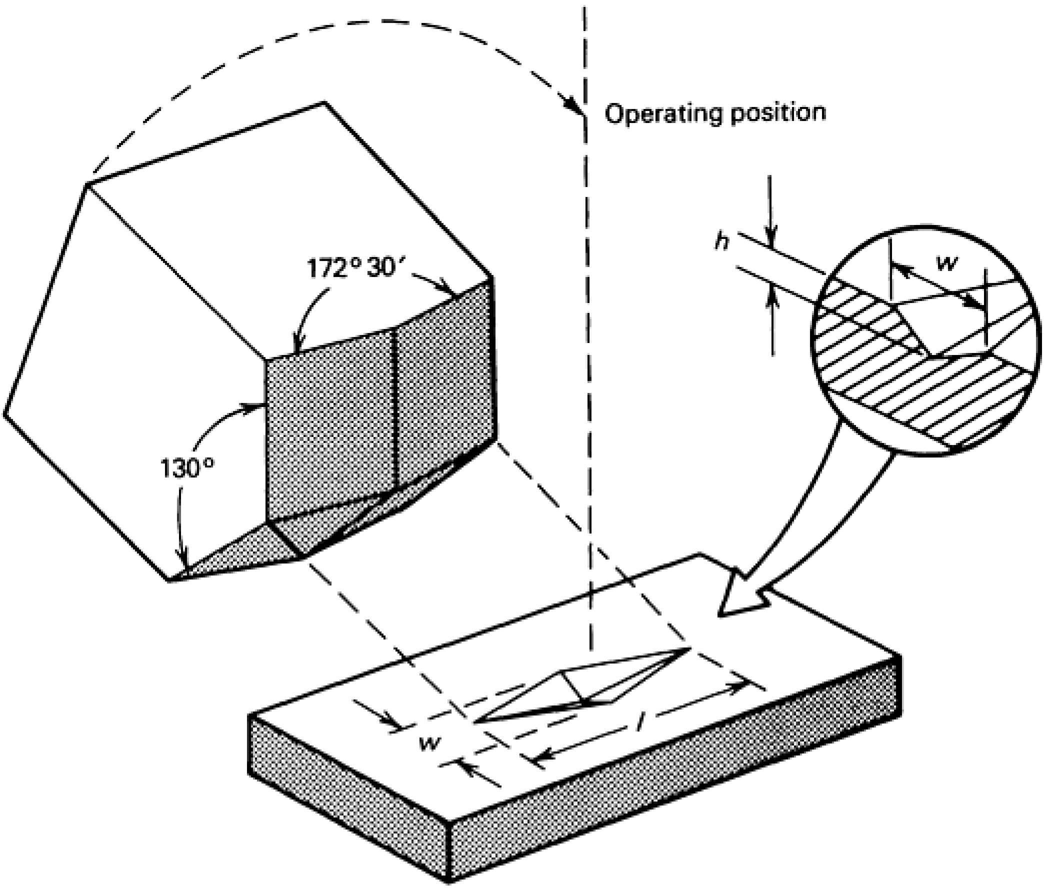

Fig. 10 Pyramidal or spheroconical Knoop indenter and resulting indentation in the workpiece

The use of the square pyramid Vickers indenter shown in Fig. 11 limits the ability to make closely spaced indentations and indentations close to the surface. To avoid error, there should always be a two-indentation-width space from the edge of the case to the first indentation and the same distance between subsequent indentations. The load selection is based on the need to have a sufficient number of indentations to obtain good reliable data and large enough indentations to be read accurately. Microhardness traverses are made using loads ranging from 100 to 1000 g.

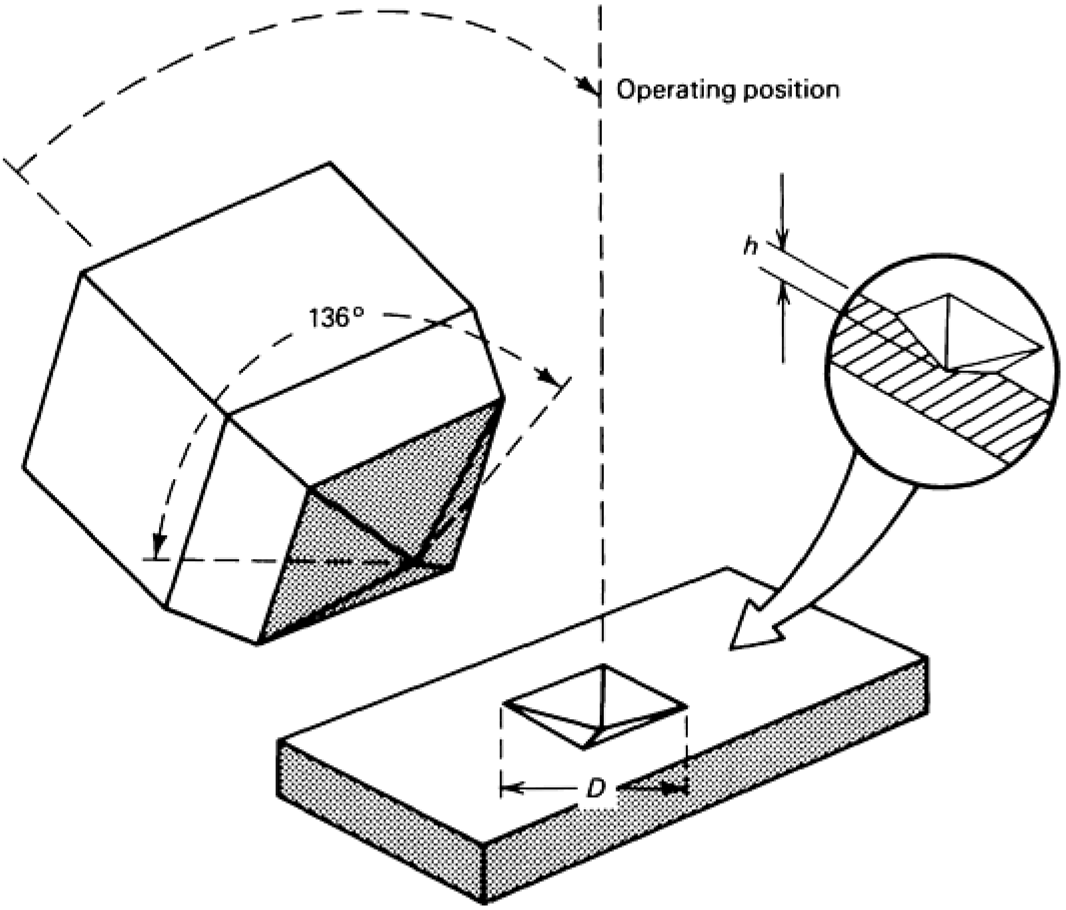

Fig. 11 Diamond pyramid indenter used for the Vickers test and resulting indentation in the workpiece. *D* is the mean diagonal of the indentation in millimeters.

Sample Preparation. The accuracy of a microhardness traverse across the case and core depends on the correct preparation of the sample to be tested. First, a representative cross section of the hardened case and adjacent core (unaffected material) must be cut from the bulk material with care to avoid altering the microstructure. The cut sample is then compression molded in a low-shrinkage thermosetting resin containing a hard filler to retain the edge of the case. The sample is ground and polished, with attention to maintaining flatness across the entire sample. To accomplish this, the same care should be taken as would be taken were the sample to be examined for microstructure. Each step must be performed thoroughly with ample lubrication to prevent microstructural deformation. The intermediate polishing step following the fine grinding sequence should be performed on a napless cloth charged with 6 μm (240 μin.) diamond abrasive compound or suspension with a suitable extender. Final polishing with 0.05 μm (2 μin.) alumina on a napped cloth should be limited to approximately 30-s duration to prevent edge rounding.

Etching. It may be necessary to etch the as-polished sample to determine the demarcation between the case and the core, but this application of the etchant must be light. A heavy etch may affect the hardness readings and also make the visual measurement of the indentations more difficult.

Accuracy. The accuracy of microhardness testers should be checked regularly using the calibration sample provided. Care must also be taken to prevent errors due to the manual conversion of ocular indentation measurements to actual hardness numbers. Some more advanced testers display actual hardness numbers, making it unnecessary to convert ocular readings.

Hardness Scale Conversions. Because the more advanced microhardness testers are equipped to convert Knoop or Vickers measurements directly into Rockwell values, the chance for error is reduced. However, it must be remembered that any conversion of hardness values from one hardness measurement system to another introduces some error.

Nondestructive Methods

Nondestructive methods of measuring case depth make use of the changing electrical and magnetic properties of the material through the depth of a case-hardened workpiece. These property changes result from localized differences of material microstructure, hardness, and/or chemistry within the case. Eddy current tests are the most frequently used nondestructive tests in the automotive industry. Primary among their valuable characteristics is the speed with which tests can be performed; this makes them suitable for the automatic testing of high production quantities. Production nondestructive evaluations of case depths are performed on parts such as piston pins; axle, transmission, and water pump shafts; and differential and transmission gears. Measured case depths range from 0.2 to 9 mm (0.008 to 0.35 in.), with agreement with destructive techniques of 0.2 mm (0.008 in.) or less. This requires equipment specifically designed for the parts being tested.

A typical system for the production precision measurement of case depths generally requires the use of master parts of known case depth to standardize the unit. With a system developed to test cold-extruded axle shafts, measurements are made on a master shaft and stored in computer memory for later comparison with measurements from unknown production parts. Desktop computers are commonly used to control the part scanner and eddy current instrument, acquire and analyze the data, and store the results. A typical test consists of placing the part within the test machine and then sequentially applying frequencies ranging from 5 to 10 kHz to the eddy current coil located at the area of interest. The computer uses the responses at certain frequencies to estimate the case depth. Then, on the basis of the estimate, it selects algorithms to make a final calculation of case depth, based on multiple linear regressions of eddy current responses at several frequencies against case depth. The particular frequencies used depend upon the location on the part. Generally, they consist of a combination of one or more low frequencies (0.1 to 1.0 kHz) with one or more higher frequencies (5 to 10 kHz). The highest frequencies (5 to 10 kHz) are used for surface hardness measurements. Figure 12 illustrates the correlation that can be achieved between destructive and nondestructive case depth measurement methods.

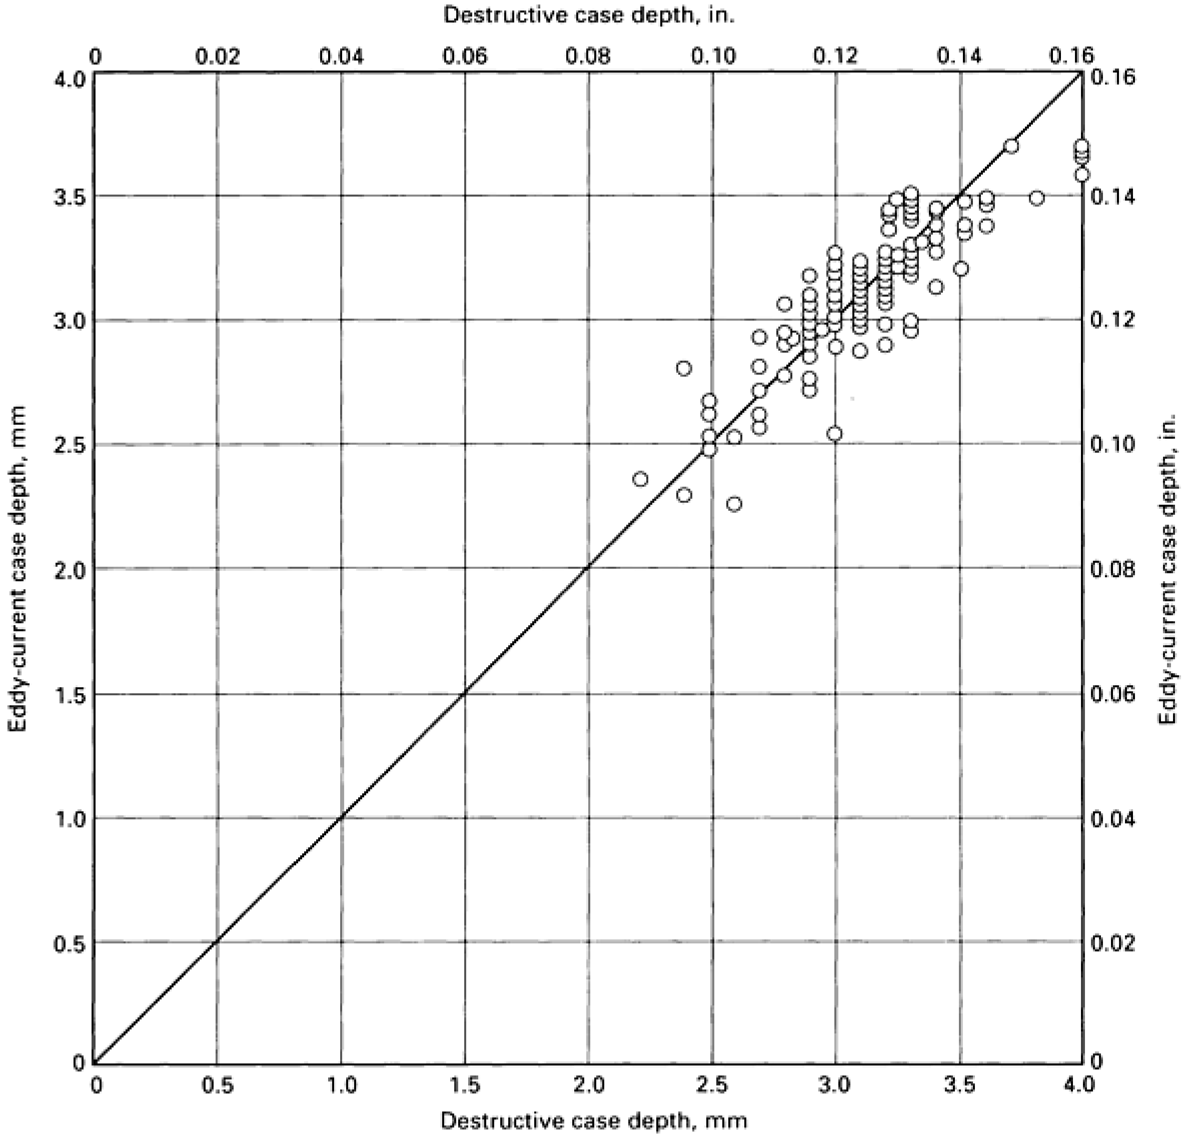

Fig. 12 Plot of axle-shaft correlation data for destructive and nondestructive case depth measurements. Source: Ref 3

The accuracy of eddy current inspection is limited by the testing conditions encountered by the instrument. Variations in workpiece temperature, material chemistry, and core microstructure can affect the impedance of the material and the resultant determination of case depth. When measuring carburized cases, varying surface carbon concentrations may introduce additional uncertainties. It is important to recognize these variables when designing and operating nondestructive measurement systems and selecting appropriate master parts.

Types of Heat-Treating Furnaces

John W. Smith, Holcroft, A Division of Thermo Process Systems Inc.

Introduction

FURNACES commonly used in heat treating are classified in two broad categories, batch furnaces and continuous furnaces. In batch furnaces, workpieces normally are manually loaded and unloaded into and out of the furnace chamber. A continuous furnace has an automatic conveying system that provides a constant work load through the unit.

Batch Furnaces

The basic batch furnace normally consists of an insulated chamber with an external reinforced steel shell, a heating system for the chamber, and one or more access doors to the heated chamber. Standard batch furnaces such as box, bell, elevator, car-bottom, and pit types are most commonly used when a wide variety of heat-hold-cool temperature cycles are required. Other types of batch furnaces, discussed in separate articles of this Volume, are salt bath, vacuum, and fluidized-bed furnaces.

The use of batch equipment for heat treating usually requires considerable labor for loading, handling, and unloading of the work and work trays. High labor costs dictated by the process must always be considered in the selection of batch equipment.

Batch furnaces are normally used to heat treat low volumes of parts (in terms of weight per hour). Batch furnaces are also used to carburize parts that require heavy case depths and long cycle times. For example, integral-quench batch carburizers treat gears or rock bits, while pit-type carburizers process parts such as drill rods or bearing races. However, there is no real advantage in the use of batch methods for deep-case carburizing. Yet, very often batch furnaces are used for deep-case work because the volumes are so low that a pusher-type continuous furnace is not cost effective. Here again, the batch furnace has the advantage in terms of part volume, not case depth. Batch furnaces are also normally used:

- To handle special parts for which it would be difficult to adapt a conveying system for continuous handling (long drill rods processed in a pit furnace, for example)
- To process large parts in small numbers, for example, stress relief or annealing of large weldments or castings in a car-bottom-type furnace
- To process various parts requiring a wide range of heat-treat cycles that can readily be changed, either manually or automatically

Batch processing is especially appropriate when the work must be heated from room temperature to a maximum temperature at controlled rates, held at temperature, and cooled at controlled rates. For example, car-type furnaces are used for critical stress-relief work or carbon baking in saggers.

Box-Type Furnace. With the addition of powered work-handling systems--integral quench tanks, slow-cool chambers, and some automatic controls--the basic box-type batch furnace is upgraded to a semicontinuous batch furnace, which is a commonly used piece of heat-treating equipment. One type of semicontinuous batch furnace is shown in Fig. 1.

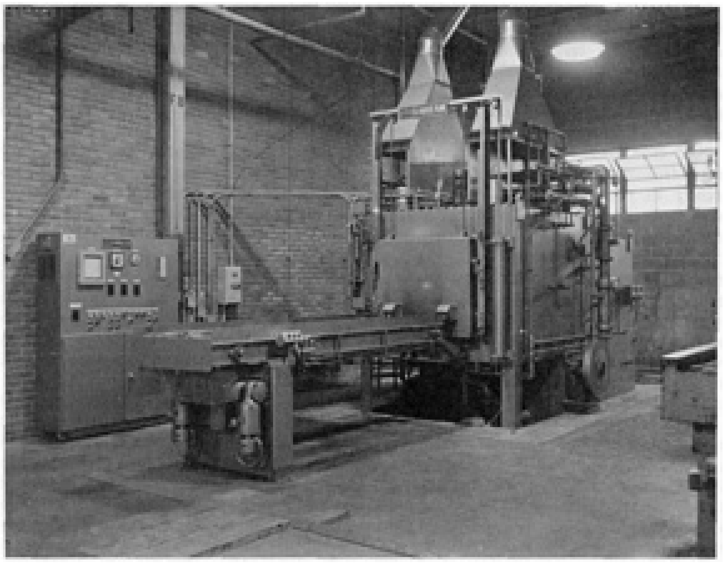

Fig. 1 Semicontinuous batch furnace with a controlled gas-heated box furnace. Courtesy of Seco/Warwick Corporation

The car furnace, also called a "bogie hearth," is normally considered an extremely large batch furnace. The bottom (or floor) of the furnace is constructed as an insulated movable car that is moved out of the furnace for loading and unloading, as shown in Fig. 2. When in position inside the furnace, the car is sealed to the furnace structure with granular-type "sand" sealing troughs or solid seals. Furnace cars can be self-propelled with the motor drive mounted on the car, or they can be moved in and out by a floor-mounted drive with a continuous chain or a rack-and-pinion drive. Most car furnaces are nonatmosphere type due mainly to the difficulty in sealing the car.

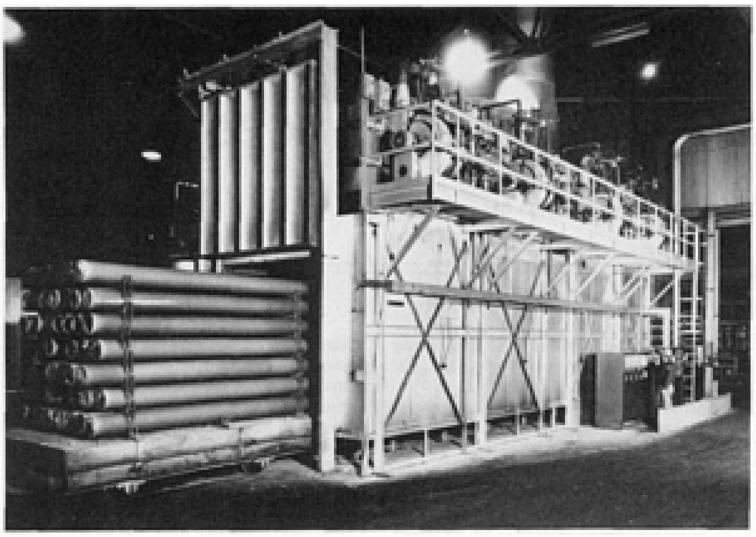

Fig. 2 Car-bottom batch furnace for homogenizing large cylindrical parts. Courtesy of Despatch Industries, Inc.

Heating systems normally are either direct fired or electrically heated with resistance elements. With direct-fired systems, it has proved advantageous to design a pressure-control system to control the flues. With the large difference in fuel burned during the heat-up portion of the cycle as compared to the soak portion of the cycle, it is extremely difficult to maintain a minimum acceptable furnace pressure with a fixed flue area. Most car furnaces are heated from room temperature with the load already in the furnace. A typical cycle would be to heat from room temperature to a control temperature at a specific rate, hold at the control temperature for a specified time, and then slow cool to discharge

temperature at a specified rate. Programmable temperature-control systems with stored menu programs are capable of performing a wide variety of heat-treat cycles, including process monitoring and recording of historical data.

The use of ceramic fiber insulation in a car furnace allows greater control of furnace temperature when following a programmed cycle. Because ceramic fiber has minimal heat storage capacity compared to hard refractories, it will heat and cool at faster rates. Also, less total heat is required to bring the furnace to the desired temperature, although the difference may be minimal because the total heat is governed more by the mass of the load. Further, continuous cyclic heating and cooling has little or minimal effect on ceramic fiber lining. Temperature limits of ceramic fiber blanketing are discussed in the article "Energy-Efficient Furnace Design and Operation" in this Volume.

Car furnaces are used from the lower stress-relieving ranges around 540 °C (1000 °F) to temperatures of over 1095 °C (2000 °F) for certain applications. Because many of the larger car furnaces are installed outdoors, increased allowances should be made for thermal holding losses caused by winds and other changes in ambient conditions.

Elevator-type furnaces are similar to car-bottom furnaces except that the car and hearth are rolled into position underneath the furnace and raised into the furnace by means of a motor-driven mechanism. Such furnaces are built to handle large, heavy loads and can be cooled rapidly by a high-velocity internal or external circulating gas system. For certain plant layouts, this type of furnace eliminates the need for crane facilities, transfer cars, and switching tracks and often saves floor space.

Elevator-type furnaces are suited for heavy work and for the precipitation-hardening nonferrous alloys, which must be quenched rapidly to retain a supersaturated solid solution. Either gas firing or electric heating is commonly used, with oil firing being employed less frequently. The temperature range for these furnaces is generally about 315 to 1200 °C (600 to 2200 °F).

Bell-type furnaces have removable retorts or covers called "bells," which are lowered over the load and hearth by crane. The inner retort is placed over the loaded hearth, sealed at the bottom, and provided with a constant supply of protective atmosphere; then the outer heating shell is lowered dover the assembly.

One bell furnace outer heating shell can take care of several retorts. For dense hearth loadings, a motor-driven fan for circulating the atmosphere inside the retort provides more rapid, uniform heating.

Pit furnaces, sometimes called pot furnaces, consist essentially of two parts: the furnace, which is placed in a pit and extends to floor level or slightly above, and a cover or lid, which extends upward from floor level. Large pit furnaces are generally installed with at least part of their heating chambers below floor level. Smaller furnaces are usually mounted on the floor. Workpieces are suspended from fixtures, held in baskets, or placed on bases in the furnaces. This type of furnace is particularly suitable for heating long parts, such as tubes, shafts, and rods suspended from a top supporting fixture or supported from the lower end and held in a vertical position. Loading in this manner gives minimal warpage.

Pit furnaces are available over a wide range of weight capacities and are well adapted to the use of devices for automatic carbon control. They are particularly suited to the processing of parts that must be cooled in the furnace. However, direct quenching is usually not feasible when large loads and large furnaces are involved.

An additional disadvantage of the pit-type furnace is that, if the work is to be direct quenched, the load must be moved from the atmosphere of the furnace into air before quenching. Although exposure in air is relatively brief, it results in the formation of an adherent black scale on the steel that for many applications must be removed by dilute mineral acids or by grit blasting. Thus, parts that must remain bright and scale free after furnace treatment, such as parts with internal threads, are processed in horizontal batch furnaces and quenched under a cover of protective atmosphere.

Continuous Furnaces

Continuous furnaces consist of the same basic components as batch furnaces: an insulated chamber, heating system, and access doors. In continuous furnaces, however, the furnaces operate in uninterrupted cycles as the workpieces move through them. Consequently, continuous furnaces are readily adaptable to automation and thus are generally (though not always) used for high-volume work. For example, continuous carburizing furnaces are generally preferred for production loads exceeding 180 kg/h (400 lb/h) and requiring the same case depth, or for loads of sufficient size that require 24-h continuous operation. Some types are equipped to provide cooling under a protective atmosphere.

Another advantage of continuous furnaces is the precise repetition of time-temperature cycles, which are a function of the rate of travel through the various furnace zones. In terms of atmosphere control, however, the frequent door openings can upset internal atmospheres during the charge and discharge cycles. Also, it is sometimes difficult to keep the atmospheres segregated by zone in single-chamber continuous furnaces, and often the zone controllers "fight" each other because of the interaction between adjacent zones. Therefore, in some applications (such as carburizing), high accuracy, temperature control, and atmosphere control may be easier to achieve in a multichamber pusher-type system where the heating, carburizing, and diffusion portions of the cycle are separated. A batch furnace could also be used.

In a general sense, continuous-type furnaces can be classified as either rotary-hearth furnaces or straight-chamber furnaces. In a rotary-hearth furnace (Fig. 3), the floor of the heating chamber rotates inside a stationary roof and inner and outer walls, with a sand or liquid seal between the floor and walls. Rotary-hearth furnaces have been in use for many years, mainly as single-chamber units for low-production manual operations with a variable-product mix. Rotary-hearth furnaces are useful in shops or operations where only one operator is employed, because the charging and discharging can be located next to one another. Rotary furnaces are also used in combination with straight-chamber furnaces (see the section "Other Continuous Furnace Systems" in this article).

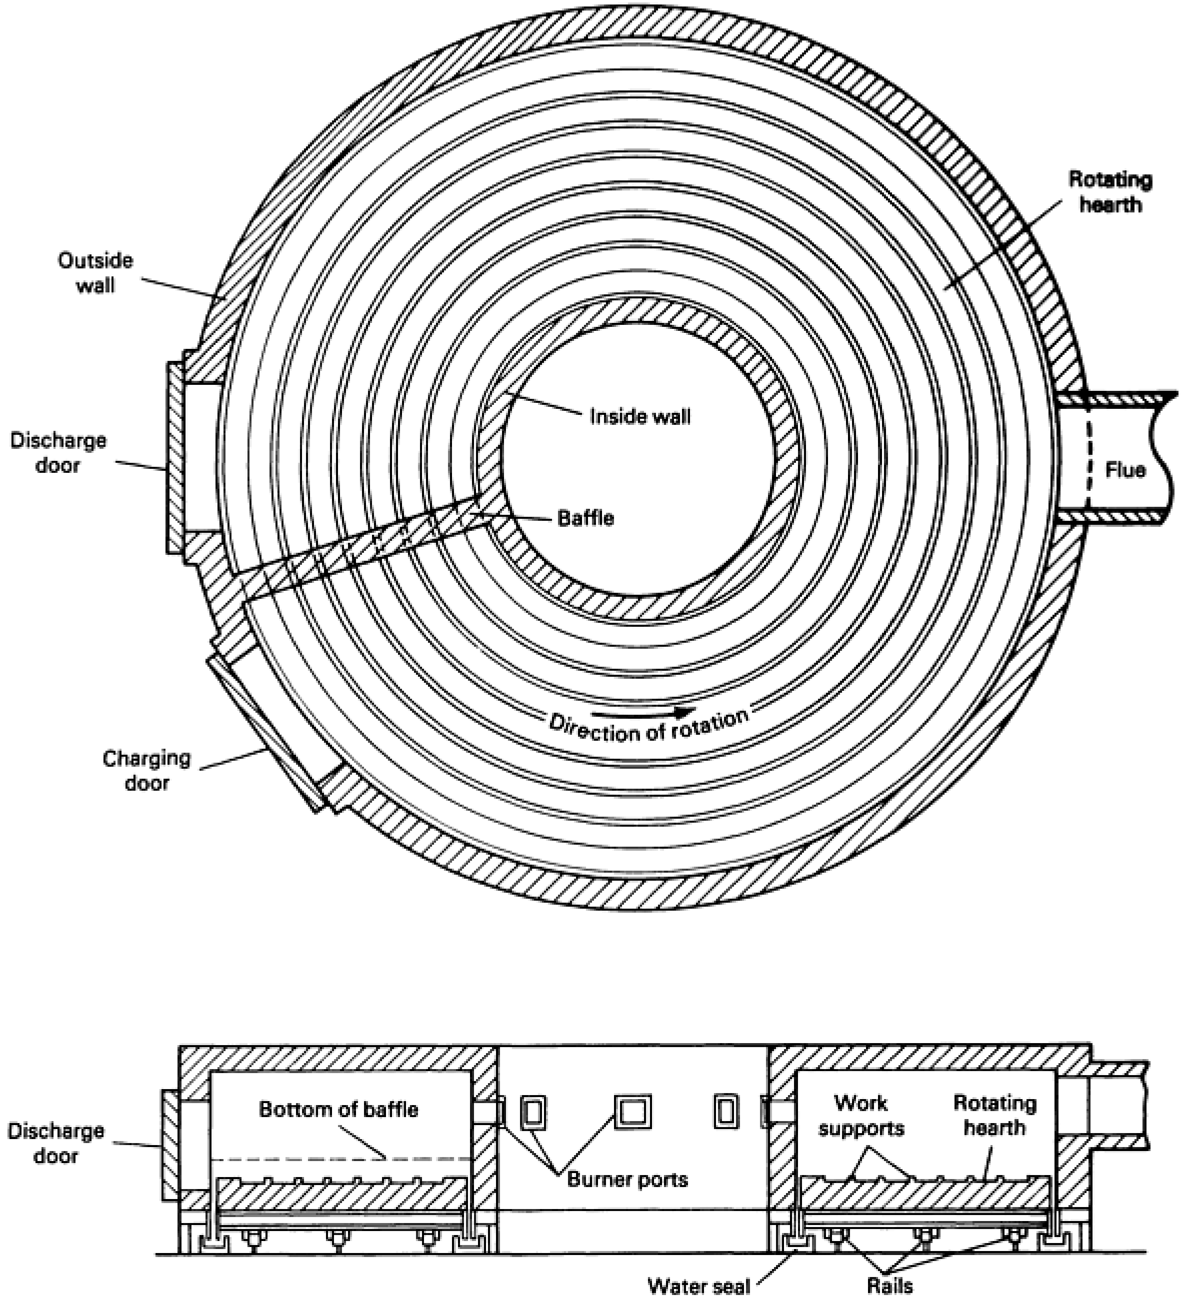

Fig. 3 Schematic arrangement of a relatively small continuous rotary-hearth heating furnace. Larger furnaces

of this type have burners firing through both inside and outside walls above the hearth, while very large furnaces (up to 30 m, or 100 ft, in diameter) use multiple heating zones that can be fired either with roof-type burners or burners located in the vertical portion of saw-tooth roof construction. Source: Ref 1

Straight-chamber continuous furnaces include various types, which can be classified as:

- Pusher-type furnaces
- Walking-beam furnaces
- Conveyor-type furnaces that use rollers or belts
- Continuous furnaces with tumbling or inertia action of the parts for movement

These four types of straight-chamber continuous furnaces are discussed in the following sections. Other types such as overhead monorail systems are also briefly mentioned. The common types of continuous furnaces are the pusher, rotary-hearth, roller-hearth, and continuous-belt furnaces. Walking-beam furnaces and the furnaces that impart tumbling or inertia of the parts (that is, the shaker-hearth and rotary-retort furnaces) are less common.

Pusher Furnaces

A pusher furnace uses the "tray-on-tray" concept to move work through the furnace, as shown schematically in Fig. 4. A pusher mechanism pushes a solid row of trays from the charge end until a tray is properly located and proven in position at the discharge end for removal. On a timed basis, the trays are successively moved through the furnace. Cycle time through the furnace is varied only by changing the push intervals.

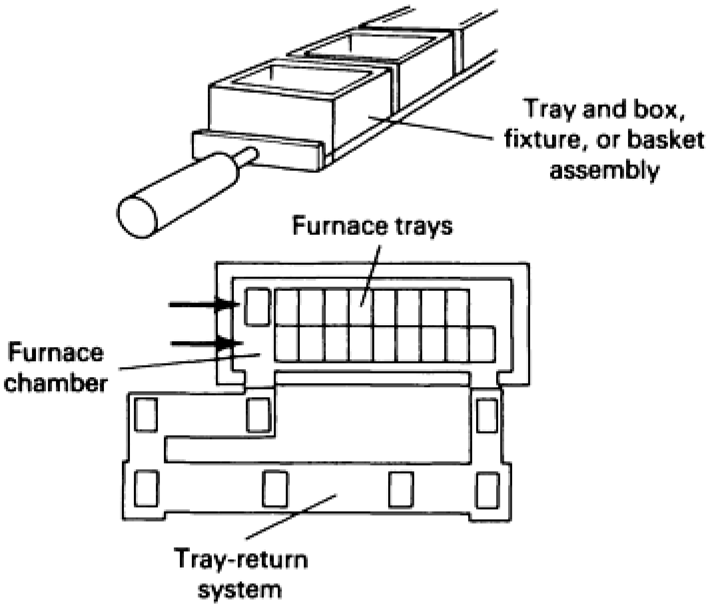

Fig. 4 Schematic of tray movement in a pusher furnace

Pusher-type furnaces are quite versatile and, depending on the size and shape of parts and on permissible distortion, parts may be loaded randomly and free quenched in an elevator-type quench tank. Alternatively, parts may be removed individually from the furnace trays for plug or press quenching. Furnaces can be designed to provide a variety of special equipment and process requirements, such as number of trays, tray size, atmosphere control, atmosphere recirculation, temperature-control zones, and quenching facilities. They may also have more than one row of work in process at the same time.

Pusher-type furnaces are by far the most widely used continuous furnace for gaseous carburization. Construction usually consists of a gastight welded shell with radiant tubes for heating. The work is pushed through on trays with or without fixtures and after completion of the carburizing cycle may be quenched or cooled slowly. Circulating fans are almost always used for more uniform temperature and carburization. Most pusher-type furnaces are built with purging vestibules at the charge and discharge ends to reduce contamination of the atmosphere by air. In many instances, washing and tempering equipment is incorporated to provide a fully automated heat-treating line.

Skid-Rail Furnaces. In a skid-rail pusher furnace, the work is placed on flat, normally reversible cast-alloy grid trays. The trays, in turn, are supported through the furnace on skid rails. The total gross load on the tray determines the number of rails necessary to minimize wear by maintaining the bearing pressure between the tray and the rail within acceptable limits. In certain applications, particularly when an endothermic or an enriched endothermic atmosphere is used, the skid rails are lubricated by the atmosphere and the coefficient of friction is reduced, decreasing wear and increasing tray and skid-rail life. Skid rails are used normally for light-to-moderate tray loadings.

Skid rails that are cast or fabricated from nickel-chrome heat-resisting alloy have been commonly used in pusher furnaces. These alloy skid rails normally are supported by and anchored to a series of cast or fabricated alloy pier caps and supporting pedestals.

Because of the ever-increasing cost of nickel-chrome alloys, alloy skid rails are being replaced where possible by less expensive silicon carbide refractory rails. Silicon carbide skid rails are molded and prefired into various rectangular shapes and are then bricked in and supported on the lower piers or are supported directly on the furnace floor. With the rails resting on edge, the alloy grid tray is thus supported on two or more rail faces, each normally 64 mm ($2\frac{1}{2}$ in.) wide. Because silicon carbide in contact with an alloy has a lower coefficient of friction than alloy on alloy, it makes excellent skid rails. However, in designing silicon carbide rails, precautions should be taken to eliminate severe temperature gradients or thermal shock in the rails, both of which could cause the rails to fracture.

Roller rails are used to both support and guide the trays as they are moved through the furnace. The rails are supported and anchored in a manner similar to that of alloy skid rails, but the mechanical advantage of the wheel and axle reduces the pushing force required to move the load when compared to skid-type support rails.

In certain instances, rails, wheels, and axles are all made of an alloy material. The use of a dissimilar material for the axle, however, can reduce the coefficient of friction between the wheel and axle, and the axle to rail, which can eliminate the natural "galling" effect of alloy on alloy.

The alloy roller rail tray usually has one or more runners and guides on its underside to keep the tray centered on the roller rails. Because the tray underside is normally not flat, it cannot be moved readily (skidded) at 90° to its normal travel, and a transfer carriage would be used. Also, the tray normally is not reversible. There are, however, designs of alloy trays employing recessed runner tracks, so that the tray will sit flat on a surface and is capable of being moved at 90° to its normal travel.

Because required pushing force is reduced, roller rails are used mostly for heavy tray loads and lengthy pushes. To keep wear in the wheel or axle to an acceptable minimum, the total load per wheel (line pressure), in pounds per inch (or kilograms per centimeter) must be kept within acceptable limits.

Buggy trays make use of the mechanical advantage of the wheel and axle in a manner similar to that of the roller rail. Wheels and axles attached to the underside of the tray are guided through the furnace in refractory or alloy troughs, supported on furnace piers or directly on the furnace floor.

This tray cannot be skidded at 90° to its normal travel, and a carriage would be required for such movement. Although buggy trays can be used for extremely heavy loads, the maximum recommended load per wheel should not be exceeded, to keep wear within acceptable limits.

A buggy tray with the wheels and axles attached normally results in a heavier tray weight per square foot. This could have an adverse effect in fuel economy as the weight of the tray to be heated and cooled is increased over other types of trays.

Walking-Beam Furnaces

A walking-beam furnace has movable rails that lift and advance parts along stationary rails inside the hearth. With this system, the moving rails lift the work from the stationary rails, move it forward, and then lower it back onto the stationary rails. The moving rails then return to the starting position and repeat the process to advance the parts again. Figure 5 shows a typical walking-beam furnace of this design used for moving steel slabs. In this type of system, the moving rail can be designed to move in an elliptical path or rectangular pattern. The frequency of lift and length of stroke determine the total processing time.

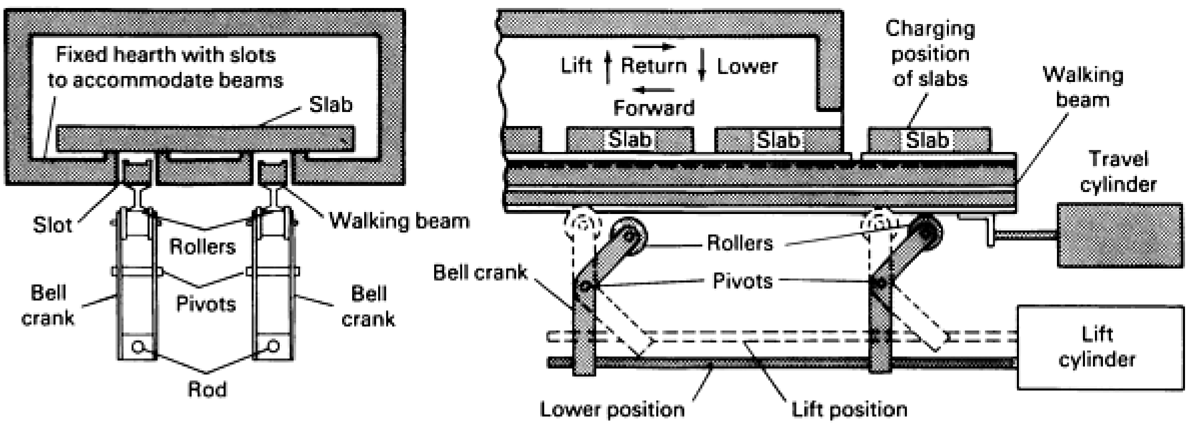

Fig. 5 Schematic of a walking-beam mechanism for advancing slabs through a furnace. In actual furnaces, water seals beneath the hearth prevent escape of furnace gases or air infiltration. Source: Ref 1

In another type of walking-beam furnace, both sets of rails move. One set of rails moves up and down, and the second set moves forward and backward. This system is known as a true rectilinear motion walking beam. The sequence normally is as follows: The lifting beam moves up and the traveling beam moves in reverse, then the lifting beam moves down and the traveling beam moves forward. The work is thus sequenced through the furnace.

Uses of Walking-Beam Furnace. Walking beams traditionally have been used in steel mills in reheat furnace hearth systems for slabs and billets. Walking-beam systems can be built ruggedly to move extremely heavy loads. In heat-treating operations, walking beams have been used successfully with flat-top beams to carry such work as flat plates or trays, or with pocketed-top beams to carry unstable parts such as rollers or shafts.

Advantages of Walking-Beam Furnaces. The typical advantages of walking-beam furnaces are:

- Only the work being processed has to be heated because normally trays or fixtures are not needed
- Friction is reduced for heavy loads because the work is never skidded
- The system can be loaded or unloaded automatically
- A part can be picked from a specific spot and placed in a specific spot by using the walking-beam mechanism
- Equipment is self-emptying on shutdown

Disadvantages of Walking-Beam Furnaces. The typical disadvantages of walking-beam furnaces are:

- Mechanisms are usually more expensive than for pusher-type systems
- On large high-temperature slab or billet reheat furnaces, there is a dramatic increase in thermal holding losses and related fuel consumption due to the water-cooled insulated walking-beam rail system
- Walking-beam mechanisms are not commonly used where protective atmospheres are required in the furnace chamber due to the inherent problems in adequately "sealing" the moving walking beams and mechanisms

Conveyor-Type Furnaces

Roller-hearth furnaces move the work-piece through a heating zone with powered, shaft-mounted rollers that contact the work-pieces or trays. This type of furnace might be used to advantage in heating much longer slabs than would be practical in a pusher-type or walking-beam furnace. These furnaces are available as single units (Fig. 6) for zone heating or cooling in a line of furnaces.

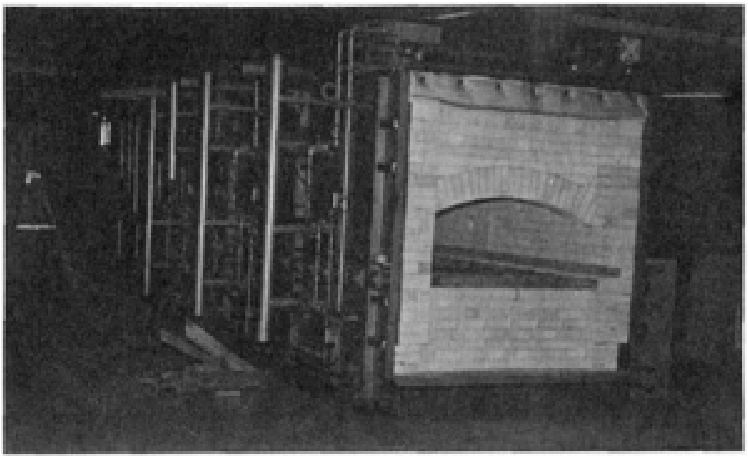

Fig. 6 Section of a roller-hearth furnace. Courtesy of Seco/Warwick Corporation

Continuous-belt furnaces are similar to roller-hearth furnaces except that mesh or cast-link belts are used to move the parts. Such furnaces are preferred for small parts that cannot be moved satisfactorily directly on rollers. Conveyors used include woven belts of suitable material, and chains with projecting lugs, pans or trays connected to roller chains.

The parts are fed automatically onto a mesh belt at the front of the furnace, which can have a liquid or gas atmosphere seal to maintain atmosphere integrity in the furnace chamber. Cast belts return inside the furnace. Belt-type furnaces generally are furnished with fans for recirculating the atmosphere.

Reciprocating and Rotary Agitation Furnaces

Shaker-hearth furnaces (Fig. 7(a) and 7(b)) use a reciprocating shaker motion to impart inertia to the work; this motion may be regulated to control the time cycle. Heating is efficient and confined mainly to the work load. Parts may be fed into the furnace by hand or by means of automatic metering and are typically drop quenched individually. Use of this type of furnace is generally limited to lightweight parts that are to be carburized to case depths of 0.3 mm (0.012 in.) or less. The furnace hearth must be kept smooth, clean, and at the proper level. Either the time cycle of work going through the furnace or uniformity of case depth should be checked at frequent intervals to detect any unwanted change in the forward force exerted by the shaker mechanism. When these precautions are adequately observed and the necessary atmosphere and temperature controls are provided, the shaker-hearth furnace can produce satisfactorily uniform case depth.

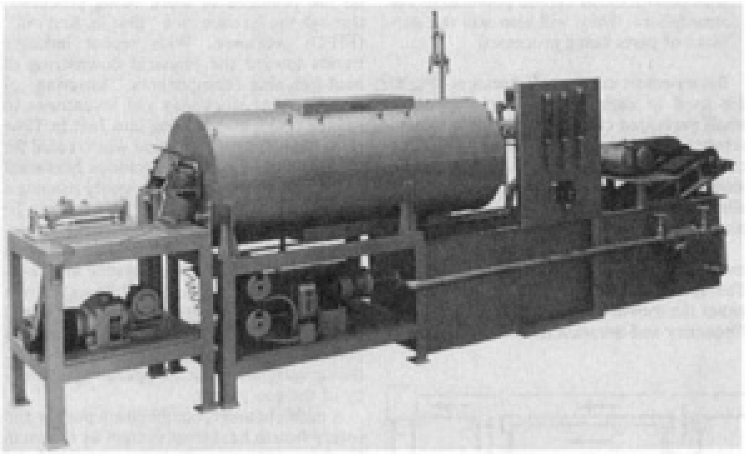

Fig. 7(a) Shaker-hearth furnace with conveyor removal of quenched parts. Courtesy of Lindberg Heat Treating Company

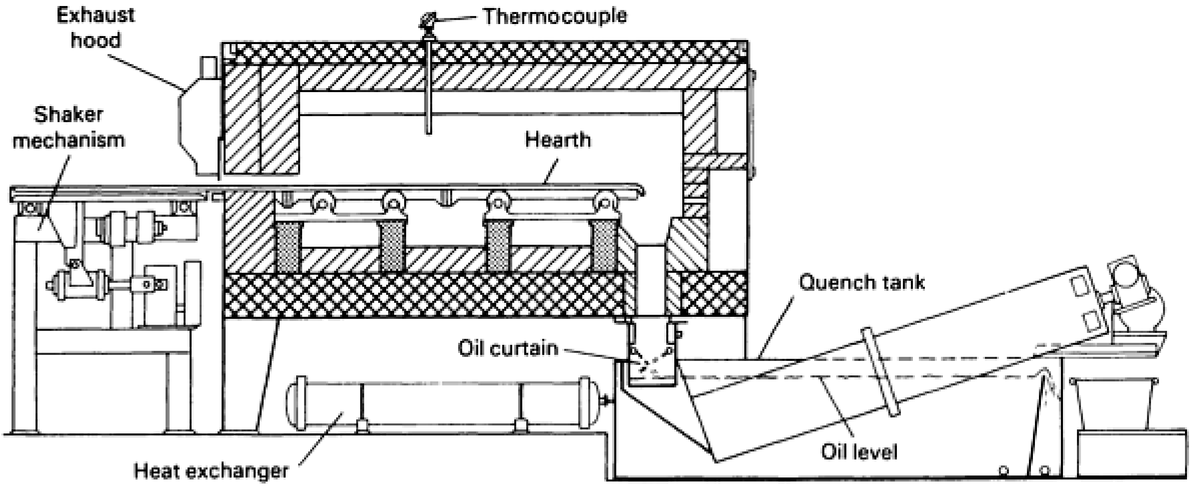

Fig. 7(b) Schematic of shaker-hearth furnace for continuous carburizing

Unless a specially designed hearth, such as a corrugated hearth, is provided, heavy, flat parts are not suited to processing in shaker-hearth furnaces, because of the difficulty of obtaining adequate and uniform case on the part surface making contact with the hearth. Delicate parts and parts with fine threads may be mutilated by the action of the conventional shaker hearth. Without a special hearth, balls and cylinders will not move and progress uniformly in this type of furnace.

Two aspects of the design of shaker-hearth furnaces require special attention:

- Hearth plates should be of suitable weight to respond to the reciprocating motion of the shaker mechanism. This action slides the parts forward randomly and ensures exposure and equal treatment to that portion of the part that rests on the hearth
- Adequate exhaust facilities should be provided to handle quenching-oil fumes. These fumes are highly carburizing and, unless properly disposed of, will interfere with control of the carbon potential of the atmosphere. They will also soil the surfaces of parts being processed

Rotary-retort continuous furnaces (Fig. 8) are used to carburize the same types of small parts that can be handled in a rotary-retort batch furnace. The advantage of the continuous rotary furnace is that it can be loaded and unloaded automatically, thus eliminating the need for removing and replacing the head.

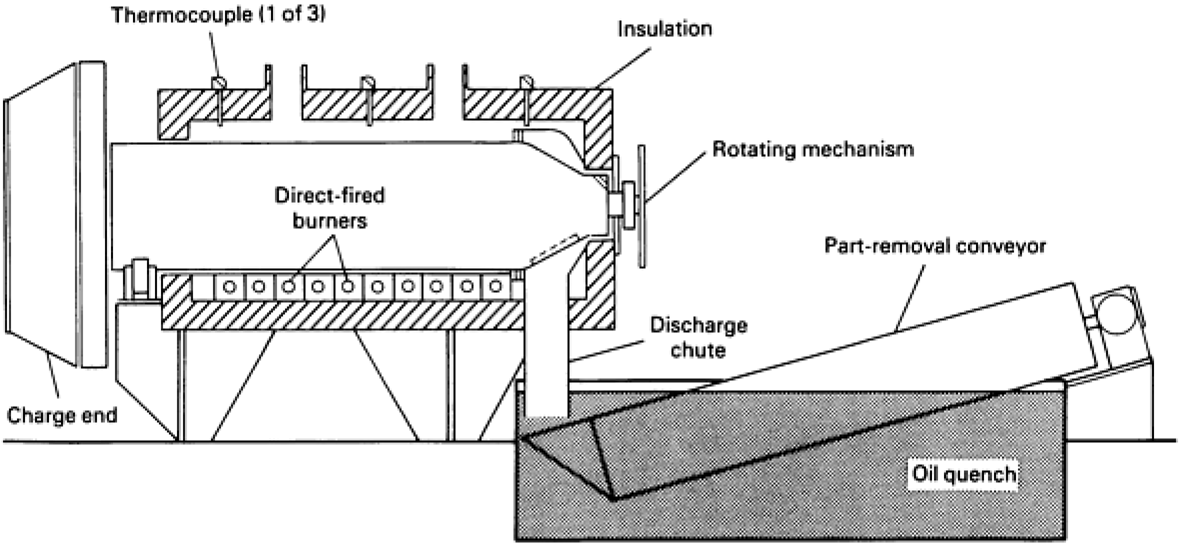

Fig. 8 Rotary-retort furnace for continuous carburizing

The inside of the retort is provided with a mechanized spiral rib throughout its length. The spiral rib can move the work load in either the forward or reverse direction. The frequency and duration of cycles of forward and reverse motion can be varied over any desired range. By this means, furnace length can be minimized, and a reasonable agitation or tumbling action of the parts is obtained. The tumbling action provides for a better uniformity of case depth. However, it can also serve to damage certain parts by nicking.

Continuous retorts cannot be tilted at will. Parts are fed at the front end and automatically issue from slots in the rear of the retort directly into the quenching medium. Because the front end of the furnace must be open to allow continuous charging, sufficient carburizing gas must be fed into the furnace to prevent the admission of outside air. These furnaces are suitable for carburizing to case depths of 0.4 to 2.5 mm (0.015 to 0.100 in.).

Other Continuous Furnace Systems

Combination Pusher-Type and Rotary-Hearth Furnace Heat-Treat System. The material above basically describes the traditional continuous-type furnace that operates on the principle of work being processed through the furnace on a "first in, first out" (FIFO) sequence. With recent industry trends toward the physical downsizing of heat-treatable components, lowering of manufacturer stockpiles and inventories to reduce costs, and moving into Just In Time (JIT) manufacturing, a need was created for a completely flexible continuous heat-treat system capable of simultaneously running a wide variety of parts to variable cycles. To accomplish this type of heat-treat processing using conventional FIFO furnaces would be extremely cumbersome and time-consuming. When changing the product mix or cycle in the FIFO-type furnaces, it would be necessary to either empty the chambers partially or completely, using empty trays, thus greatly affecting the operating efficiency of the equipment.

A multichamber, combination pusher and rotary-hearth heat-treat system as shown in Fig. 9 has only recently been conceived and built to address many of the shortcomings encountered when adapting existing continuous FIFO furnace systems to the new JIT manufacturing demands of industry. With pusher-type, continuous-type furnaces, it is not possible to simultaneously process side by side, a random mix of work parts, each requiring a different cycle time. When changing the process variable of "time" in a pusher-type continuous FIFO furnace, it is necessary to run a number of empty trays between the different types of tray loads in the furnace chamber. This has a negative effect on furnace efficiency, particularly if process cycle time changes are frequent.

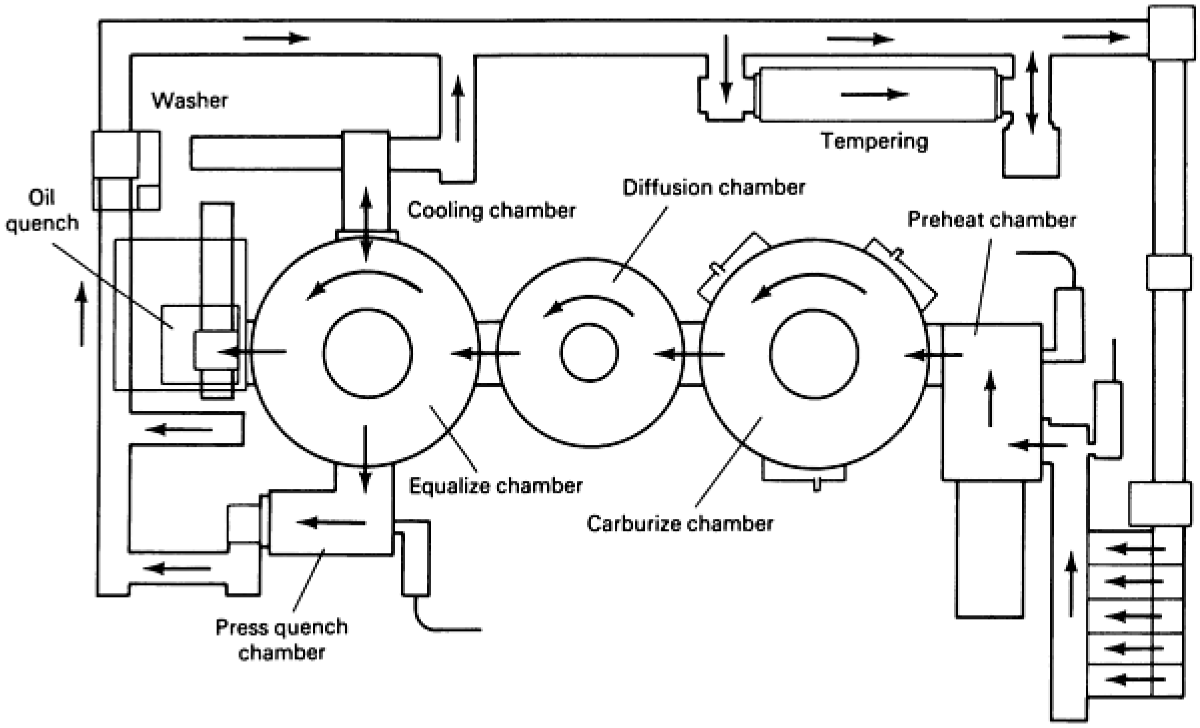

Fig. 9 Pusher-type and rotary-hearth heat-treat system

When shutting down a continuous pusher-type furnace, it is necessary to run empty trays into the charge end of the system to allow the work parts in the system to empty. The reverse is true on start-up, in that the system must first push out all the empty trays in the system before the product emerges. This arrangement wastes fuel and manpower in the heating and handling of empty trays.

The unique rotary hearth and pusher chamber concept allows tray loads with variable cycle times to be run simultaneously, side by side, in the same furnace chamber. This system also is built to be completely self-emptying without the use of empty trays. A complex system of this type is shown in Fig. 9, comprising three donut-shaped rotary furnaces: a carburize chamber, a diffusion chamber, and an equalize chamber, each having a circular rotatable hearth for supporting and moving trays of parts within an annular furnace chamber. Each rotary furnace is connected to the adjacent rotary furnace or pusher chamber through a tunnel with a special sealing door. The rotary hearths permit movement of any tray in any position within a furnace, at any time, by rotation of the selected position on the hearth to the charge or discharge door of that furnace, thus providing a high degree of flexibility in operation of the system. One or more pusher mechanisms are included within the circular space or "hole" of each donut-shaped furnace for moving the trays of parts between chambers.

The third rotary furnace of the system (equalize chamber) serves as a cooling chamber to 840 °C (1550 °F), a mechanism for transporting trays of parts to a selected quench system or to an atmosphere cooling chamber, and as a reheat chamber for trays of parts returned from the atmosphere cooling chamber. Trays that have been pushed into the atmosphere cooling chamber from the equalizing chamber can, after cooling, be reintroduced into the equalizing chamber for reheating and quenching or can be removed directly from the atmosphere cooling chamber to a tray-return transfer line.

Strand-Type Furnaces. Continuous strand-type furnaces for heat treating uncoiled strip reduce the handling and cycle times required with batch-type furnaces for sheet in coil form. Furnaces of this type also permit combining other operations, such as cleaning and/or coating. These furnaces usually have high production rates.

Overhead-Monorail Furnaces. In these furnaces, workpieces to be heat treated are suspended from rods attached to carriers on a monorail. Most continuous enameling is performed in overhead monorail furnaces.

Direct-Fired Furnace Equipment

With direct-fired furnace equipment, work being processed is directly exposed to the products of combustion, normally referred to as flue products. To minimize the scaling (oxide) effect on the work, the flue products can be controlled or varied by adjusting the fuel-air ratio of the combustion system. Although fuel-air adjustments can be made manually, more precise control can be achieved automatically by a wide variety of fuel-air ratio control systems on the market today. When direct-fired burner equipment is used in a heat-treating furnace, the parts being processed often are in some primary or intermediate stage of manufacture. The oxide formed is not detrimental to the part because it will be removed later in the manufacturing process. For example, forged parts are sometimes hardened in the as-forged condition, and rough castings are annealed prior to machining.

Gas-Fired Equipment. Gaseous fuel used in heat-treating furnaces can be natural gas, straight propane, a propane-air mix, or a relatively low-energy manufactured gas.

With the proper selection of burners, controls, orifices, and pipe sizes, a combustion system can be designed to operate on 2500 Btu (2635 kJ) propane gas, 1000 Btu (1055 kJ) natural gas, or 160 Btu (170 kJ) producer gas. The number refers to the energy contained in a cubic foot (0.028 m^3) of the gas. Manual adjustments are required for conversion from one gas to another.

Oil-Fired Equipment. Almost any grade of oil that can be satisfactorily atomized can be burned in direct-fired equipment. Lower-viscosity oils such as diesel fuel and No. 2 fuel oil can be easily atomized with pressurized (room-temperature) air. These are probably the fuel oils most commonly used for heat treating. Even with easily atomized oils, caution should be employed in using them on flame-supervised furnaces operating below 760 °C (1400 °F) with interrupted pilots. At low oil flows and excess air conditions, nuisance shutdowns can occur from the flame supervision devices. In certain instances, as dictated by the National Fire Prevention Association, "constant pilots" may be used to eliminate the shutdowns. Insurance carriers must approve the use of constant pilots for the particular application, however. Heavier grades of oil must be atomized by a method other than low-pressure air. Normally, high-pressure air and steam are used.

Burners that can be fired by either gas or oil are available. In most instances, oil is used as the standby fuel to be used in peak periods when natural gas supplies are curtailed. Oil is considered desirable by some in the forging industry because it creates a "softer" scale on the billet, which is more easily removed in forging. High vanadium, potassium, and sulfur contents in fuel oil burned in the direct-fired process can reduce the useful life of various furnace components, especially the nickel-chrome heat-resisting alloys.

Advantages of Fuel-Fired Furnaces. The following advantages are common to fuel-fired furnaces:

- Lower energy cost
- Easy to adjust or alter connected input
- Recuperator heat-saving devices can be added easily, and controlled cooling can be initiated easily with proper design of combustion systems
- Faster heat-up times because inexpensive control factors can be added to accommodate the difference in fuel burned during heat-up

Disadvantages of Fuel-Fired Systems. The following disadvantages are common to fuel-fired furnaces:

- Requires extensive ventilation systems
- Potential explosion or fire hazard
- Requires more manpower for start-up and shutdown
- Adjustment more difficult to maintain, resulting in excessive fuel use
- Only certain materials or types of products can be run in direct-fired furnaces due to the effect of high

dew point and oxidizing flue gases on the part surface

Electrically Heated Furnace Equipment

Electrically heated furnaces are commonly found in all temperature ranges: from low-temperature tempering furnaces, through the heat-treating range, and up to forging temperatures. The basic consideration in selecting the type of heating element is to determine whether the elements are to be the open type, which are exposed to the furnace environment, or the indirect type, which are protected from the furnace environment by some means such as a radiant tube, muffle, or retort. Factors affecting this decision are furnace atmosphere, need to protect the element from mechanical damage, and space required for placement of the element.

Material Selection. Almost all furnace atmospheres other than air will in some way affect the overall performance and subsequent life of each type of heating-element material. Manufacturers of heating-element materials provide charts that allow designers to predict the material performance with any of the given atmospheres. Each heating-element material can be exposed to the different furnace atmospheres with varying degrees of success.

The notable exception is with a carburizing-type atmosphere. The conventional nickel-chrome strip heating element does not perform well in a carburizing atmosphere because the element itself carburizes, affecting element performance. Generally, in a carburizing atmosphere, heating elements are placed inside radiant tubes or outside work-protecting muffles or retorts. However, some alternative elements are designed specifically to operate when exposed in a carburizing atmosphere.

The selection of open or indirect elements is a choice also determined by the need to protect the element against mechanical damage from parts being heated, from accumulations of metallic scale, or from broken refractories. In furnaces where bottom heat is mandatory and scale can be formed readily on the parts, or where parts may fall from a tray or conveyor, electric elements should be protected in radiant tubes below the hearth. Open elements could still, however, be used throughout the upper portion of the furnace.

In some furnace designs, the physical space available determines the design of the element.

A further consideration is whether to use an element material other than nickel-chrome strip or rod. Silicon carbide elements (globar) or molybdenum disilicide rod elements have been used with success when directly exposed to various atmospheres, although the former normally is not recommended for use in a carburizing atmosphere. Silicon carbide elements have been used on occasion inside radiant tubes for protection against carburizing atmospheres.

Metallic Resistance Heating Elements. The following are general types of furnaces, with a description of the kinds of heating elements used in each. More detailed information on resistance heating elements is given in Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Low-Temperature Furnaces with Open Elements. The temperature range of this type of furnace varies from approximately 150 to 675 °C (300 to 1250 °F), and the furnace is normally a recirculated-wind convection heating type. The simplest type of heating element is a commercially available duct heater, usually full-voltage, 440 V or 220 V heaters. These are quite useful when the designer can stay within the manufacturer limitations. Maximum use temperature of the commercial duct heater element is normally limited to 400 °C (750 °F).

The heater should be large enough to cover the entire recirculated wind-duct cross section, but designs are limited to the heater sizes available. The design watt density for this type of duct heater is normally 34 000 W/m^2 (22 W/in.^{2}). Watt density is the expression commonly used for connected power of each element in watts divided by its total surface area. Watts per unit area is an important design consideration, and the allowances vary greatly with temperature, type of element, and furnace.

As an alternative to the commercial unit, a custom-built duct heater can be used. A steel or alloy frame can then be designed to completely fill the air-duct cross section, and such a unit can be removed easily through a sidewall bulkhead.

The nickel-chrome ribbon material is supported in ceramic insulators mounted in tiers. A common element material is 35Ni-18Cr-44Fe, and it is normally selected in the lighter gage thicknesses and narrower widths. A typical cross section for the ribbon material would be 13 by 0.8 mm (0.50 by 0.030 in.).

Variable with temperature and wind flow, the design watt density would be in the 23 250 to 46 500 W/m^2 (15 to 30 W/in.^{2}) range. This heater is also normally designed to operate at full-line voltage of 440 or 220 V.

High-Temperature Furnaces with Open Elements. The temperature range of this type of furnace varies from approximately 675 to 955 °C (1250 to 1750 °F), and the furnace is normally a radiant-heating type.

Where large wall areas are available inside a furnace, a common method of mounting the nickel-chrome strip element is to attach it in a serpentine pattern from insulated alloy or ceramic anchors normally on the vertical walls only. With this design, especially at the higher temperatures, the structural strength of the element material and configuration for expansion must be considered. The element must support itself at operating temperatures without excessive droop or warping. Sufficient warping to cause the element to touch at various points could shorten the effective length of the element, decrease the resistance, and cause premature failure due to excessive currents and watt densities.

On larger furnaces with accessible wall areas, maintenance on this design element, although done from inside the "cold" furnace, is relatively easy. On smaller furnaces, accessibility for replacement of wall elements becomes a problem.

Other types of modular or drawer-type elements are available, which makes element removal and maintenance much easier.

The element strip material used with open elements is generally one of the following types: 80Ni-20Cr, 68Ni-20Cr, or 35Ni-18Cr-44Fe. The nickel-chrome element is generally selected in the heavier gage thicknesses and wider widths. A typical cross-section range would be from 1.3 to 2.3 mm (0.050 to 0.090 in.) thick and 19 to 38 mm ($\frac{3}{4}$ to $1\frac{1}{2}$ in.) wide. Variable with temperature and location of elements, the design watt density would be 12 400 to 23 250 W/m^2 (8 to 15 W/in.^{2}).

An alternative to the nickel-chrome strip element is the cast nickel-chrome heating element. This element has good structural strength, stability, and resistance to atmospheric attack. The quality control necessary in the manufacture of this element has made it slightly less flexible and popular than nickel-chrome strip. The casting must have uniform density and cross section to ensure a guaranteed resistance without danger of hot spots. Castings made with the investment casting (or lost-wax) process generally meet the quality requirements. Low voltages at the element and high currents tend to make the control hardware and wiring quite expensive. A common cast element material would be 35Ni-15Cr, and the watt-density range again would be 12 400 to 15 500 W/m^2 (8 to 10 W/in.^{2}).

Nonmetallic Resistance Heating Elements. In general, the nonmetallic heating elements are used in furnaces operating above 1010 °C (1850 °F). Silicon carbide elements are generally used in temperature ranges of 1010 °C (1850 °F) and above. They tend to be very fragile, so care should be taken in the design to allow for proper support and freedom for the element to expand and contract as the furnace is heated and cooled.

Silicon carbide elements undergo resistance increase with age; thus, to maintain constant power over the life of the elements, it is necessary to have a voltage adjustment available, usually with a step transformer. The useful life of a silicon carbide element is usually established at the point when its resistance has increased four times. To maintain constant power would mean that a total voltage demand of twice the initial voltage would be required because power, P, is equal to E^2/R.

Silicon carbide elements are provided in various diameters and lengths, with published "hot" resistances. Design watt densities vary with such factors as temperature and atmosphere, but with silicon carbide elements, conservatively designed watt densities result in better element life.

In a sintering furnace operating at 1150 °C (2100 °F) with an endothermic atmosphere, a design watt density of 31 000 to 46 500 W/m^2 (20 to 30 W/in.^{2}) would be considered appropriate. Molybdenum disilicide elements are commonly formed in U-shaped rod configurations and normally are mounted vertically. The published maximum temperature-use range in air is above 1650 °C (3000 °F), which covers all furnace temperatures up through the forging range.

Element location for molybdenum disilicide elements is an important consideration because these elements are designed to operate at very high watt densities and related high thermal heads. These elements undergo a high resistance change from cold to hot, with resistance increasing with temperature. The control hardware and wiring must be properly designed to handle the high initial currents. A typical selection for a 955 °C (1750 °F)furnace with an endothermic atmosphere

would be a 9 mm (0.35 in.) rod element, rated at 244 900 W/m^2 (158 W/in.^{2}), with an element temperature of 1430 °C (2610 °F).

Advantages of Electrically Heated Furnaces. The following are advantages associated with electrically heated furnaces:

- Systems are clean and free of the pollution normally found with fuel-fired systems
- Cooler plant environment without exhaust stacks and hoods for some furnaces (atmosphere furnaces may still require stacks and hoods)
- Quieter because of the absence of blowers and combustion noise
- More uniform heat pattern from grid elements or from side-to-side of chamber temperature uniformity on electric radiant tubes
- No exhaust system required to affect building air pressures; no make-up air system required
- Does not generally (though not always) require purge or flame safety systems
- Electrical power available almost everywhere

Disadvantages of Electrically Heated Furnaces. The following are disadvantages of electrically heated furnaces:

- Inflexible system makes changing connected heating capacities or varying individual element capacities in the same zone difficult
- High initial equipment costs
- With numerous electric furnaces in a plant and no form of peak-demand control, the user pays at a high demand rate for all power
- Higher operating costs
- Cool-down times are longer because no combustion air is available
- Nonmetallic elements tend to become brittle as they age and are subject to breakage from handling, vibration, or shock

Radiant-Tube-Heated Furnace Equipment

With fuel-fired, radiant-tube-heated furnaces, the work chamber is protected from the products of combustion. With a radiant-tube furnace, the work chamber normally contains a controlled atmosphere as dictated by the process. There are, however, cases where the chamber remains filled with air, and the only purpose of the radiant tubes is to protect the work from the high dew point flue gas products. Electrically heated radiant tubes normally are used to protect the heating-element material from attack by the furnace atmosphere.

Gas-fired radiant tubes, as shown in Fig. 10, are by far the most common type of fuel-fired indirect method of heating. This is mainly due to the wide availability of natural gas. The proper selection of combustion system components such as burners, controls, orifices, and piping, will allow the same radiant tube to be fired with a wide variety of gases: natural gas, propane-air mix, straight propane, and certain low-Btu manufactured gases.

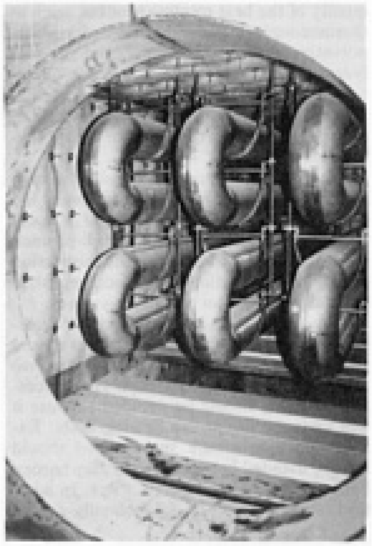

Fig. 10 Radiant tubes for indirect gas-fired furnace heating. Courtesy of Despatch Industries Inc.

Radiant-tube burners are of two basic types, sealed-head and open-type burners. A particular advantage of the sealed-head burner is that it is readily recuperable by using the products of combustion and an air-to-flue-gas heat exchanger to preheat the combustion air prior to its entering the burner. This advantage can result in considerable fuel savings (see the article "Energy-Efficient Furnace Design and Operation" in this Volume).

Open-type radiant-tube burners use room air for combustion, which is entrained into the radiant tube by an eductor on the exit end of the radiant tube. Open-type radiant-tube burners cannot be recuperated, although in most cases, they can be replaced with a sealed-head burner. Radiant tubes are normally constructed from centrifugally cast tubing of various diameters, with wall thicknesses of 3 to 8 mm ($\frac{1}{8}$ to $\frac{5}{16}$ in.). In many cases, tubes fabricated from 3 and 5 mm ($\frac{1}{8}$ and $\frac{3}{16}$ in.) wrought alloy are used.

With the high metal temperatures attained in radiant tubes in most heat-treating furnaces, the alloys commonly used are the higher-grade cast alloys HT, HK, and NA22H, or the wrought alloys 330, 601, and Incoloy 800. Additional information on the materials for radiant tubes is given in the article "Heat-Resistant Materials for Furnace Parts, Trays, and Fixtures" in this Volume.

Oil-Fired Radiant Tubes. Straight oil-fired radiant tubes are somewhat uncommon in heat-treating furnaces and are used mainly where an adequate supply of gaseous fuel is not available. Radiant tubes equipped to burn both oil and gas are more common, with the oil, usually No. 2 fuel oil, used as the standby fuel.

High vanadium, potassium, and sulfur contents in oil have a great effect on the useful life of nickel-chrome heat-resisting alloys. With the high temperatures attained inside the radiant tubes acting as a catalyst, attack on the radiant-tube alloy is accentuated.

When oil-fired radiant tubes are used, the construction and types of materials used are similar to those described for the gas-fired radiant tubes. Recuperation is also possible with certain sealed-head oil burners. When recuperation is employed, the burner manufacturer should be consulted regarding possible damage to or problems with the atomizing system in the burner, from the preheated combustion air, normally supplied at 370 to 540 °C (700 to 1000 °F).

Electrically Heated Radiant Tubes. With this design, the radiant tube protects the resistance heating element from the furnace atmosphere. A common design uses nickel-chrome alloy rod inside the radiant tube. These rods are formed into continuous hairpin shapes supported and contained by ceramic spacer discs.

With the heating element contained in a tube, it is very important to conservatively select the heating element watt density. The design watt density of the internal element is a direct function of furnace temperature and varies from 18 600 to 46 500 W/m^2 (12 to 30 W/in.^{2}). Some designs use nickel-chrome strip material rather than rod, formed into similar hairpin patterns.

If a gas-fired "U"-tube furnace is to be converted to electrically heated radiant tubes, it is desirable to directly replace the "U" tube with two straight tubes, rather than a single straight tube, for improved uniformity and reduced watt density. Thus, the conversion from natural gas to electricity can be accomplished without loss in production capacity.

Other types of electric radiant tubes are available, where the radiant tube itself becomes the resistive heating element. As with cast elements, however, the quality and condition of the radiant tube will determine whether it functions properly as the resistance element. Silicon carbide elements have also been used inside radiant tubes to protect them from carburizing atmospheres.

General Furnace Maintenance

Maintenance on a furnace should be performed on a regular basis to prevent unscheduled shutdowns. In most plants, major maintenance is performed once each year, normally during the plant vacation period.

Because unscheduled maintenance is very disruptive to production, especially in plants without backup heat-treating capabilities, some plants prefer a number of smaller furnaces rather than a single large furnace capable of handling all production.

Many components of furnaces must be considered as consumable items, although lifespan normally can be predicted from accurate maintenance records. Many furnace owners regularly inspect and change internal furnace components such as radiant tubes, thermocouples and wells, retorts, and electric heating elements. Trying to get a few more months of life from a certain internal component could result in an unscheduled shutdown, and an extended loss of production can occur if a replacement part is not readily available. Most furnace equipment manufacturers provide a recommended list of spare parts that the furnace owner should maintain in stock to ensure reasonably uninterrupted production.

In addition to the consumable items that have to be regularly replaced, many furnace components must be adjusted and/or calibrated at regular intervals to maintain the efficiency and accuracy of the heat-treating operation--once each shift, daily, weekly, monthly, or annually. Components that require regular monitoring for adjustment and calibration are mainly those that control the quality of the heat-treating process, such as thermocouples, temperature- and carbon-potential-control instruments, and gas analyzers. For example, some furnace operators regularly change all thermocouples at specified intervals to avoid the gradual deterioration that occurs prior to indiscriminate failure.

In addition, maintenance required to minimize wear and thus prolong component life must also be considered. This form of maintenance usually consists of a well-planned and documented adjustment and lubrication schedule. Lubrication can be accomplished manually or with an automatic system.

Care should be taken in the proper selection of the various greases and oils to ensure compatibility with the various furnace components and furnace atmospheres. Excessive greasing should be avoided because it will limit the life of the bearing seals. Excessively long grease supply lines should also be avoided because grease may harden before it reaches the point of use. In addition, supply lines are not normally routed through high-temperature areas to the lubrication points.

On manual systems, lubrication points should be carefully coded. Many special greases are incompatible with each other, and lubricating components with the wrong grease can have disastrous results.

For major maintenance, such as complete refractory replacement or complete rebuilding of mechanisms and systems, it is normally best to consult the original equipment manufacturer. Because this type of maintenance usually occurs when the equipment is quite old, the manufacturer will normally make recommendations that will improve the equipment and upgrade the system to the present state of the art and to comply with current recognized industry safety standards.

Salt Bath Heat-Treating Equipment

W. James Laird, Jr., The Metal Works Industrial Furnaces, Inc.

Introduction

HEAT TREATERS can no longer use heat-treating methods that are only uniform, quick, efficient, and economical. They must also be environmentally responsible. Salt bath heat-treating methods are uniform, quick, efficient, economical, and environmentally responsible.

Salt baths are used in a wide variety of commercial heat-treating operations including neutral hardening, liquid carburizing, liquid nitriding, austempering, martempering, and tempering applications. Salt bath equipment is well adapted to heat treatment of ferrous and nonferrous alloys.

Parts that are heated in molten salt baths are heated by conduction; the molten salt bath provides a ready source of heat as required. Although materials being heated come in contact with heat through their surfaces, the core of a part rises in temperature at approximately the same rate as its surface. Heat is quickly drawn to the core from the surface, and salt baths provide heat at an equal rate over the total part.

Neither convection nor radiation heating methods are able to maintain the rate of heating required to reach equilibrium with the rate of heat absorption. The ability of a molten salt bath to supply heat at a rapid rate accounts for the uniform, high quality of parts heat treated in salt baths. Heat-treating times are also shortened; for example, a 25 mm (1 in.) diam bar can be heated to temperature equilibrium in 4 min in a salt bath, whereas 20 to 30 min would be required to obtain the same properties in either convection or radiation furnaces.

Salt baths are very efficient methods of heat treating; about 93 to 97% of the electric power consumed with a covered salt bath operation goes directly into heating of the parts. In atmosphere furnaces, 60% of the energy goes for heating, and the remaining 40% is released up the furnace stack as waste. Steels that are heat treated in molten salts typically are processed in ceramic-lined furnaces with submerged or immersed electrodes containing chloride-based salts.

Applications

Applications of the various furnace designs and auxiliary equipment to specific heat-treating processes, such as austempering and martempering, are described in this and other articles in this Volume. Basic advantages of salt bath treatment include surface protection and control of distortion.

Surface Protection. Parts immersed in a molten salt bath develop a thin cocoon of solidified salt, which can be easily washed from the surface after treatment. This surface protection afforded by salt baths can eliminate the formation of damaging oxide scales. Moreover, because salt baths do not contain the oxygen, carbon dioxide, and water vapor levels found in most non-vacuum (or atmosphere) furnaces, immersed parts are protected further from scale formation. Decarburization of steel parts from contact with oxygen and carbon dioxide are also eliminated by the use of molten salts. Vacuum furnaces provide similar advantages in surface protection.

Control of Distortion. Salt baths offer a way to minimize the bad effects of nonuniform heating, lack of support, and poor quenching that may cause size and shape distortion. Unlike parts in an atmosphere or vacuum furnace, parts immersed in molten salts are supported by the density of the medium. Due to its buoyancy, sagging or bending of the parts is minimized in a molten salt bath.

Heating in molten salts is also very uniform. The temperature uniformity in a molten salt bath averages ±3 °C (±5 °F) throughout the bath, depending on furnace design. The layer of solidified salt around a part can also protect the part from rapid initial heating and the resulting thermal shock. As the cocoon of salt melts, the part is gradually and uniformly heated, minimizing distortion and preventing cracking.

Selecting a Salt for a Given Application. Information concerning the various salts suitable for heat-treating furnaces is available from many sources, such as the many competent salt companies. Also, military specification MIL-10699 describes the salts in detail. When selecting a salt for a given application, the following must be considered:

- The salt must have the proper working range to meet the operating temperature requirements
- The salt must have the proper melting point to avoid prolonged heat-up times for heavy loads
- The salt must be compatible with other salts and oil used in the same heat-treating line
- The versatility of the salts application
- The ease with which the salt is washed from the work after heat treatment and affinity of the salt for moisture

By balancing these factors, a salt best suited for a particular application can be chosen. Naturally, if a single salt must perform several functions, it will be necessary to make compromises and sacrifice some advantages to obtain the required versatility. Salts used in heat treating tool steels are described in the following example.

Example 1: Molten Salt Bath Treatment for Hardening High-Speed Tool Steel.

The use of molten salt baths for high-speed steel hardening has progressed during recent years. The greater degree of control and versatility, coupled with a simplicity of process, has been the chief reason for this progress. In addition to these factors, salt bath hardening ensures greater uniformity and rapid heating as well as freedom from scaling of the tools being heated.

The greater rate of heat transfer obtained through the use of molten salts permits the use of hardening temperatures approximately 15 °C (25 °F) below those in muffle-type furnaces, thereby reducing the possibility of sweating (melting of the surface) as well as undesirable grain growth. For best results, high-speed steel should be hardened in four steps. One procedure is described below.

1. Preheating. To safeguard against cracking and distortion, preheating tool steels before austenitizing is recommended. Small pieces of simple shape, which are not as susceptible to the damaging effect of thermal shock as are larger, more complex pieces, may not require preheating. Other more intricate shapes may require one or more preheating steps. Preheating is usually done in a ternary eutectic chloride mixture, which melts at approximately 541 °C (1006 °F) and is usable from 600 to 1010 °C (1100 to 1850 °F). These salts are formulated to preheat or harden steel without decarburization and with a minimum amount of sludge formation. Usually, the replenishment offered by mechanical dragout is sufficient to control bath chemistry. After a period of idling, however, it is usually necessary to rectify the bath as well as remove any sludge to be certain that the bath is neutral. The heating rate in this type of salt is rapid. It thoroughly heats most tools in 10 min or less. Prolonged heating times are not detrimental to steel and will help achieve thermal equilibrium negating the need for long austenitizing cycles.

2. Austenitizing. The most critical treatment in tool steel hardening is that of austenitizing. Austenitizing of high-speed tool steel is done at temperatures close to its melting point. Long heating times, or excessively high temperatures, will cause increased grain growth, distortion, loss of strength, and loss of ductility. Low hardnesses and low wear resistance will result from inadequate heating of the steel. Achievement of thermal equilibrium is a must before quenching to eliminate damaging the workpieces, Heating for 1 min for each 6 mm ($\frac{1}{4}$ in.) of total steel section thickness being heated is a good rule of thumb.

Austenitizing baths generally consist of anhydrous barium chloride, which begins to melt at approximately 960 °C (1760 °F) and has a working range of 980 to 1315 °C (1800 to 2400 °F). Neutrality of barium chloride operating above 1090 °C (2000 °F) is maintained by using a 50 mm (2 in.) diam carbon rod with a length of 300 or 600 mm (12 or 24 in.). The carbon rod reacts chemically to reduce metal oxides that are then deposited in droplets on the carbon rod. Frequency of immersion is usually 1 h, divided into 15 to 20 min intervals, for every 5 h of heat-treating operation. Too long an immersion will allow droplets of metal to flow together and run off the rod. The user should take caution not to allow this to happen, as it will recontaminate the bath.

Methyl chloride rectification is highly recommended in neutral salt baths operating between 1040 and 1315 °C (1900 and 2400 °F). The bath temperature should be kept below 1040 °C (1900 °F) while methyl chloride is being introduced. Methyl chloride is introduced under the surface of the bath to avoid a chemical breakdown above the surface of the bath, which would result in gas loss. The broken down methyl chloride supplies chloride ions, which combine with the harmful metallic oxide to form neutral metallic chlorides. Self-rectifying neutral salts are also available from most salt suppliers. It

is recommended that the users thoroughly familiarize themselves with the disadvantages and detrimental effects rectifying salts can have on equipment before deciding to use self-rectified salts.

3. Quenching. For the quenching bath, the use of water is recommended for most cold heading tools, while the use of triple eutectic chloride salts is suggested for high-speed steels. For quenching air hardening steels, it is recommended that a 540 °C (1000 °F) triple eutectic chloride salt be used to reduce the temperature of the steel to a point where the heat color has been taken out of the workpiece so that it will not rapidly oxidize when air cooled. These are typical salts mentioned previously for use as a preheating medium.

As a majority of high-speed steels are quenched to temperature between 540 and 700 °C (1000 and 1300 °F), the triple eutectic chloride salts will have sufficient fluidity at these temperatures to allow effective quenching without the serious corrosion resulting from the use of salts containing highly hygroscopic constituents. Lower melting point salts usually contain calcium chloride and, if allowed to remain on the workpiece until it is cooled to room temperature, may severely corrode the surface.

The exact quenching temperature to use is dependent chiefly upon the composition of the steel. In some instances, use of low quenching temperatures cause the salt to freeze on the surface. This condition is caused by contamination of quench salt by barium chloride carried from the high heat bath, which gradually raises the freezing point of the quench bath. Proper salt handling techniques will eliminate this problem.

4. Drawing or tempering is done to obtain the desired strength, hardness, and toughness by modifying the microstructure of the quench hardened tool steel. More than one tempering cycle may be required to alter the ausquenched and heterogeneous mixture of retained austenite, untempered martensite, and carbides. All retained austenite and untempered martensite will be transformed when tempered, using a few short cycles rather than one long one. Some steels may require three or four cycles before the optimum structure is obtained. Each cycle will require not less than one hour at tempering temperature. Tempering is accomplished in nitrate/nitrite mixtures, which melt at approximately 140 to 600 °C (290 to 1100 °F). Neutral chloride salts can be used to temper small parts and light loads, but they are not recommended for production unless the temper temperatures are above 600 °C (1100 °F).

Externally Heated Furnaces

Externally heated salt bath furnaces may be fired by gas or oil, or heated by means of electrical resistance elements. Figure 1 shows typical externally fired furnaces used in liquid carburizing applications. Pots may be press formed from a single piece of low-carbon steel or iron-nickel-chromium alloy; a composition of Fe-35Ni-15Cr is usually preferred for the latter. Less expensive welded pots may be fabricated from either of these materials.

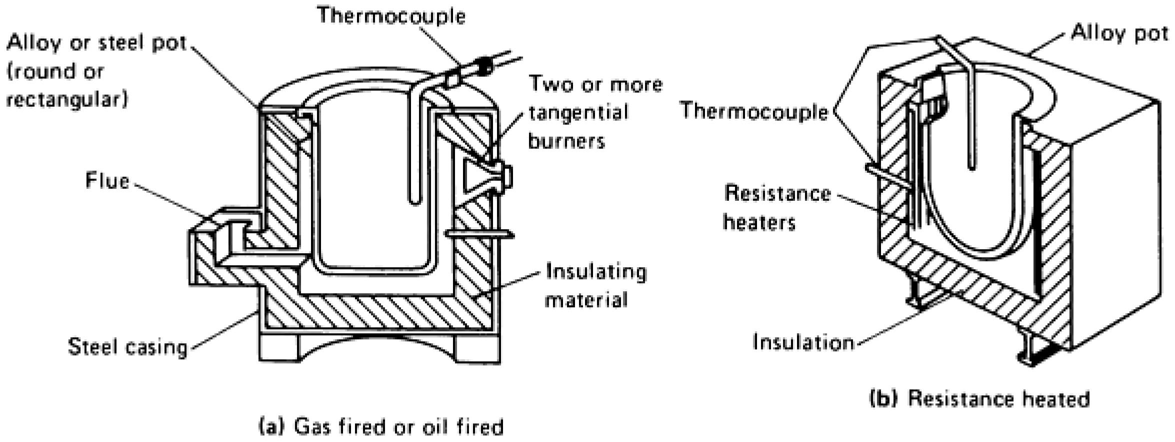

Fig. 1 Externally heated salt bath furnaces for liquid carburizing

A flange usually supports salt pots; consequently, pot size is limited by the strength of the flange material. Round pots for gas- and oil-fired furnaces range from 250 to 900 mm (10 to 35 in.) in diameter and from 200 to 750 mm (8 to 30 in.) in depth; they are about 10 mm (0.4 in.) thick. Larger sizes have been built for special applications and have operated

successfully. Pots larger than about 350 mm (14 in.) in diameter and 450 mm (18 in.) deep are rarely used for electrical resistance furnaces. Although it is physically possible to support the bottom of a large pot on a refractory pier, excessive temperature gradients may result.

Gas- or oil-fired salt bath furnaces (Fig. 1 a) are generally lower in initial cost than electrode- or resistance-heated furnaces and are simple to install and operate. As described above, gas- and oil-fired salt bath furnaces also have larger salt pots than resistance-heated furnaces.

To contain the molten salt, fuel-fired furnaces employ a round or rectangular pot made of either steel or alloy. Heat is applied by two or more self-cooling burners that fire tangentially between the outer wall of the pot and the inner surface of the furnace lining. The hot gases are vented through a flue located near the top for atmosphere-type type burners, or near the bottom for pressure-type burners and atmosphere-type burners for which the flue is connected to a stack about 1 to 2 m (3.3 to 6.6 ft) high. The height and placement of the flue allows a negative pressure to be maintained within the firing chamber. Firebrick and additional required insulation lines the combustion chamber. A steel casing completely surrounds all sides of the furnace housing and provides adequate safety in the event of pot failure.

Electrical resistance furnaces (Fig. 1b) for neutral heating of liquid baths are less widely used than furnaces fired by gas or oil. A series of resistance heaters surrounding the salt pot heat these furnaces. For this reason, pot failure may result in the total destruction of the electrical heating elements. Operating temperatures below 900 °C (1650 °F) are used to reduce pot failure.

Pot Service Life. In a well-designed furnace, the life of a round alloy pot will vary with the maximum operating temperature approximately as follows:

Temperature		Service life, mo
°C	°F	
840	1550	9-12
870	1600	6-9
900	1650	3-6

In one installation, the placement of an additional control thermocouple in the combustion chamber to prevent the temperature of the chamber from exceeding 1095 °C (2000 °F) served to extend the life of high-temperature (HT) alloy pots to 2 years (previous life had been 6 months). Pot temperature was maintained at 900 °C (1650 °F) during a work week of 120 h (24 h/day, 5 days/week). Other factors affecting pot life are considered in the section "Design and Operating Factors."

Temperature of the salt is measured by a thermocouple and suitable pyrometer. Operating within the range from 790 to 920 °C (1455 to 1690 °F), the externally fired furnaces may vary as much as 10 °C (18 °F) above and below the set temperature when using on-off or high-low control systems. This is considered acceptable for many applications. Where closer control of the temperature is required, a proportional control system, which will hold temperature variations to less than ±5 °C (±9 °F), should be used.

Design and Operating Factors. In the design of fuel-fired furnaces, ample space must be provided for combustion so that the flame will not impinge on the pot. If flame impingement is unavoidable, the pot should be rotated slightly at least once a week. Rotating the pot and/or using a sleeve reduces local deterioration in the region of flame impingement and prolongs the service life of the pot. The combustion-chamber atmosphere also has important effects on pot life. A system with a control range from high-fire to low-fire is preferable to an on-off system because the latter allows air to enter the combustion chamber during the "off" portion of the cycle, thereby increasing the rate of sealing of the outer surfaces of the pot.

Electrical-resistance-heated furnaces should be equipped with a second pyrometer controller whose thermocouple is located within the heating chamber. This will prevent overheating of the resistance elements, particularly during meltdown, when the thermocouple that controls the temperature of the main bath is insulated by unmelted salt. Because heating elements and refractories are severely attacked by salt, all salt must be kept out of the combustion chamber. For this purpose, a high-temperature refractory fiber rope may be used to seal joints where the pot flange rests on the retaining ring at the top of the furnace.

Externally heated pots should be started on low fire (low heat input) regardless of the method of heating. Once the salt appears to melt around the top, heat can be gradually increased to high fire to complete meltdown. *Caution: Excessive heating of the sidewalls or pot bottom during startup may create pressures sufficient to expel salt violently from the pot.* For added safety, the pot should be covered during meltdown with either a cover or an unfastened steel plate.

The waste heat of flue gases may be fed to an adjacent chamber and used to preheat work. Flue gases should always be visible to the operator. The appearance of bluish-white or white fumes at the vent indicates the presence of salts within the combustion chamber; prompt action is required.

Advantages and Disadvantages. Because of the ease with which they can be restarted, externally heated furnaces are well suited to intermittent operations. Another advantage of furnaces of this type is that a single furnace can be used for a variety of applications by simply changing the pot for one containing the proper salt composition.

Externally heated furnaces do have several characteristics, however, that limit their usefulness in certain operations. They are less adaptable to close and uniform temperature control because the furnace dissipates heat by convection, creating temperature gradients in the bath. Also, the temperature lag of the thermocouple and the recovery time of the furnace may result in overshooting or undershooting the desired temperature by 15 °C (25 °F). In addition to requiring an exhaust system for generated flue gases, externally heated furnaces may overheat at the bottom and sidewalls in restarting, which creates a pressure buildup in the thermally expanding molten salt and may cause an eruption. Finally, externally heated furnaces are seldom practical for continuous high-volume production because of the limitations of pots with respect to size and maximum operating temperature. High maintenance cost is also a factor.

Immersed-Electrode Furnaces

Ceramic-lined furnaces with immersed (over-the-side) electrodes (Fig. 2), when compared to externally heated pot furnaces, have greatly extended the useful range and capacity of molten salt equipment. The most important of these technical advances are:

- The electrodes can be replaced without bailing out the furnace
- Immersed electrodes allow more power capacity to be put into the furnace, thus increasing production
- Immersed electrodes permit easy startup when the bath is solid. A simple gas torch is used to melt a liquid path between the two electrodes, thus allowing the electrodes to pass current through the salt to obtain operating temperatures

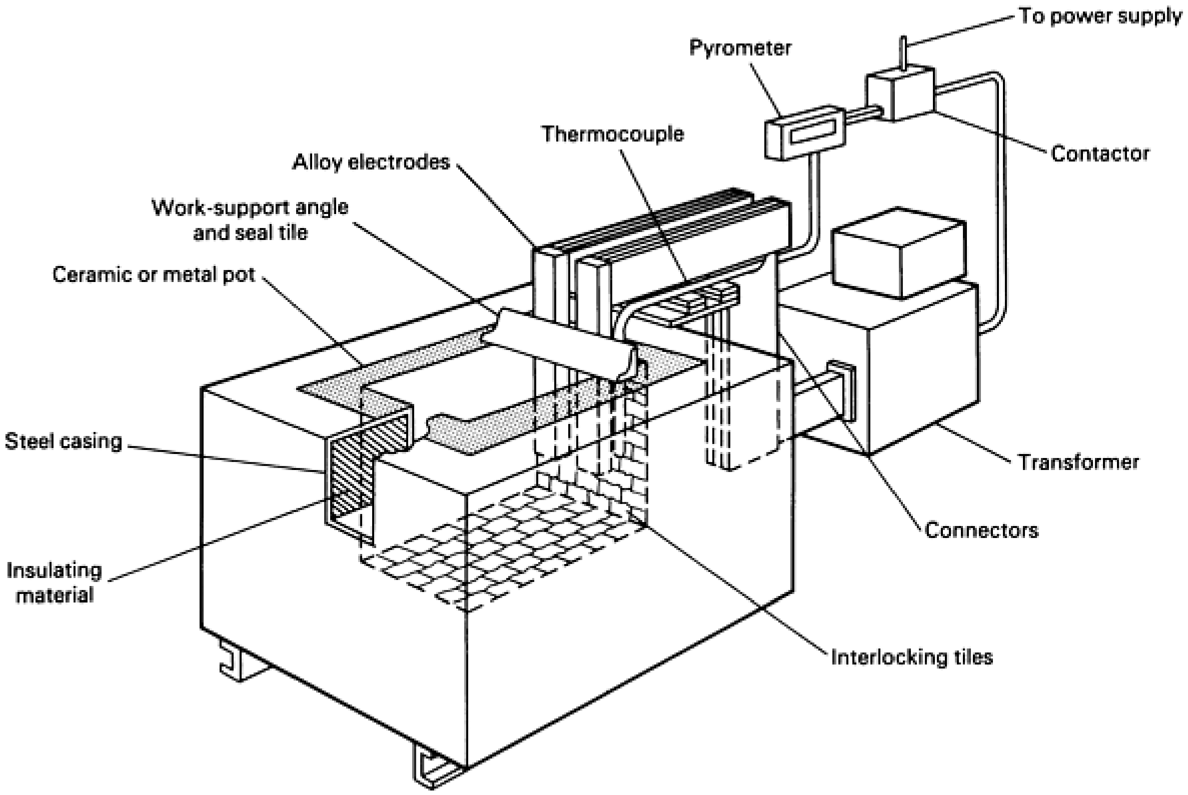

Fig. 2 Internally heated salt bath furnace with immersed electrodes and ceramic tiles

Immersed-electrode furnaces, however, are not as energy efficient as submerged electrode furnaces. The area in which the immersed electrodes enter the salt bath allows additional heat loss through increased surface area. As exhibited in Table 1, the surface area of the salt bath (A) in the submerged-electrode furnace is smaller than the surface area plus the immersed electrodes (A + B) in the immersed-electrode furnace. However, a good cast ceramic and fiber-insulated cover placed over the bath and electrodes will reduce surface radiation losses up to 60%.

Table 1 Service life of electrodes and refractories

Operating temperature		Service life, years	
°C	°F	Electrodes	Refractories
Submerged-electrode furnaces			
Furnace A			
535-735	1000-1350	15-25	15-25
735-955	1350-1750	6-12	6-12

Furnace E

(a) Hot leg only

Super-duty fireclay brick lines the immersed-electrode furnace. Approximately 130 mm (5 in.) of castable and insulating brick then surrounds the fireclay brick on five sides. Figure 2 is a schematic drawing of an immersed-electrode furnace with interlocking tiles and removable electrodes. The removable electrodes enter the furnace from the top, and a seal tile is located in the front of the electrodes to protect them from exposure to air at the air-bath interface. This protection helps prolong electrode life. Table 1 compares service life of electrodes and refractories for some basic furnace designs.

Over-the-top (or over-the-side) electrodes are usually built with laminated cold legs, and water cooling is always required. A typical life expectancy for electrodes operating in such a furnace at 840 °C (1550 °F) is approximately 6 mo to 2 y for over-the-top electrodes, compared to 4 to 8 y for submerged electrodes.

The salt is heated by passing alternating current through it with immersed electrodes. As a result of the resistance built up to passage of current through salt, heat is generated within the salt itself. This heat is quickly dissipated by a downward stirring action created by the electrodes. The electrodes are attached by copper connectors to a transformer that converts the line voltage of the plant to a much lower secondary voltage (approximately 4 to 30 V) across the electrodes. Temperature is measured and automatically controlled by a system containing a thermocouple, pyrometer, relay, and magnetic contactor.

The energy required by an immersed-electrode furnace is a function of:

- Furnace size necessary to hold the load and electrode well
- The energy (Q_w) needed to heat the load to the desired temperature. (The value of Q_w is a function of load mass, the specific heat of the load, and bath temperature)
- Energy losses and safety factors

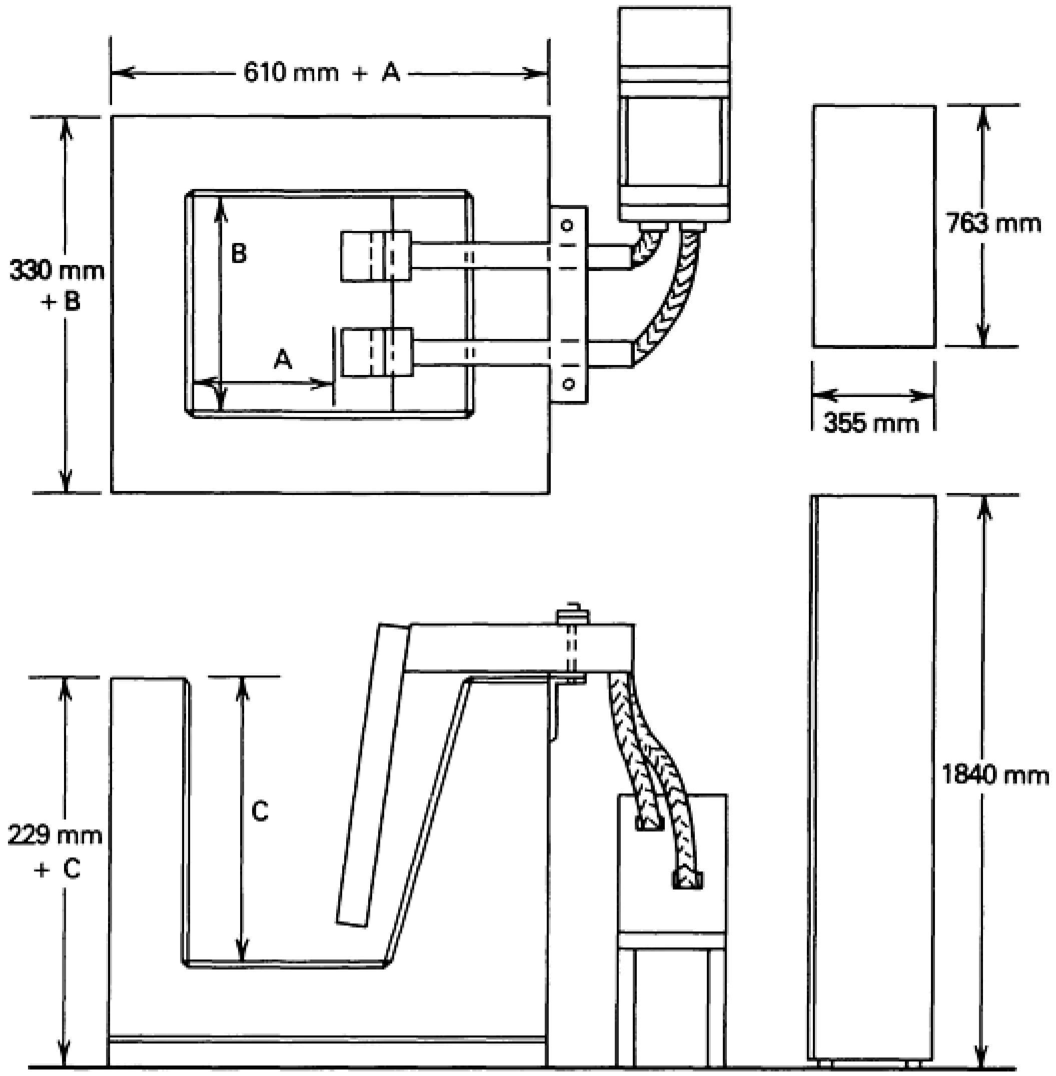
Once energy requirements are determined, then electrode number, size, and spacing can be determined.

Microcomputers are used to calculate the rate of heat generation per unit length of the electrode to ensure that the current is uniform from the top and bottom of the electrodes, taking into account the complexity of the current paths between the electrodes, the electromagnetic forces, and the circulation (influenced by the viscosity of the salt).

The electrode spacing is usually selected between 25 and 100 mm (1 and 4 in.); the height of the electrode should be smaller than the depth of the pot, the difference depending on electrode spacing. The electrode width is usually 50 to 75 mm (2 to 3 in.) and rarely exceeds 125 mm (5 in.). Transformer voltages usually range from 4 to 30 V, with the ratio of maximum to minimum voltage of a given transformer approximately 4.5 (Ref 1).

Steel-Pot Furnaces. Some metal-treating processes are performed in salt compounds that cannot be contained in a ceramic liner. For these applications, furnace manufacturers make use of a welded steel pot with immersed electrodes. This type of furnace is suitable for special applications such as case hardening in straight cyanide baths, tempering, and marquenching.

The steel pot often has a sloped back wall, which produces a bottom heating effect resulting in better circulation and uniform temperature. This is accomplished by sloping the electrodes shown in Fig. 3 and 4. As the current passes through the salt between the electrodes, the salt is heated, decreasing its density and causing it to rise toward the bath surface. Control of the rate of rise of the salt is effectively gained by decreasing the distance from the electrodes to the steel pot. At the lower extremity of the electrode, the current enters the metal pot upon leaving the electrode to follow a shorter path to the other electrode. This arrangement ensures current flow through the salt along the entire electrode length. Due to the close proximity of the lower portion of the electrode to the pot, most of the heating is done in the lower part of the bath. This is the desired method of heating any liquid.



Typical standard sizes

Fig. 4 Metal pot, immersed-electrode salt bath furnace for liquid carburizing, cyaniding, and carbonate baths

The metal pots are made of either plain steel or hot-dipped aluminized steel, depending on the application. Thicknesses range from 12 to 38 mm ($\frac{1}{2}$ to $1\frac{1}{2}$ in.). Reinforcing members for light plate, usually angular in shape, are welded from the top. Where depth of the pot so requires, additional members are used at the midsection.

The pot is housed in an insulated 230 mm (9 in.) thick wall furnace either with a brick outside wall contained in a rigid welded steel frame or in a steel-clad frame, depending on personal preference. In either type of construction, the frame is self-supporting on a lattice formed by welding channels or beams to the underside of a steel base plate. The pot is supported on an insulated refractory pedestal.

Electrode Arrangement. Immersed electrodes are made of either mild steel or an alloy "hot" leg welded to a mild steel "cold" leg. As previously mentioned, these are shaped to follow approximately the slope of the pot wall. The portion of the electrode that crosses over the top of the salt bath and is connected to the plant power source is referred to as the cold leg. This is welded to the hot leg, the portion of the electrode that is immersed in the bath, with sufficient weld cross section to provide necessary current conductor capacity. The shanks are drilled and tapped at the tinned terminal connection end for water cooling when necessary. If the latter is not required, the electrical connection is water cooled. Suitable clamping devices are used to facilitate electrode replacement.

Electrode arrangements can vary as follows:

- *Single-phase operation with metal or ceramic pots:* Several electrode arrangements can be used, depending on the size of the bath. If only two electrodes are required, they are normally positioned on the sloped-wall side and at least 125 mm (5 in.) apart. Three electrodes are usually placed so that the center electrode, equal in size to two of the other electrodes, is used as a common conductor with equal current paths to each of the outer electrodes. More than three electrodes would be arranged in multiple groups
- *Three-phase operation with metal pots:* Three electrodes are used and spaced in a manner similar to the spacing described above. They are connected to three single-phase transformers that have Y-connected secondaries and delta-connected primaries. The current flows from the electrodes to the metal pot, which is the neutral point. Several variations of the three-phase connections are used, depending on the type of furnace and load requirements

All accessories, such as starting units, sludging tools, and secondary connectors, are the same for steel-pot immersed-electrode furnaces as for ceramic furnaces.

Advantages and Disadvantages. Immersed-electrode furnaces do not require the use of iron-chromium-nickel alloy pots.

These furnaces require minimum floor space and maintenance and can be used for all types of neutral salts. Electrodes made of alloy steel should have an average service life equivalent to that indicated for steel pots in the section "Pot Service Life." Worn electrodes can be replaced while the furnace is in operation.

Depending on the positioning of electrodes, control to within ±3 °C (±5 °F) is easily obtained with immersed-electrode furnaces. Heat is generated within the bath, and overshooting is readily avoided. These furnaces lend themselves to mechanization and are suitable for high-volume production in the range of 815 to 1300 °C (1500 to 2370 °F).

The depth of salt pots for immersed-electrode furnaces is not restricted for ceramic or ceramic-lined pots. Metal pots may be restricted to depths of about 0.6 m (2 ft). Pots may vary in length and width to suit requirements, and multiple pairs of electrodes can be installed to furnish the necessary heating capacity.

The immersed-electrode furnace is not recommended for intermittent operation. Depending on furnace size, reheating the salt charge may require a day or more. Pots are not intended to be interchangeable. Removal of the pot usually involves replacement of the surrounding insulation.

Submerged-Electrode Furnaces

Submerged-electrode furnaces (Fig. 5 and furnaces A and B in the figure to Table 1) have the electrodes placed beneath the working depth for bottom heating. Many submerged-electrode furnaces are designed for specific production requirements and are equipped with patented features, which offer certain economical and technical advantages. General characteristics of submerged-electrode furnaces include:

- *Maximum work space with minimum bath area:* The electrodes do not occupy any portion of the bath surface, so that they only come in contact with the salt. Bath size is consequently smaller, and electrode life increases many times over by incorporating unidirectional wear and eliminating excessive deterioration at the air-bath interface
- *Circulation-convection currents:* Bottom heating provides more uniform bath temperatures and bath movement through the use of natural convection currents
- *Triple-layer ceramic wall construction:* The temperature gradients through the wall cause any salt penetrating the wall to solidify before it can penetrate the cast refractory material that forms the center portion of the wall construction. The design requires from 5 to 8% of the initial salt charge to fill the ceramic pot. By comparison, in some designs 140 to 150% of the initial charge is needed to seal the ceramic walls of furnaces built with two layers of ceramic brick, backed up and supported by a steel plate. Salt penetrates the ceramic walls of any furnace and distorts the geometry of the walls. Reducing the amount of salt allowed to penetrate the ceramic walls aids in maintaining dimensions and in promoting a longer furnace life
- *Electrode placement:* Enclosing the electrode in a clear rectangular box, free of any protruding obstructions, eliminates any potential hazards to operating personnel during cleaning. Any sludge formed in the furnace is removed easily by operating personnel

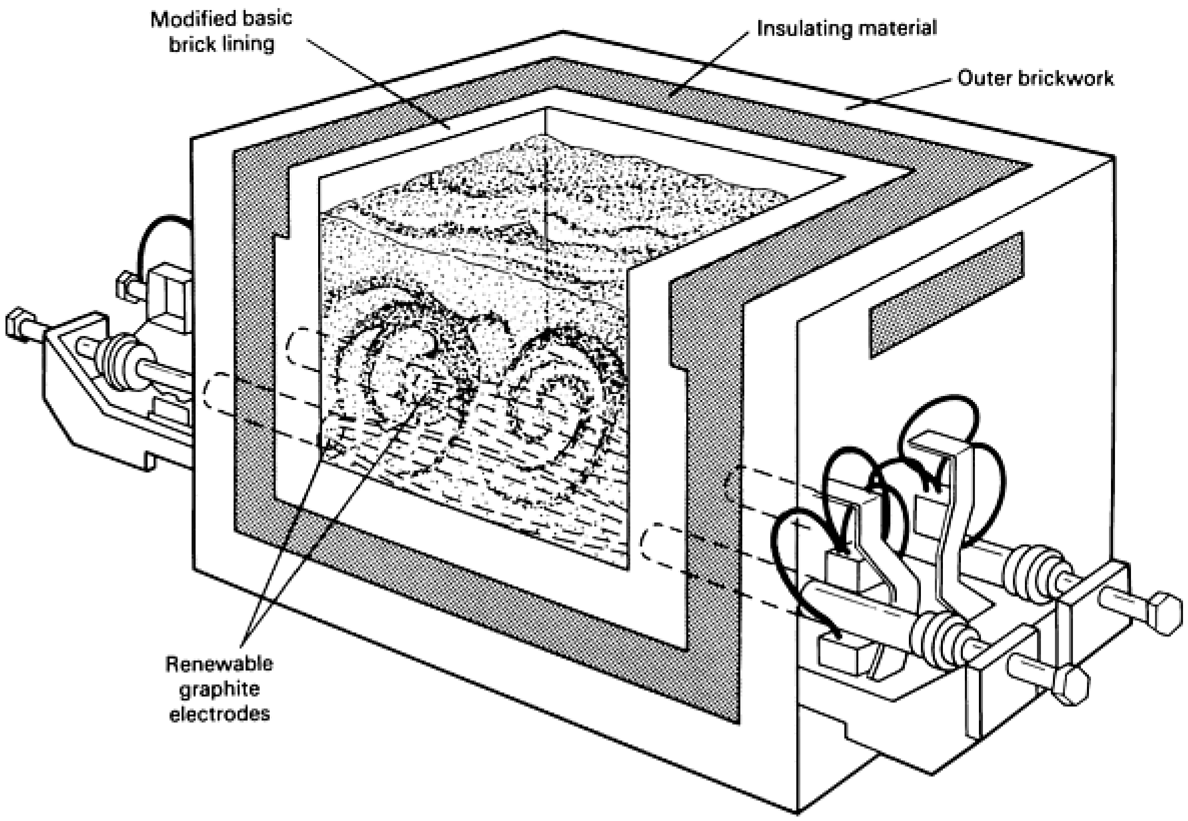

Fig. 5 Internally heated salt bath furnace with submerged electrodes. This furnace has a modified brick lining for use with carburizing salts.

Frame Construction. A typical submerged-electrode furnace is made of brick and ceramic material reassembled, regardless of size, in a rigid, self-supporting welded steel frame (see, for example, Table 1). This frame consists of supporting channels or beams welded to the underside of a heavy steel plate that forms the frame base. To this base are welded lengths of heavy angle iron around the outside and on top of the plate. These pieces are notched to permit welding of the heavy angle-iron posts to the plate and vertical sides of the base-plate angle iron. Lengths of heavy angle iron are welded similarly to the top of the posts. When required, additional vertical reinforcing members are welded between the bottom and top pieces of angle iron, and prestressed horizontal members also are used to ensure that the refractory material cannot move after the furnace has been brought to operating temperature.

Brick Construction. Three types of refractory materials are commonly used in submerged-electrode furnaces. A typical design is shown by furnace A in Table 1.

Submerged-electrode furnace liners are constructed with 230 mm (9 in.) thick high-temperature burned bricks. Consisting of approximately 42% alumina and 52% silica, the brick material is used in standard brick sizes such as 60 by 115 by 230 mm ($2\frac{1}{2}$ by $4\frac{1}{2}$ by 9 in.) and in various brick shapes, such as straights, flat backs, and splits. The bricks are laid with a high-quality air-setting mortar that resists abrasion, erosion, and chemical attack by chloride, fluoride, and nitrate-nitrite salts. The mortar offers sufficient wear and corrosion resistance to be economically used with some salts containing cyanide. For straight cyanide or carbonate salts, a welded steel pot or a furnace with a modified brick lining (Fig. 5) is used.

The outer wall of the salt bath furnaces is made of a second-quality firebrick with the same dimensions as brick used for the liner. The important qualities of this brick are the strength of the material and uniformity in size and shape.

The inner castable wall is constructed with a maximum of refractory cement and aggregate that is poured between the liner and outer wall to form a 240 mm (9.5 in.) thick monolithic wall structure. This dimension provides a temperature

gradient sufficient to cause the salt to freeze in the wall, thus making the wall self-sealing. With this design, salt penetration into the wall amounts to less than 8% of the bath volume. The maximum temperature of the outside wall during furnace operation is 60 °C (140 °F).

Electrode Construction. The electrodes used in submerged-electrode salt bath furnaces vary widely in size and shape, depending on the geometry of the furnace and the power requirements. All of the electrodes are located near the bottom of the bath and are built into the wall (furnace A in Table 1) so only one face of the electrode is in contact with the salt. This placement leaves the bath area free of obstruction for ease of cleaning and eliminates the possibility of touching the electrodes to the work.

Alloy electrodes are made by welding a 1610 mm^2 (2.50 $in.^2$) alloy material to a mild steel backing, or by welding a 125 by 125 mm (5 by 5 in.) alloy material directly to the mild steel tank. The spacing between electrode pairs is usually 65 mm (2.5 in.), or 190 mm (7.5 in.). The spacing is fixed and nonadjustable. For this reason, computation of the secondary tap voltages is critical to the successful operation of the furnace throughout its lifetime.

The durability of typical electrode and ceramic components of submerged-electrode furnaces is described in Table 1. Alloy electrodes can be replaced with graphite electrodes, which are renewed as they become consumed without disconnecting them (Fig. 5) or shutting off the power.

Startup and Shutdown. The submerged-electrode furnace can be started by adding molten salt from another furnace or by using a gas-fired torch or electric starting coil to melt a pool of salt that will wet both electrodes and provide molten salt for the current path. After the current path has been established in the molten salt between the electrodes, salt may be added to bring the bath up to working level. Additional salt will be required to maintain this level because a small amount, approximately 5%, will seep into the brickwork and freeze.

If the furnace must be shut down, the molten salt should be bailed from the furnace before it freezes. However, if the salt is allowed to remain in the furnace, a resistance-heated starting coil should be submerged in the bottom of the furnace while the salt is still molten. This coil remains in the frozen salt and it is connected to the transformer leads to start up the furnace.

Newer designs have one pair of electrodes close to the surface of the bath. When the furnace cools, the surfaced electrode pair is exposed, thus simplifying startup.

Advantages and Disadvantages. In common with the immersed-electrode furnaces, submerged-electrode furnaces require minimum floor space and maintenance and are highly adaptable to mechanization.

Because the submerged-electrode furnace employs water to cool the electrodes and transformer, it may be operated at 50% overload without overheating the transformer, whereas the immersed-electrode furnace, being air-cooled, should not be operated at an overload above 10%.

Because a ceramic pot is used, unexpected pot failure is rare with submerged-electrode furnaces, and the furnaces can be rebuilt on a planned schedule during annual shutdowns. In common with other electrical equipment, submerged-electrode furnaces are at a disadvantage where electric power rates are high, but this can be overcome to some extent by working the furnace in nonpeak periods when lower power rates are applicable.

Because of the erosive effects on ceramic pots of water-soluble salts with high sodium carbonate or high sodium cyanide contents, submerged-electrode furnaces can be used with only low-cyanide, low-carbonate salts. Baths with high cyanide or carbonate salt require a modified basic brick. The furnace with modified brick and submerged alloy electrodes provides many years of service in noncyanide and cyanide operations. To increase furnace life, the furnace shown in Fig. 5 is recommended. This furnace has a modified basic brick lining for use with basic carburizing salts. The alloy electrodes are replaced with continuing graphite electrodes. The electrodes are renewed as they become consumed without disconnecting them or even shutting off the power.

Air-Quality Assurance

Salt bath furnaces that operate at temperatures above 650 °C (1200 °F) will fume. An open furnace containing a 50-50% NaCl/KCl mix, operating at 870 °C (1600 °F) at sea level, will fume at a rate of 0.2 kg/m^2 per h (0.04 lb/ft^2 per h).

Sodium chloride and potassium chloride are both edible; however, in large quantities they can be a nuisance. The best way to overcome this nuisance is to capture it at the source.

Figure 6 illustrates two ways of capturing fumes from a salt bath furnace. The 380 mm (15 in.) location of a capture hood (Fig. 6a) requires treatment of 200 m^3/min (7120 ft^3/min) of air and fumes, whereas a canopy hood (Fig. 6b) at 305 mm (120 in.) requires treatment of over 900 m^3/min (32 000 ft^3/min) of fumes and air. When the basket and parts are lifted from the salt bath, fumes are greatly increased, probably in proportion to the total surface area of the basket and parts exposed to air (plus the bath surface fumes). It is important to remember that the fumes coming off a salt bath are hotter and have more energy than fumes at standard temperature and pressure. To calculate the type and amount of ventilation required, consult Ref 2.

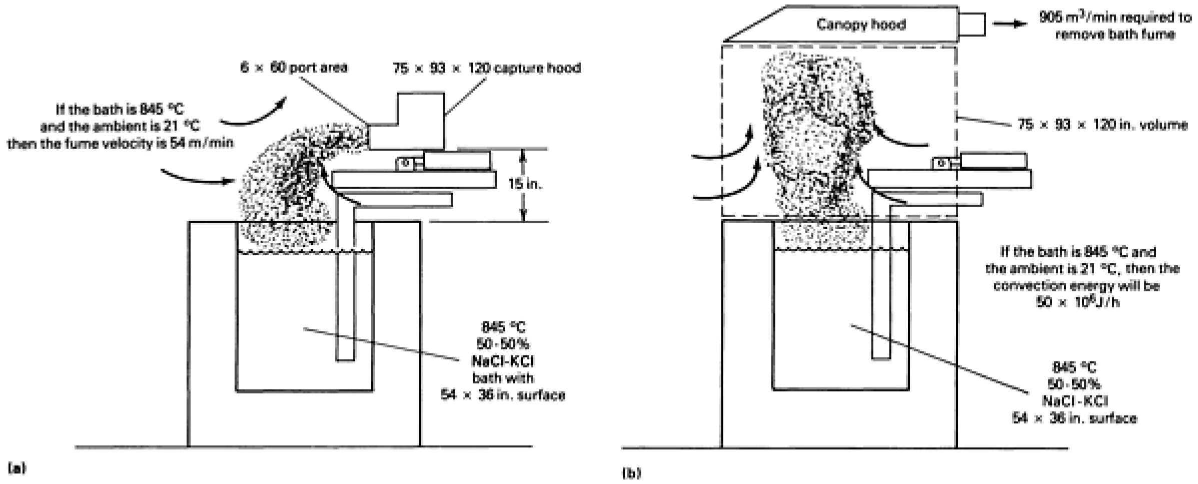

Fig. 6 Ventilation of a salt bath furnace with (a) a capture hood and (b) a canopy hood. The capture hood in (a) requires a ventilation rate of 200 m^3/min (7120 ft^3/min), whereas the canopy hood in (b) requires a larger ventilation rate of 905 m^3/min (32 000 ft^3/min). All dimensions given in inches

Isothermal Quenching Furnaces for Austempering or Martempering

Isothermal quenching furnaces are pot-type furnaces with salt agitation, cooling, and chloride-elimination features. As little as 10% chloride salt will cause the quench rate of a salt quench to be reduced by 50%. Isothermal quenching furnace systems were designed to eliminate the occurrence of chloride carryover from the austenitizing bath to the quench bath, through salt separation and uniform vertical lamellar flow agitation. The three most common approaches to alleviating the salt concentration are chemical, temperature, and gravity separation.

Chemical Precipitation. Chemical agents have been used to attempt to lower the solubility of the chloride salts so that they will precipitate in the quenching salt. When the salts settle to the bottom of the quench tank, they are removed as sludge. This method offers little success because the precipitate that forms is fine textured and buoyant and therefore tends to remain in suspension rather than to precipitate out.

Temperature Precipitation. The elimination of carryover salts has also been attempted by continuously pumping salt through a small auxiliary chamber whose temperature is maintained at a lower level than the main chamber. As the salt is processed through the auxiliary chamber, chlorides are continuously precipitated out.

Although this method appears practical, a fundamental error exists in its application. The salt is cooled by air blown through a space between the pot and the outer shell of the precipitation chamber. Air is blown through this space to maintain the temperature levels of the main chamber and precipitation chambers. The moving air cools the pot walls below the salt-precipitation point so that the salt freezes and cakes to the sides. Salt buildup continues until the bath is

unusable. Consequently, depending on the level of salt concentration, the bath would have to be shut down, possibly after only a few weeks of operation, to remove the remaining molten salt and chip away the caked salt.

Gravity Separation. This system of carryover salt removal also uses a two-chamber design. The caking problem is eliminated by heavily insulating the pot walls at all points and using an internal air-water heat exchanger. Because the pot walls and the salt are at the same temperature, there is no caking action. The chloride salts settle into an easily removable shallow pan at the bottom of the precipitation chamber, or, if they are fine textured and buoyant, the salts float to the top of the tanks and are easily skimmed off.

The main advantages of two-chamber gravity-separation equipment include:

- Easily removable variable-speed propeller-type agitator with suitable baffling to provide vertical lamellar flow within the quench area, therefore ensuring maximum quench power and minimum distortion
- Separate chloride precipitation chamber with adjustable weirs to maintain a low chloride level and subsequently high quenching power
- Easily removable internal heat exchanger to maintain quench temperature and precipitate chlorides
- Easily removable settling pan to ensure maximum efficiency in removal of chlorides
- Heavily insulated pot and precipitation chamber to eliminate salt caking on walls

Furnace Heating. Generally either gas or electricity may be used to heat isothermal quenching furnaces. When gas heating is desired, immersion tubes are recommended because they are usually made of mild steel and provide long service life.

Further, if the pot should develop a leak, the insulation and outer shell will contain the salt. *Caution: If a furnace with an externally heated pot were to develop a leak, the nitrate-nitrite salt would drip on the hot refractory and may cause a fire hazard.* One or more immersion tubes normally are used, depending on bath size. Generally, they will have nozzle-mix sealed-in burners and will be available to Factory Mutual or Factory Insurance Association specification.

Electric heating may be by one of the following methods, depending on the maximum operating temperature:

- *Sheathed resistance strip heaters* are mounted externally to the side walls near the bottom. Maximum operating temperature is 425 °C (800 °F). They are easily removable through the insulated plug-type door. Protection against overshooting is achieved by locating a sensing device close to the heaters. The sensors operate directly on line voltage
- *Sheathed resistance immersion heaters* have a maximum operating temperature of 425 °C (800 °F). They can operate without a transformer but are susceptible to premature burnout due to the sludge accumulation or operator tampering and abuse
- *Immersed-electrode heaters* operate in the same manner as electrode pot furnaces for carburizing and tempering

Furnace Construction. The pot is fabricated from firebox-quality steel plate, double welded inside and out and properly supported to maintain its shape. Steel plate offers adequate resistance to chemical attack by the standard alkaline nitrate-nitrite salts at normal austempering and martempering temperatures. The pot is insulated with 100 to 150 mm (4 to 6 in.) of slab-type mineral insulation to prevent the chloride-saturated nitrate salt from freezing to the side walls or the bottom. The insulation is externally contained by a continuously welded outer steel shell. The shell is reinforced to ensure retention of the original shape and dimensions throughout its designed operating temperature range.

Automatic and Semiautomatic Lines

The use of automated hoists makes possible the combination of austempering, martempering, and tempering or carburizing in one line. One or more hoists travel back and forth, automatically advancing the fixture carriers of work through the required stations.

The hoist movement is controlled by a solid-state programmable control with functions that would normally require hundreds of relays, counters, switches, and extensive wiring. Once programmed, the controller performs the desired commands and functions. Time cycles, sequences, drills, and skips are easily entered or changed to meet metallurgical requirements. For instance, parts can be programmed to be carburized, air cooled, washed, rinsed, and returned for unloading. A push-button command then returns the program to standard processing.

Parts suitable for fully automatic or semi-automatic installations are those that can be fixtured by wiring, racking, or placing in baskets and that do not present problems in either buoyancy or drainage.

Fluidized-Bed Heat-Treating Equipment

Revised by Robert F. Sagon-King, Can-Eng Ltd

Introduction

FLUIDIZED-BED TECHNIQUES are not new to the metalworking industry. A 19th century American patent describes the roasting of minerals under fluidized-bed conditions. Other established applications include potter's clay and miner's hydraulic slurries. Systems of fluidized solid particles, such as quicksand, occur in nature.

Early attempts to use fluidized beds in the heat treatment of metals were limited in the temperatures that could be employed. Electrically heated furnaces capable of maintaining fluidized beds at temperatures up to 500 °C (930 °F) could be produced commercially, but difficulties were encountered when attempts were made to attain higher temperatures. A principal problem was the high rate at which refractory distributors, which distribute the hot fluidizing gases, were consumed.

In early gas-fired fluidized-bed furnace design, gas entered the base of the container after being mixed with air to make it ignitable at the point of entry. With newer designs, the mixtures are introduced separately and thus cannot be ignited accidentally. This design eliminates the danger of explosion at the point of entry. The surface of the bed is heated first, and the heating of surface particles causes progressive ignition downward through the container until the entire contents of the bed achieves uniform heat-treating temperature. Newer furnace designs extend fluidized-bed technology into the higher temperature ranges (540 to 1040 °C, or 1000 to 1900 °F) required for most common heat treatments.

Principles of Fluidized-Bed Heat Treating

In fluidization, a bed of dry, finely divided particles, typically aluminum oxide in the heat-treating context, is made to behave like a liquid by a moving gas fed upward through a diffusor or distributor into the bed. A gas-fluidized bed is considered a dense-phase fluidized bed when it exhibits a clearly defined upper limit or surface. At a sufficiently high fluid-flow rate, however, the terminal velocity of the solids is exceeded, the bed goes into motion, and the upper surface of the bed disappears. This state constitutes a disperse, dilute, or lean-phase fluidized bed with pneumatic transport of solids. The general phases or stages of fluidization are shown in Fig. 1. Usually the aggregative or bubbling-type stage is used for heat-treatment processes.

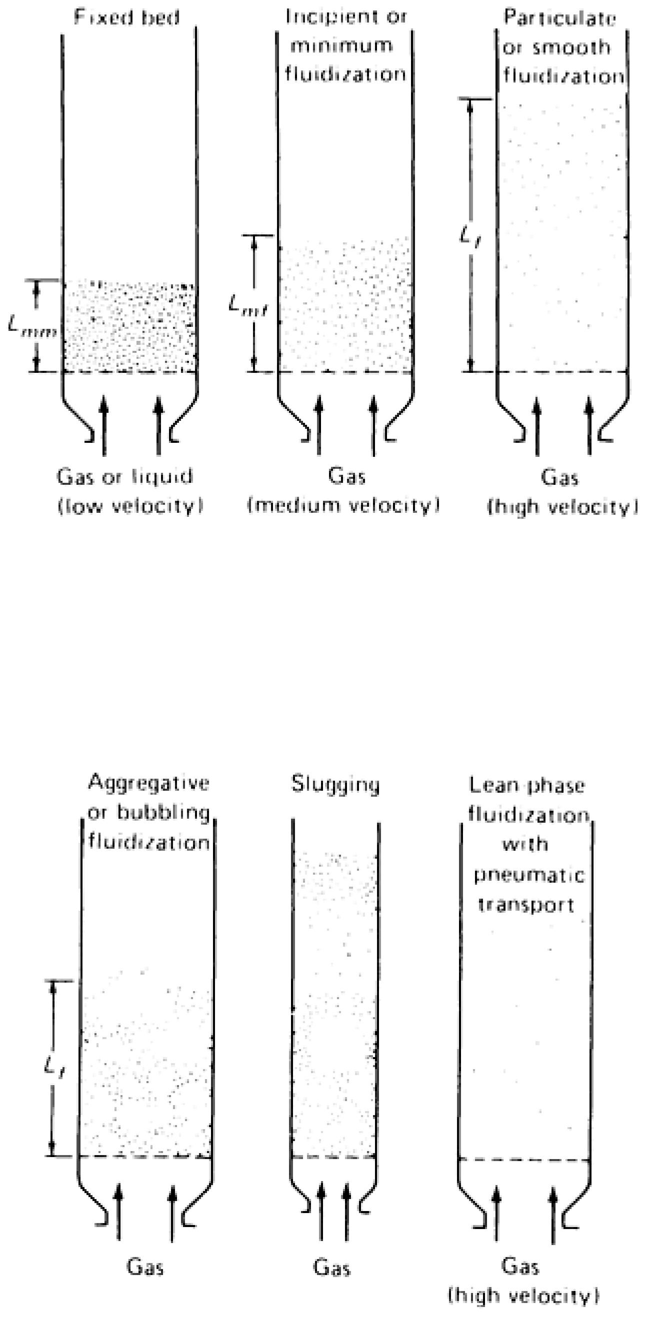

Fig. 1 Various types of contacting in fluidized beds

Although the properties of solid and fluid alone determine the quality of fluidization (that is, whether smooth or bubbling fluidization occurs), many factors influence the rate of solid mixing, the side of the bubbles, and the extent of heterogeneity in the bed. These factors include bed geometry, gas-flow rate, type of gas distributor, and internal-vessel features such as screens, baffles, and heat exchangers.

Determination of Fluidization Velocity. In determining the quality of fluidization, a diagram of pressure drop (Δp) versus velocity (μ_0) is useful as a rough indication when visual observation is not possible. A well-fluidized bed will behave as shown in the diagram in Fig. 2, which has two distinct zones. In the first, at relatively low flow rates in a packed bed, the pressure drop is approximately proportional to the gas velocity and usually reaches a maximum value (Δp_{max}) slightly higher than the static pressure of the bed. With an increase in gas velocity, the packed bed suddenly "unlocks" and becomes fluidlike.

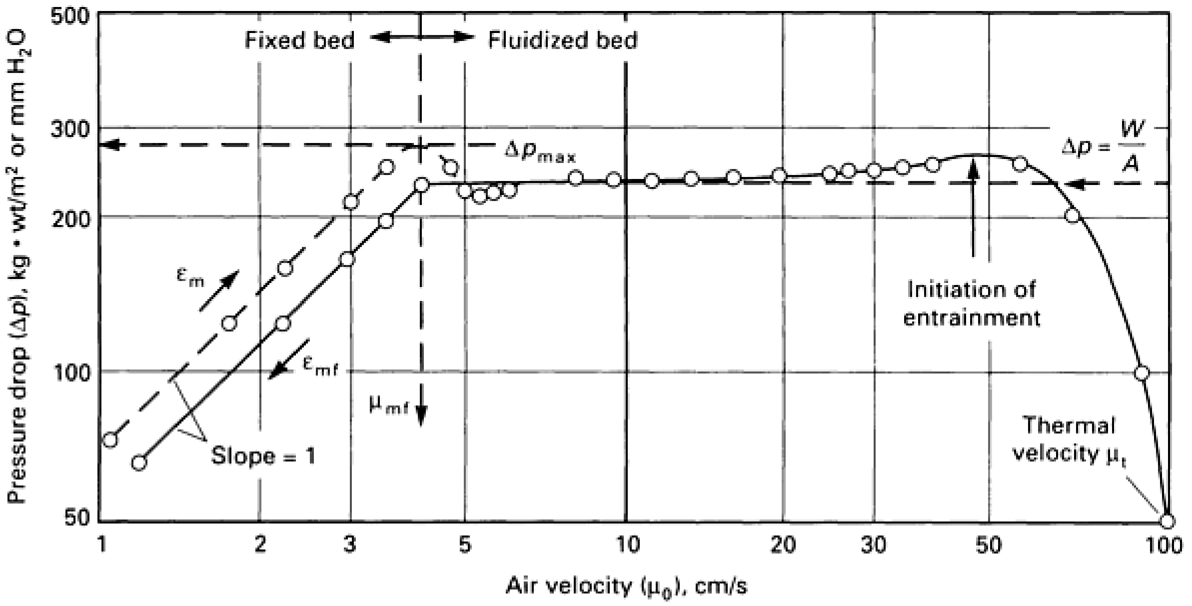

Fig. 2 Pressure drop versus gas velocity for a bed of uniform-sized particles. M_{mf}, minimum fluidization velocity. Source: Ref 1

When gas velocity increases beyond minimum fluidization (μ_{mf}), the bed expands and gas bubbles rise, resulting in a heterogeneous bed. This is the second zone, in which, despite a rise in gas flow, the pressure drop remains practically unchanged. The dense gas-solid phase is well aerated and can deform easily without appreciable resistance. In its hydrodynamic behavior, the dense phase can be likened to a liquid. If a gas is introduced into the bottom of a tank containing a liquid of low viscosity, the pressure required for injection is roughly the static pressure of the liquid and is independent of the flow rate of the gas. The constancy in pressure drop in both the bubbling liquid and the bubbling fluidized bed may be taken intuitively to be analogous.

The diagrams in Fig. 3 show poorly fluidized beds. The large pressure fluctuations in Fig. 3(a) suggest a slugging bed. In Fig. 3(b), the absence of the characteristic sharp change in slope at minimum fluidization and the abnormally low pressure drop suggest incomplete contacting, with particles only partly fluidized.

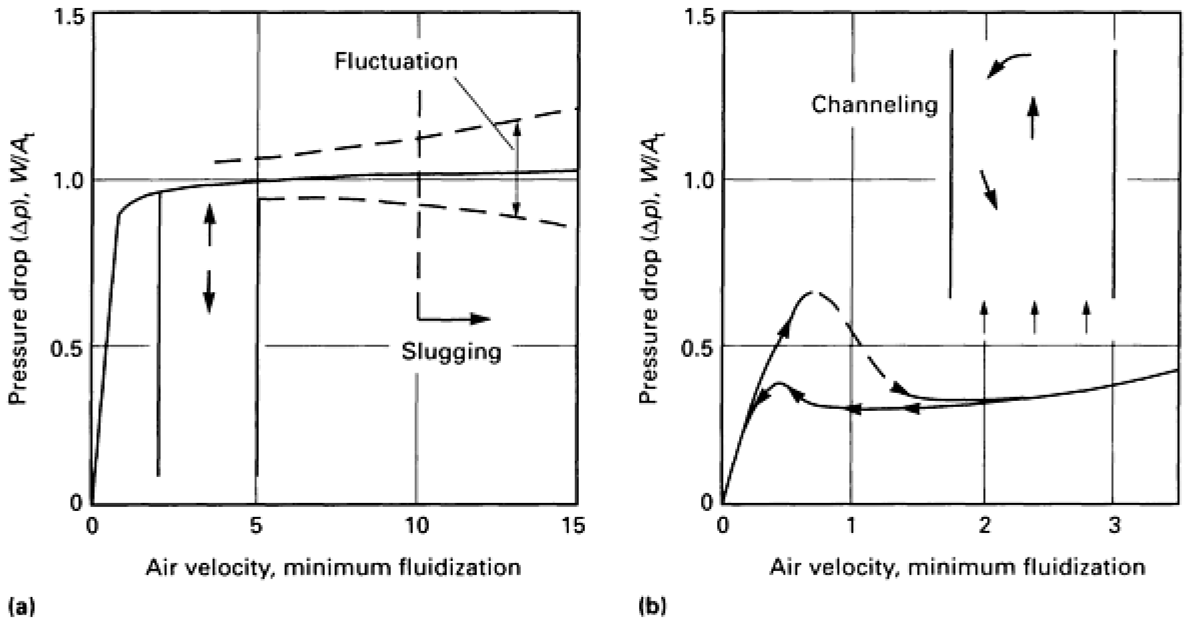

Fig. 3 Pressure drop diagrams for poorly fluidized beds. Source: Ref 1

One of the most important factors influencing the quality of fluidization is the uniformity of gas flow across a constant pressure drop. Figure 4 illustrates this schematically.

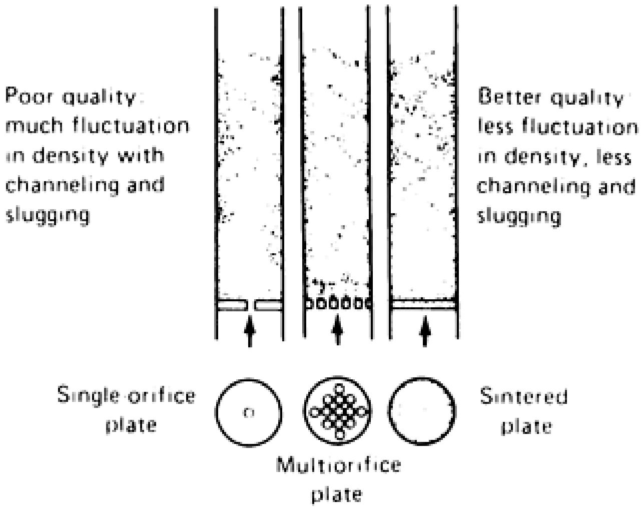

Fig. 4 Quality of fluidization as influenced by type of gas distributor. Source: Ref 1

Temperature Effect on Minimum Fluidization Velocity. One of the most important parameters of a fluidized bed is the minimum fluidization velocity. In simplified terms, minimum fluidization velocity (μ_{mf}) approximates to a function of the square of the particle diameter (*d*) and a linear function of particle mass (*p*) as:

$$\mu_{mf} \cong d^2 p \qquad \textbf{(Eq 1)}$$

In the design of heat-treating furnaces, the effect of temperature must be considered. Figure 5 shows that the flow of gas required for fluidization decreases rapidly with increases in temperature.

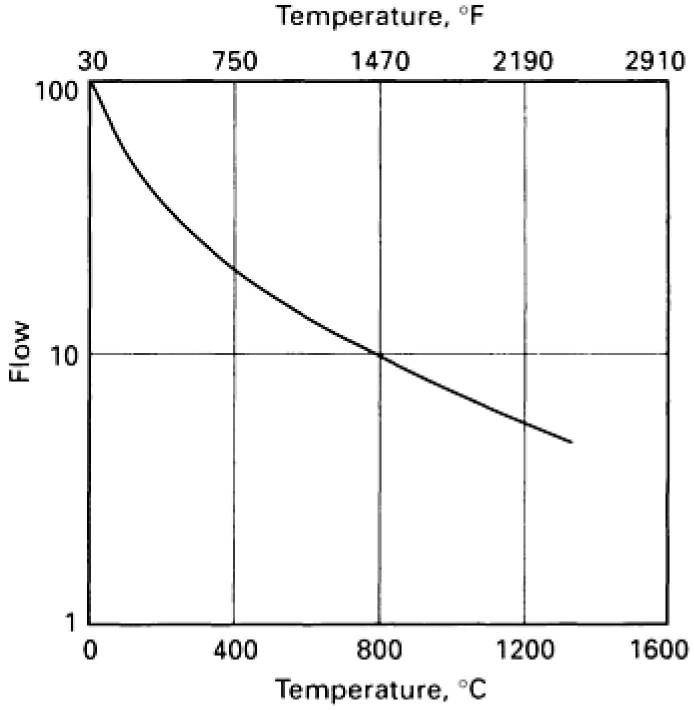

Fig. 5 Effect of temperature on the flow corresponding to minimum fluidization for particles 0.1 mm (0.004 in.) in diameter having an apparent density of 2

Defluidization. One of the common concerns about fluidized beds is that, because of their principle of operation, they are not well suited for large, solid parts with horizontal surfaces that remain stationary in the bed. This a result of the incorrect belief that fluidization occurs only in a vertical direction. With parts of this type, a cap of nonfluidized particles collects on the horizontal surfaces, forming a thermal screen. The higher the temperature of operation, however, the greater the energy and agitation of the bed and the smaller the likelihood that the bed will collapse. Moreover, various methods can be used to overcome this apparent disadvantage, and these are designed into most fluidized beds. These methods are:

- Movement of the part being treated
- Introduction of additional agitation in the zone of fluidization around the part, either by localized injection of fluidizing gas or by careful design of the outline of the basket that holds the parts
- Increased fluidizing velocity
- A more favorable orientation of the part

Selective Heat Treatment. Bed collapse can be turned to advantage for special heat treatments in which one area of the path must be hard and tough and the remainder must be soft and more ductile, as in the case of the engineered parts of the shape described above. In this case, after uniform heating, the part is removed from a hot fluidized bed and partially submerged in a fluidized quenching bed, with the part to be hardened facing down. The top horizontal surface becomes covered with a cap of particles that form a thermal screen, which retards the vigorous cooling caused by the fluidized bed.

Heat Transfer in Fluidized Beds

An important characteristic of fluidized beds is high-efficiency heat transfer. The turbulent motion and rapid circulation of the particles in the fluid furnace provide a heat-transfer efficiency comparable to that of conventional salt bath or lead bath equipment.

The heat transfer coefficient of a fluidized bed is typically between 120 and 1200 W/m^2 · °C (21 and 210 Btu/ft^2 · h · °F). The turbulent motion and rapid circulation rate of the particles and the extremely high solid-gas interfacial area account for this feature. The following factors are important in heat transfer.

Particle Diameter. Of all the parameters that affect the heat transfer coefficient in fluidized beds, particle diameter exerts the greatest influence. Particle diameter is generally a compromise between conserving fluidized gas flows and avoiding entrainment or carry-out. Normally a sieve size of 80 to 100 grit is used.

Bed Material. The governing physical property of any bed material is its density. There appears to be an optimum density for bed materials: about 1280 to 1600 kg/m^3 (80 to 100 lb/ft^3). High-density materials tend to produce lower heat transfer coefficients and in addition require more power for fluidization. Carry-out problems occur with low-density materials. Other properties, such as thermal conductivity and specific heat, are less important.

Fluidization Velocity of Gas. It is essential to use the optimum flow rate, that is, one that provides the maximum heat transfer rate for a particular particle density and diameter. Generally, this flow rate is considered to be between two and three times the minimum fluidization velocity. Too high a velocity leads to particle entrainment, high consumption of fluidizing gas, and poor heat transfer; too low a velocity leads to poor heat transfer and lack of uniformity in processing.

Heating Rates. Relative heating rates of a 16 mm (0.6 in.) steel bar in salt, in lead, in a fluidized bed, and in a conventional furnace are illustrated in Fig. 6(a); relative cooling rates for air, oil, water, and a fluidized bed are shown in Fig. 6(b). Figure 7 presents heating and recovery rates for a fluidized bed. Results of both hardening and isothermal quenching of type D3 tool steel with salt baths and with fluidized beds are given in Table 1. The difference between the two installations in total time for final heating and holding resulted from a difference in preheating conditions.

Table 1 Comparison of the effects of hardening and isothermal quenching of type D3 tool steel in salt baths and in fluidized beds

Heating or cooling medium	Diameter of test pieces		Preheating temperature		Total time for final heating and holding at 960 °C (1760 °F), min	Hardness, HRC	
	mm	in.	°C	°F		At surface	At center
Salt bath	80	3.2	500	930	44	65.5	65
Fluidized bed[(a)]	80	3.2	490	915	51	65	65
Salt bath	40	1.6	540	1000	36	64.5	64
Fluidized bed	40	1.6	500	930	41	64.5	64

(a) Small parts of the same steel but with a diameter of 8 mm (0.3 in.) were treated at the same time; hardness of these parts was 66 HRC.

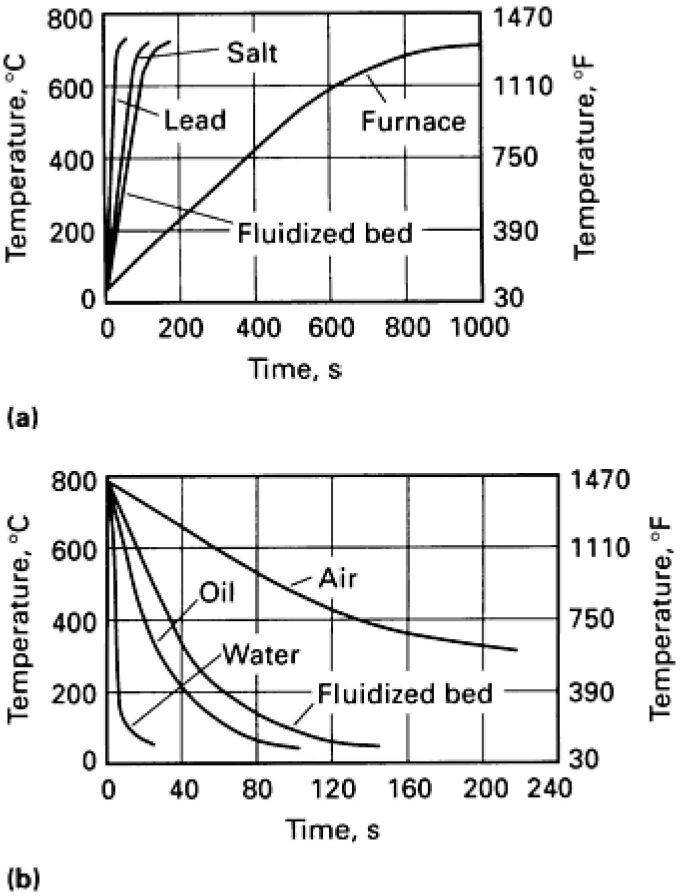

Fig. 6 Relative heat transfer rates. (a) Heating rates for 16 mm (0.6 in.) diam steel bars in lead, in salt, in a fluidized-bed furnace, and in a conventional furnace. (b) Quenching rates for 16 mm (0.6 in.) diam steel bars in air, in oil, in water, and in a fluidized-bed furnace. Source: Ref 1

Control of Atmospheres

A full range of atmospheres can be used within the work zones of fluidized beds. The volume of gas used is clearly dictated by particle size, temperature of operation, and optimum fluidization velocity. However, it can be shown that, with careful design and the use of low-cost carrier gases such as nitrogen, even low-temperature surface treatments can be both effective and economical. In addition, one of the major advantages of a fluidized bed is that expensive gas need not be consumed while there is no work in the bed. Atmosphere conditioning is rapid: within about 30 to 60 s after an inert gas is introduced into the bed, the purity of the atmosphere is equivalent to that of the gas supply. In fluidized beds, various types of atmospheres can be obtained, as discussed below.

Reducing or Oxidizing Atmosphere. Adjustment of a gas-air mixture to the bed so that it is either gas-rich or oxidizing causes some decarburization or oxidation reactions in the materials being processed (the gas-rich mixture produces somewhat less severe reactions). However, these are time-dependent reactions, and, because of the rapid heating rates of parts being processed and the subsequent short immersion times needed to obtain the correct structure and through hardness, little surface effect other than discoloration and slight scaling is exhibited in section sizes up to 25 mm (1 in.). For larger sizes, the user must be aware of surface reactions that can occur, particularly as the processing temperature increases. Figure 8 shows the relative decarburization bands for steels held in a fluidized bed.

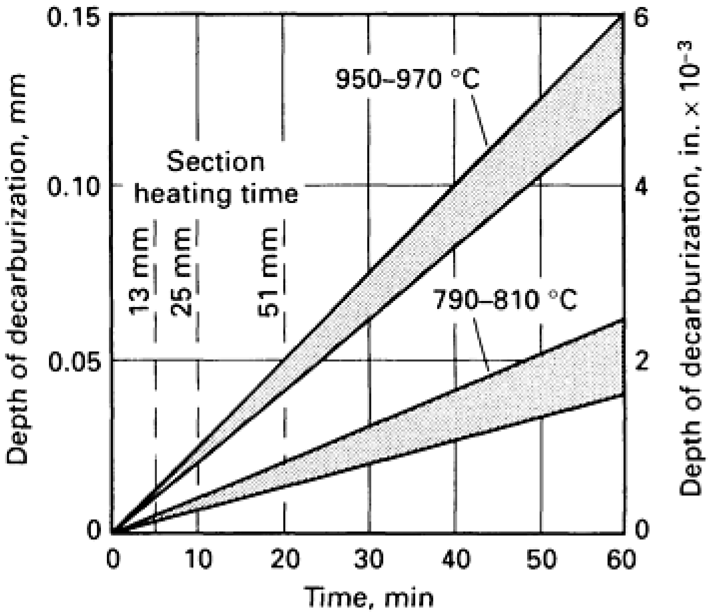

Fig. 8 Representative decarburization bands for steel held in a fluidized bed. Steels used: type O1 and type D3 tool steels and 0.75% C plain carbon steel. Source: Ref 1

Neutral Hardening and Carburizing. Atmospheres for the neutral hardening of tool steels or the carburizing of low-carbon steels can be used for bed flotation. This practice allows oxygen-free heating of tool steels. However, care must be taken during the transport of workpieces to the quench tank to prevent decarburization or oxidation.

1. R.W. Reynoldson, Controlled Atmosphere Fluidized Beds for the Heat Treatment of Metals, *Heat Treatment of Metals,* University of Aston in Birmingham, 1976

Fluidized beds, using atmospheres composed of ammonia, natural gas, nitrogen, and air, or similar combinations, are capable of performing low-temperature nitrocarburizing treatments equivalent to conventional salt bath processes or other atmosphere processes. High-speed steel tools oxynitrided in a fluidized bed are comparable to similar tools treated by the more conventional gaseous process. Carburizing and carbonitriding in a fluidized bed can yield results similar to those achieved in conventional atmosphere furnaces.

Mixtures of propane and air produced the results shown in Fig. 9, which compares the case depths obtained on SAE 8620 steel bearing rings carburized in a fluidized bed and by the conventional atmosphere process. An effective case depth of 1 mm (0.04 in.) was achieved in 1.5 h using the fluidized-bed technique. Developmental work on this process is still being performed, but sufficient knowledge exists to compare the mechanisms of conventional gas carburizing and the fluidized-bed process.

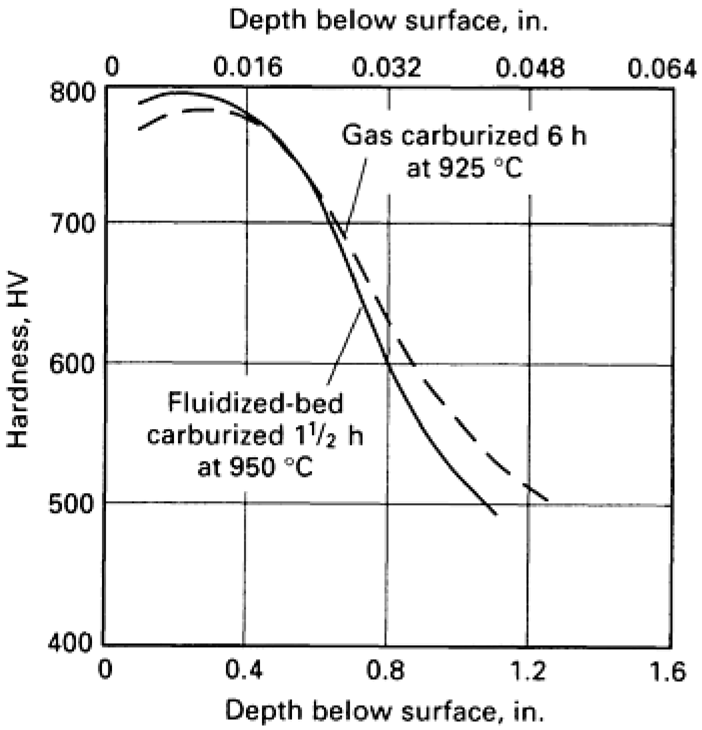

Fig. 9 Comparison of hardness profiles obtained by fluidized-bed and conventional gas carburizing. SAE 8620 steel, rehardened from 820 °C (1510 °F). Source: Ref 1

Conventional Gas Carburizing. Carburizing occurs through the catalytic decomposition of CO according to:

$$CO + H_2 \rightarrow C_{Fe} + H_2O \quad \textbf{(Eq 2)}$$

Propane enrichment aids this reaction according to:

$$C_3H_8 + 3CO_2 \rightarrow 6CO + 4H_2$$
and
$$C_3H_8 + 3H_2O \rightarrow 3CO + 7H_2 \quad \textbf{(Eq 3)}$$

Fluidized-Bed Carburizing. The relatively large volumes of propane consumed during fluidized-bed carburizing, together with high gas velocities, favor carburization by the thermal decomposition of propane to precipitate carbon in accordance with:

$$C_3H_8 \rightarrow C \downarrow + 2CH_4 \qquad \textbf{(Eq 4)}$$

The amount of carbon precipitated is proportional to the number of carbon atoms in the hydrocarbon fuel gas; that is, propane forms more carbon than does methane. In addition, the purity of propane is important, especially with respect to unsaturated hydrocarbon content, which increases its carbon-forming capability.

The precipitated carbon reacts instantaneously with the oxidizing products of combustion:

$$C_3H_8 + 5O_2 \; f \; 3CO_2 + 4H_2O \qquad \textbf{(Eq 5)}$$

to form carbon monoxide and hydrogen:

$$\begin{array}{l} C + H_2O \rightarrow CO + H_2 \\ \text{and} \\ C + CO_2 \rightarrow 2CO \end{array} \qquad \textbf{(Eq 6)}$$

Carburization then proceeds by the catalytic decomposition of CO by H_2 as in conventional carburizing. It is possible that carburization is further complemented by thermal dissociation of the methane formed during carbon precipitation:

$$CH_4 \rightarrow C_{Fe} + 2H_2 \qquad \textbf{(Eq 7)}$$

The carbon potential of the atmosphere varies with the air-to-gas ratio. For each type of hydrocarbon gas (typically propane, methane, or vaporized methanol), a relationship can be established among air-to-gas ratio, temperature, and carbon potential. Control of the reaction and carbon potential of the atmosphere by conventional gas analysis is possible, and fluidized-bed furnaces are equipped with sample ports and probes so that suitable measurements can be taken.

Types of Furnaces for Heat Treating with Fluidized Beds

The type of fluidized bed most widely used for heat treatment is the dense-phase type, although units based on the dispersed-phase bed have been constructed, with particle circulation for the heat treatment of long, thin metal parts such as shafts and plates. In a typical dense-phase fluidized bed, the parts to be treated are submerged in a bed of fine, solid particles held in suspension, without any particle entrainment, by a flow of gas.

Liberation of adequate quantities of heat within fluidized beds is a prime consideration in adapting them for metal processing. Because transfer of heat from the bed to the workpiece is usually much more efficient than transfer of heat from the heat source to the fluidizing medium, the greatest difficulty is encountered in transferring suitable quantities of heat to the fluidizing medium. In addition, the major part of the heat loss from any practical fluidized system is the heat content of the spent fluidizing gas. In instances in which thermal efficiency is unduly influenced by this factor, recirculation of the fluidizing gas or installation of a recuperative system may be justified. Each has been used in practical applications. Heat input to a fluidized bed can be achieved by several different methods; the most accepted, however, are described in the paragraphs below.

External-Resistance-Heated Fluidized Beds. A fluidized bed contained in a heat-resisting pot can be heated by external resistance elements (Fig. 10). Waste heat recovery can be used to increase thermal efficiency, and the fluidizing gas can be maintained at any desired composition. Heat-up time from ambient to operating temperatures of 815 to 870 °C (1500 to 1600 °F) typically takes 3 to 4 h.

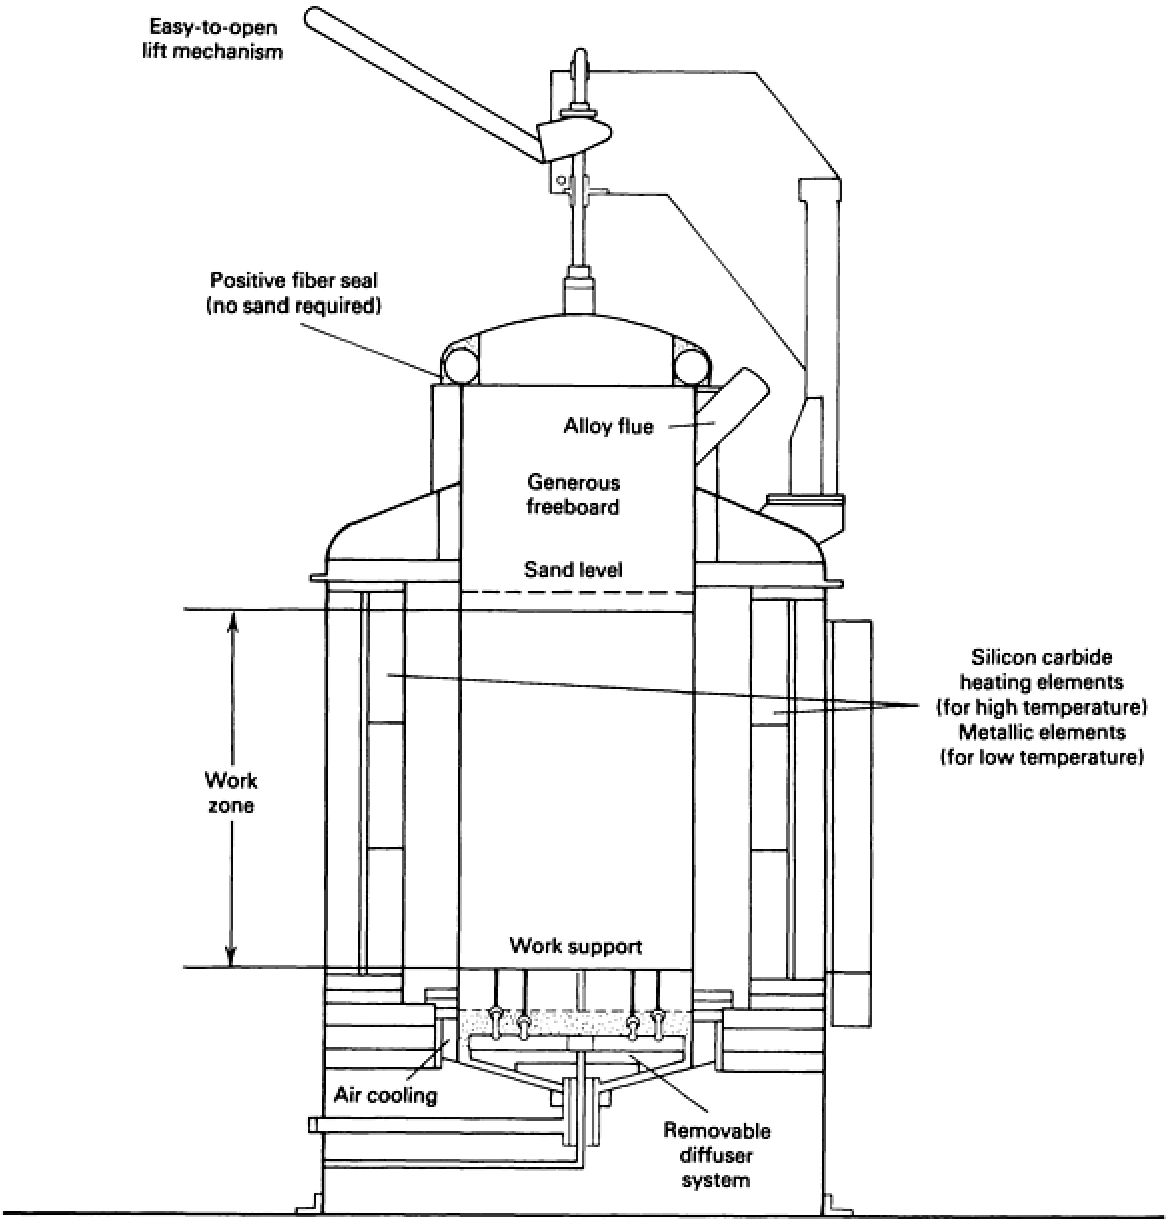

Fig. 10 Fluidized-bed furnace with external heating by electrical resistance elements

External-Combustion-Heated Fluidized Beds. A fluidized bed contained in a heat-resisting pot can be heated by external gas firing (Fig. 11). In this arrangement, a fuel-air mixture is introduced through a standard commercial burner. The burner can be controlled very accurately down to low temperatures for low-temperature tempering. The products of combustion are then removed by flue in the normal fashion.

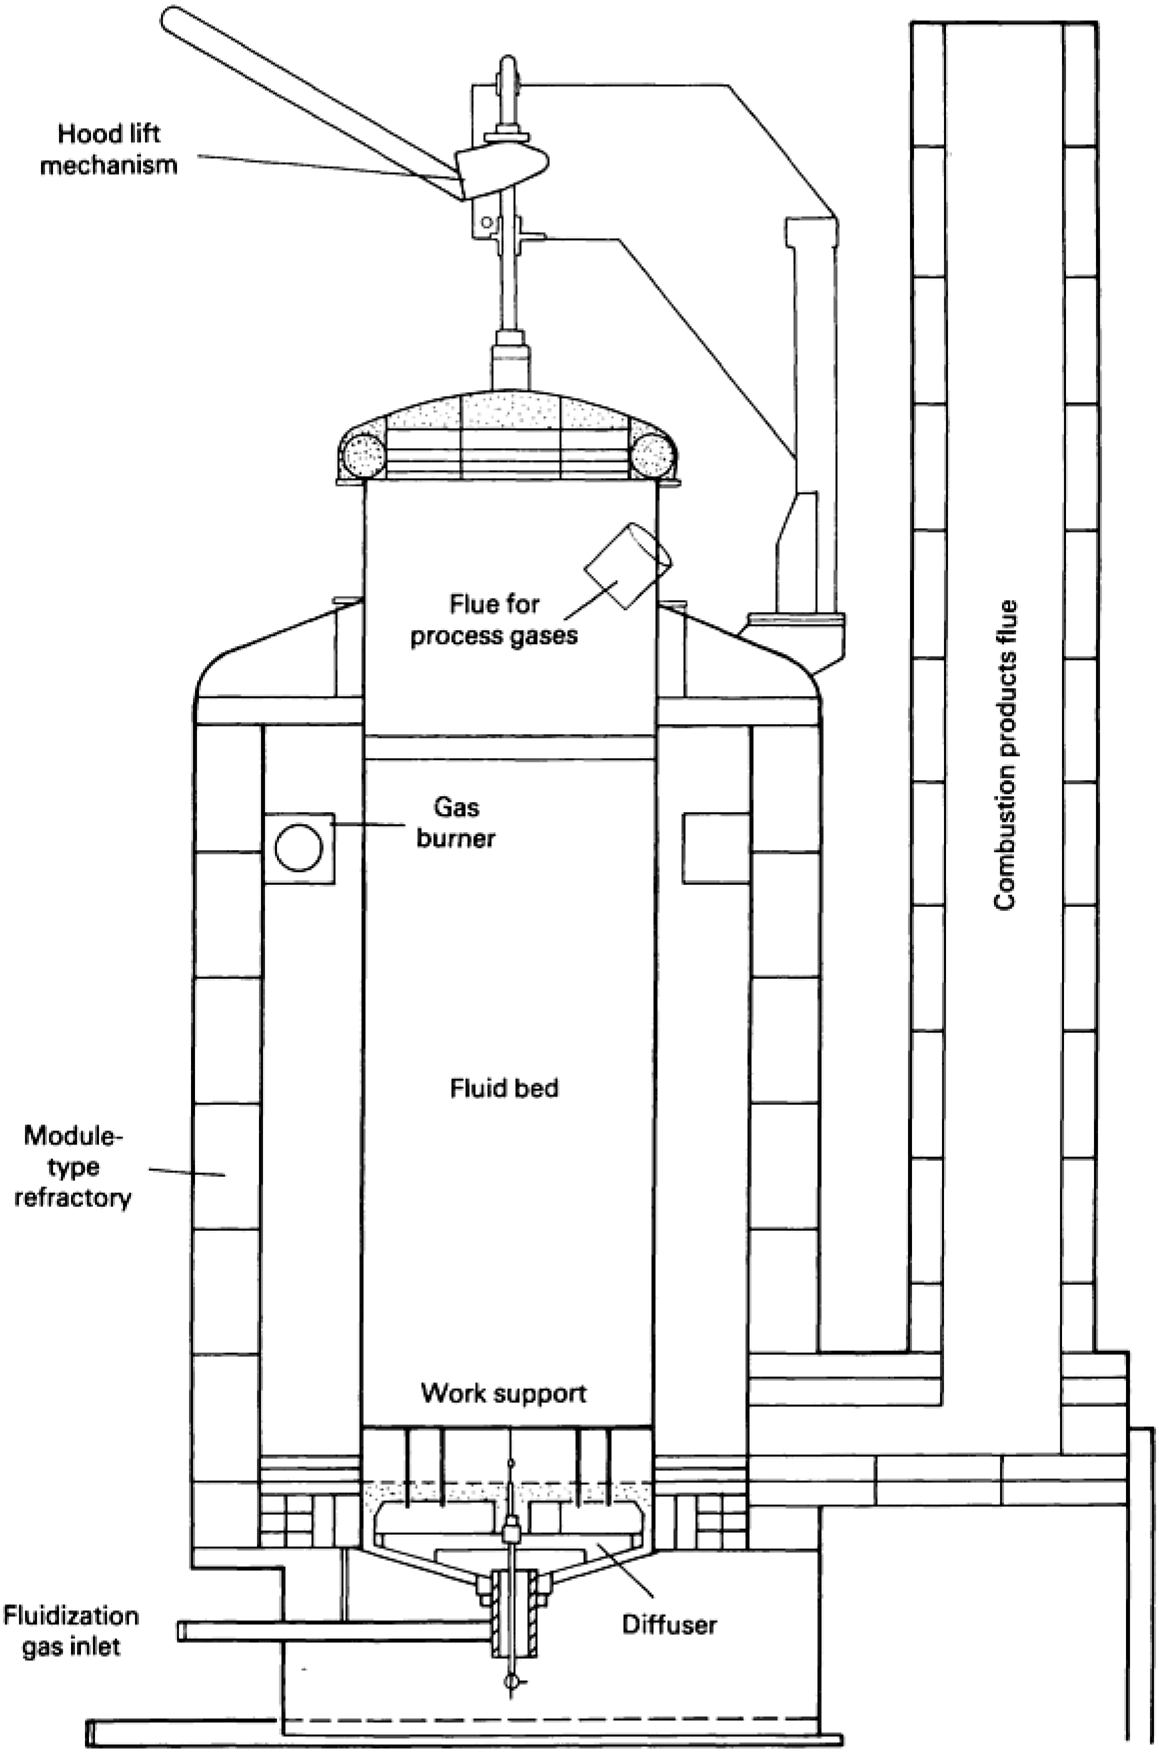

Fig. 11 Externally gas-fired fluidized-bed furnace

Submerged-Combustion Fluidized Beds. The technique of submerged combustion consists of passing the combustion products directly through the mass to be heated. This method provides an excellent rate of heat transfer and is now well established for a wide range of liquid-heating applications, from the heating of swimming pools to the concentration of acid solutions. The application of this method to the heating of a fluidized bed requires that the burner be used such that it provides strong agitation of the suspended particles, thereby achieving the desired properties of excellent heat transfer and uniformity of bed temperature.

Equipment developed for this purpose consists essentially of a burner, two concentric tubes, and a particle separator. A suitable gas mixture is fed through the burner into the central tube, where it is ignited. The flame develops in the tube, and the combustion products escape at its lower end, where they impart heat to the suspended particles before moving up through the annular space between the two tubes. As they rise, a quantity of particles is entrained. These are separated from the gas stream by the deflector plate and fall back into the bed by virtue of gravity. Figure 12 shows a system that incorporates submerged combustion with a controlled atmosphere for the low-temperature treatment of metals.

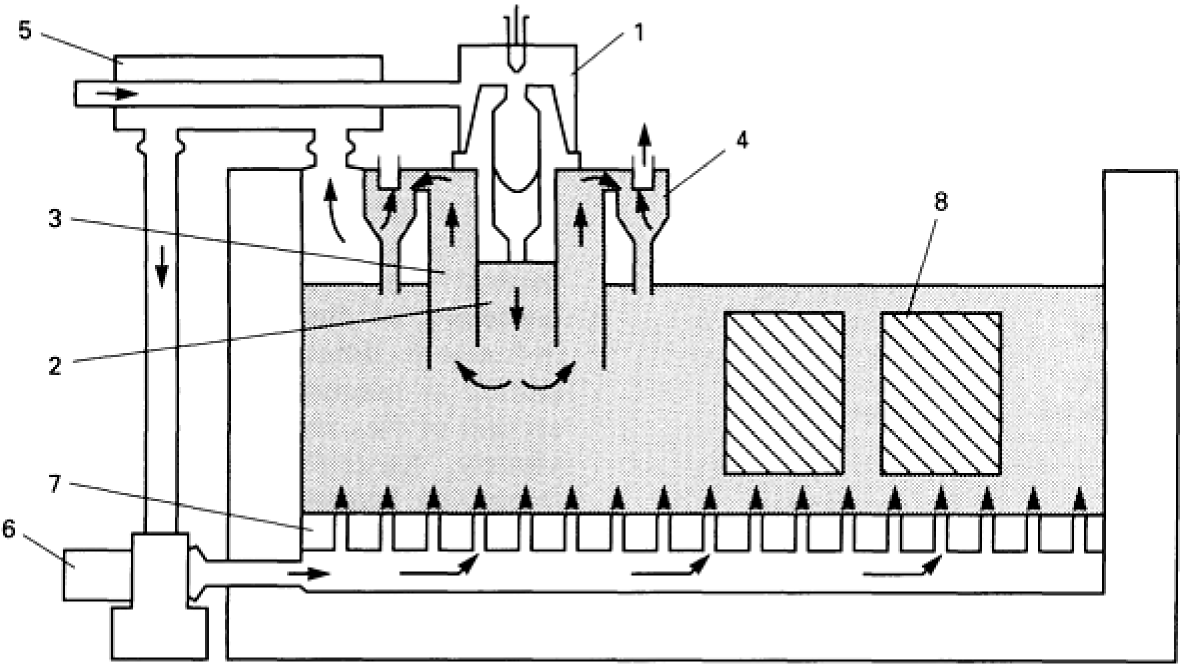

Fig. 12 Controlled-atmosphere fluidized-bed furnace heated by submerged combustion. 1, burner; 2, combustion tube; 3, tube through which combustion gases and particles rise; 4, particle separators; 5, heat exchanger; 6, gas recycle compressor for fluidization; 7, distributor plate; 8, parts to be treated

Internal-Combustion Gas-Fired Fluidized Beds. A major development in the heating of fluidized beds occurred when an air-gas mixture was used for fluidization and was ignited in the bed, generating heat by internal combustion. Prior to this breakthrough, many technical difficulties prevented the use of this mode of fluidized-bed heating. A typical furnace design incorporating this technique is shown in Fig. 13.

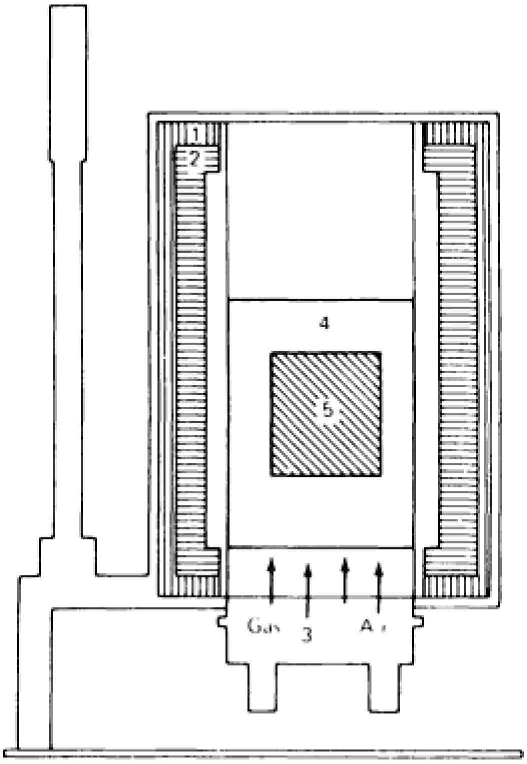

Fig. 13 Gas-fired fluidized-bed furnace with internal combustion. 1, insulating lagging; 2, refractory material; 3, air and gas distribution box; 4, fluidized bed; 5, parts to be treated

The advantage of this system is that the bed is fluidized by burning gases, and thus the heat is generated within the bed. In gas-fired fluidized beds, the supporting gas or fluidizing medium is a near-stoichiometric mixture of gas and air. This combustible mixture is ignited above the bed and quickly imparts its heat to the particles, which in turn heat the incoming gas further down the bed. After a period, combustion takes place spontaneously within the bed and is complete within the first 25 mm (1 in.) of the diffuser once the spontaneous combustion temperature for the gas being used is reached. This temperature commonly varies between 600 and 800 °C (1110 and 1470 °F). If the vessel is well insulated, the bed temperature can rise to a theoretical combustion temperature, and heat-up times from cold to 800 °C (1470 °F) are typically between 1 and $1\frac{1}{2}$ h. However, problems inherent to the basic technique are:

- The bed is fluidized by burning gases. To obtain good temperature control and optimum fluidizing conditions, however, it is desirable that the fuel input rate and fluidizing velocity be independently variable
- Combustion is somewhat unstable below the spontaneous combustion temperature
- Very high temperatures can occur in the immediate vicinity of the distributor/diffuser tile. When the bed is incorrectly fluidized so that this heat cannot be removed from the top of the distributor, theoretical flame temperatures are achieved with consequent deterioration of the distributor. The thermal stresses of expansion and contraction on the distributor tile at these high temperatures tend, even with the best fixing techniques available, to cause failure of joints, which enhances the problem

Two-Stage, Internal-Combustion, Gas-Fired Fluidized Beds. The basic problem of separating the control of heat input from the control of fluidizing velocity has been overcome in two alternative designs (Fig. 14). In both designs, the initial heat-up from cold to operating temperatures is carried out by two-stage internal combustion. A noncombustible mixture of gas and air is introduced beneath the distributor tile. Secondary air is added to make up a stoichiometric or slightly gas-rich mixture immediately above the tile by means of jet holes drilled into heat-resisting tubes. This is done to reduce the possibility of explosion and to avoid high flame temperatures at the surface of the tile. The technique has an

adverse effect on good fluidization, but this is unimportant during initial heat-up, in which the prime objective is to raise the temperature of the bed to operating temperature as quickly as possible. Once this has been accomplished, the remaining objective is to isolate the heat-up control from the control of the fluidizing velocity. This is achieved in two ways:

- *Three-chamber design:* In this design (Fig. 14a), the heat control outer chambers are separated from the treatment zone by a muffle. The fluidizing velocity and atmosphere are independently controlled in the inner chamber, while the outer two zones are still supplying heat by internal combustion. To achieve adequate heat input, fluidization levels in these outer chambers are above the optimum for heat transfer and surface reactions, but this is relatively unimportant
- *Back-radiation design:* When fuel-rich gases are permitted to burn by the injection of secondary air immediately above the control chamber of the fluidized bed, a back-radiation effect causes a rise in bed temperature. This design (shown operating in the heating/controlling and cooling modes in Fig. 14b and c) makes use of this effect and at the same time utilizes heat that is normally dissipated when gases are burned outside the furnace. It therefore uses fuel more economically. In principle, the gas-rich mixture is supplied to the central chamber, and extra air is added to produce stoichiometric conditions during initial heating of the bed. When cold work is loaded for treatment, the extra air is injected above the bed to produce a radiating flame and recover bed temperature. If bed temperature exceeds set temperature, the extra air is switched to the outside of the furnace wall to provide cooling and finally is mixed with the rich gas/air to produce combustion at the top of the specially constructed hood

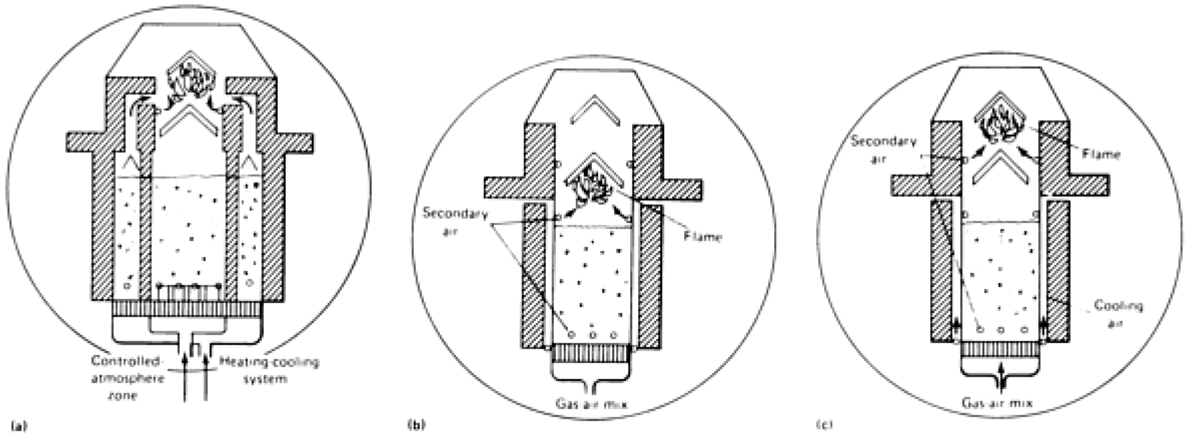

Fig. 14 Two-stage, gas-fired, internal-combustion fluidized beds. (a) Three-chamber design. (b) Back-radiation design in heating mode. (c) Back-radiation design in cooling mode

Internal-resistance-heated fluidized beds are not accepted by users. The elements and work load will make contact if insufficient care is taken.

Applications of Fluidized-Bed Furnaces

The potential applications of fluidized-bed technology to heat treating are many. Figure 15 specifies those applications in which fluidized beds can compete with conventional furnaces.

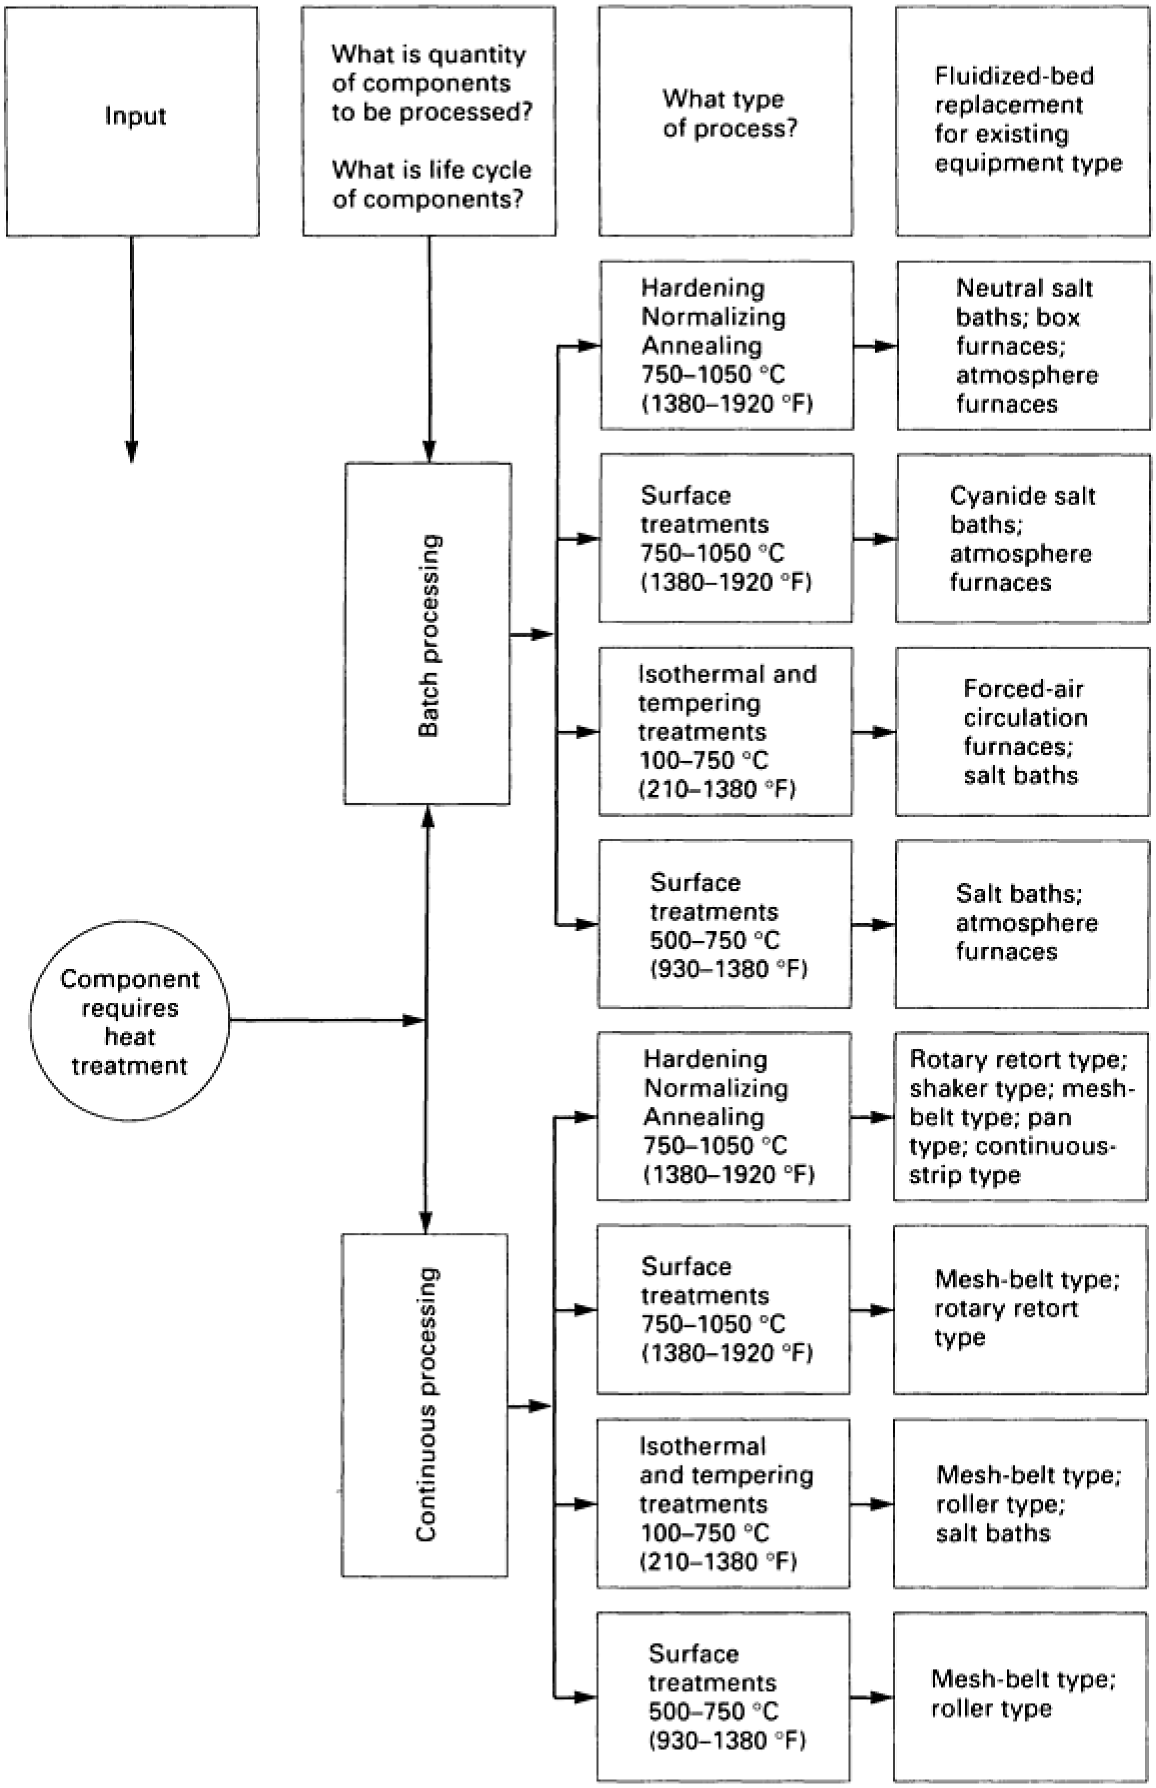

Fig. 15 Fluidized-bed applications; decision model. Source: Ref 1

Applications of fluidized-bed furnaces to the heat treatment of metals include continuous units for all types of wire and strip processing (patenting, austenitizing, annealing, tempering, quenching, and so on) and all configurations of batch-type units for general heat-treating applications. A typical batch-type unit with an output of approximately 150 kg/h (330 lb/h) is available as a standard furnace. Using mechanical handling equipment, it can be automated into a continuous heat-treatment line. The following example describes one firm's decision to install fluidized-bed furnaces for heat treatment.

Example 1: Improved Turnaround Time with Fluidized-Bed Treatment.

A company specializing in the design and production of aluminum extrusion dies had relied on sub-contract heat-treatment facilities for the hardening of dies. The decision to install in-house facilities came as a result of difficulties in meeting the 7- to 14-day turnaround of dies required by customers. Previously, hardening, case hardening, and tempering had been done by salt bath immersion. After studying alternatives, the firm decided to employ the latest fluidized-bed technology. Approximately one year later, the firm installed a second fluidized-bed furnace and made available its surplus capacity to other firms on a subcontract basis.

Carburizing, Nitriding, and Carbonitriding. In recent years, design innovation has led to the use of fluidized-bed furnaces as a practical tool for carburizing, carbonitriding, nitriding, and nitrocarburizing processes. In this technique, 80 mesh or 180 μm aluminum oxide particles produce a fluidizing effect so that the bed behaves like a liquid. When gas or electricity is used as the heat source, the bed provides a faster heat transfer medium. This is provided with quench and tempering furnaces.

Previously, gas-fired internal-combustion units or submerged combustion units were used successfully to provide both heat source and fluidizing/carburizing medium. Recently, more attention has been directed toward the use of externally heated fluidized beds, which is claimed to allow greater control over the carburizing process as a result of separate heating and fluidizing functions (Ref 2, 3). *The advantages* of the fluidized-bed process include:

- High rates of heating and flow cause the utilization of higher treatment temperatures, which, in turn, provide rapid carburizing
- Temperature uniformity with low capital cost and flexibility is ensured
- A fluid bed furnace is very tight; the upward pressure of the gases minimizes air leakage
- The process produces parts with very uniform finish

Operational Safety

As with all forms of gas heating, normally accepted safety devices are incorporated on the majority of beds presently manufactured. The "flexible-tile" concept ensures that any failure of joints does not influence the performance of the bed.

Parts carrying surface oil or moisture do not create an explosion risk because the contaminants simply vaporize and are removed with the waste gas, as in conventional furnaces. The heat transfer medium (aluminum oxide) is nonhazardous and as such is not subject to disposal restrictions.

Cleaning Operations

Fluidized solids are nonabrasive and non-corrosive and do not wet immersed objects. There is some drag-out loss of the aluminum oxide, however, because some particles accumulate on flat surfaces as work loads are removed from the fluidized bed. These particles can be removed in part by agitation, bouncing, or blowing with an air pipe. Particles can be reused by being dried, sieved, and returned to the bed. When parts already scaled or preoxidized are placed in a fluidized

bed, particles tend to adhere to the scale to a greater degree than if the workpieces were clean. These particles can be removed by water spraying.

Heat Treating in Vacuum Furnaces and Auxiliary Equipment

Revised by the ASM Committee on Vacuum Heat Treating*

Introduction

VACUUM HEAT TREATING consists of thermally treating metals in heated enclosures that are evacuated to partial pressures compatible with the specific metals and processes. Vacuum is substituted for the more commonly used protective gas atmospheres during part or all of the heat treatment. Furnace equipment used in vacuum heat treatment differs widely in size, shape, construction, and method of loading.

Although originally developed for the processing of electron tube materials and refractory metals for aerospace applications, vacuum furnaces are now employed in brazing, sintering, heat treating, and the diffusion bonding of metals. Vacuum furnaces also are used for annealing, nitriding, carburizing, ion carburizing, heating and quenching, tempering, and stress relieving. Furnaces for vacuum heat treating are equipped for workloads ranging from several pounds to 90 Mg (100 tons), and heated working chambers range in size from 0.03 m^3 (1 ft^3) to hundreds of cubic feet. Although most vacuum furnaces are batch-type installations, continuous vacuum furnaces with multiple zones for purging, preheating, high-temperature processing, and cooling by gas or liquid quenching also are used. Vacuum heat-treating furnaces also:

- Prevent surface reactions, such as oxidation or decarburization, on workpieces, thus retaining a clean surface intact
- Remove surface contaminants such as oxide films and residual traces of lubricants resulting from fabricating operations
- Add a substance to the surface layers of the work (through carburization, for example)
- Remove dissolved contaminating substances from metals by means of the degassing effect of a vacuum (removal of H_2 from titanium, for example)
- Remove O_2 diffused on metal surfaces by means of vacuum erosion techniques
- Join metals by brazing or diffusion bonding

Vacuum Measurements

A theoretical or ideal vacuum is an empty space that does not contain either vapors, particles, gases, or other matter and consequently has no absolute pressure. Because this condition does not exist, even in outerspace, an ideal vacuum cannot be achieved. Normally, when the term vacuum is used, it refers to an absolute pressure below that of the normal atmosphere.

The standard absolute pressure of the atmosphere at sea level, 45° latitude, and 0 °C (32 °F) can be expressed in various values and units:

$$
\begin{aligned}
1 \text{ atm} &= 760 \text{ torr} \\
&= 760 \text{ mm Hg} \\
&= 760{,}000\ \mu\text{m Hg} \\
&= 29.921 \text{ in. Hg} \\
&= 14.696 \text{ psia}
\end{aligned}
$$

The standard absolute pressure of the atmosphere is the reference or 0 gage pressure for a normal pressure gage. Hence, gage pressure is negative for a vacuum condition. For some technologies other than vacuum furnaces, a degree of vacuum is measured by pressure below gage pressure. It is important to know how degrees of vacuum are expressed in the various technologies.

Most vacuum furnace pressure levels are expressed in terms of absolute pressure rather than gage pressure. Normally the units of measure used are torr, mm Hg, or μm Hg. When vacuum furnaces are pressurized above atmospheric pressure, such as for gas quenching, the pressure is expressed in terms of bars. One bar is slightly less than one standard atmosphere of absolute pressure. A bar is equal to 14.50 psia, 29.53 in. Hg, 750 torr or mm Hg, or 750,000 μm Hg.

The vacuum or pressure value of Hg refers to the height of a mercury column sustained by the differential between standard atmospheric pressure and an attained level of vacuum (or, more accurately, partial pressure) or pressure level (above standard atmospheric pressure) being measured.

Table 1 compares vacuum and pressure to standard atmospheric pressure. The normal pressure range of vacuum heat treating should be noted.

(a) Equal to 133.322387415 Pa, it differs from torr by one part in 7×10^6.

(b) psia = psig + 14.7 psi.

Comparison of Vacuum and Atmosphere Furnace Processing

In most heat-treating processes, when materials are heated, they react with normal atmospheric gases, which consist of approximately (by volume) 21% O_2, 77% N_2, 1% H_2O vapor, and 1% other gases. If this reaction is undesirable, the work must be heated in the presence of some gas or gas mixture other than normal air. This is done in normal atmosphere furnace processing.

The gas or gas mixture may be varied to cause desirable reactions with the material being processed or it may be adjusted so that no reactions occur. At different temperatures, different reactions may occur with the work and furnace atmosphere. In most atmosphere furnaces it is not possible to change the atmosphere composition rapidly enough for optimum reactions or to control the atmosphere composition with the degree of precision required for some heat-treating processes. Vacuum furnaces allow gas changes to be made quite rapidly because they contain gases of low weight.

Vacuum furnace technology removes most of the components associated with normal atmospheric air before and during the heating of the work. An analysis of the residual atmosphere in a leakproof vacuum furnace at a vacuum of about 0.1 Pa (10^{-3} torr) indicates that less than 0.1% of the original air remains. The residual gases primarily consist of water vapor, with the remainder largely comprised of organic vapors from the seals, vacuum greases, and vacuum oils. The oxygen content at 0.1 Pa (10^{-3} torr) is less than 1 ppm. If all of the residual gas in the vacuum furnace were converted to water vapor, the water vapor content would be approximately 1.5 ppm, or equal to that of a gas with a dew point of about -80 °C (-110 °F). At a vacuum level of 10 Pa (10^{-4} torr), the equivalent dew point of gas is estimated to be approximately -90 °C (-130 °F) or less.

These low dew point equivalents compare favorably with the driest inert gases available from highly efficient gas dehydration equipment. With suitable vacuum pumping systems, the concentration of oxygen and water vapor can be reduced to lower levels than those achieved in inert or reducing-gas atmospheres.

After a vacuum heat-treating furnace has been evacuated, gaseous reactions such as those encountered with atmosphere heat treatment are virtually eliminated. Moreover, the vacuum extracts many gases, surface contaminants, and processing lubricants that would be difficult and costly to remove by any other method. Gases drawn from the metal surface into the vacuum surrounding the charge are trapped by the vacuum pumps and exhausted from the system as the work is being processed. This advantage of a vacuum system is of greater significance when parts with complex shapes, blind holes, or deep recesses are heat treated. A complete purging of such parts in a protective atmosphere requires an extended purging period. Even long-time purging, however, may not ensure the complete removal of entrapped air, other contaminants, or contaminants generated by reactions with the atmosphere.

When more thorough purging is required, the furnace can be evacuated with a simple vacuum system, and the enclosure or retort can be backfilled with the desired protective or reactive atmosphere (see the article "Furnace Atmospheres" in this Volume). This method markedly reduces the amount of protective atmosphere and time required to produce satisfactory results.

Volatilization and Dissociation

In a vacuum furnace, materials can be pressed at temperatures and pressures at which the vapor pressure of the materials becomes an important consideration. Vapor pressure, which is the gas pressure exerted when a substance is in equilibrium with its own vapor, increases rapidly with temperature because the amplitude of molecular vibration increases with temperature. Some molecules in the outer surface of the solid material have higher energies than others, and they escape as free molecules or vapor. If a solid substance is contained in an enclosure devoid of any other material, molecules will continue to escape from the solid surface until their rate of escape is exactly balanced by the rate of condensation or recapture of the gaseous molecules. The equilibrium pressure developed is the vapor pressure of the substance at that temperature. The vapor pressure of a metal is dependent on temperature and pressure only but the effect is time dependent.

It is normally desirable to use a vacuum-temperature combination that accelerates the desorption of gases without producing the vaporization of more volatile alloy constituents. Alloys with high concentrations of volatile elements, such as brass, are not heat treated in vacuum furnaces.

If brass is heated in a vacuum at a temperature of 540 °C (1000 °F) and a vacuum level on the order of 13 mPa (0.1 μm Hg), the zinc component will vaporize (volatilize) and the brass will eventually be converted to copper sponge. The zinc will deposit in the cold section of the furnace and can revolatilize on subsequent runs at higher temperatures, causing unwanted pitting or other surface reactions on the work load.

Metals such as lead, zinc, and magnesium have relatively high vapor pressures; if heated above a temperature at which the vapor pressure of the element exceeds the pressure in the furnace, they will evaporate or sublime rapidly. Thus, high-vacuum heat treatment is not applicable to some metals and alloys. To handle certain metals and alloys properly, either the pressure must be limited to the soft (fine) vacuum range (Table 1) or a backfill to a higher vacuum pressure level must be employed.

Alloys with lower concentrations of volatile elements can be processed in vacuum by using the backfill pressure of an inert gas such as nitrogen or argon that exceeds the sublimation pressure of the element at the temperature involved. A backfill pressure of a few hundred μm Hg at temperatures of about 980 °C (1800 °F) precludes the vaporization of elements such as chromium, copper, or manganese from steels processed at these temperatures.

For example, if pure manganese were heated to approximately 790 °C (1455 °F) at a pressure of 13 mPa (10^{-4} torr), it would vaporize. If the material were held at a higher temperature or lower pressure for an adequate period of time, the metal would become depleted and would eventually disappear, and the vapors would condense on the colder areas of the furnace and/or pumping system. Backfill or higher pressures greatly slow the rate of evaporation or volatilization. The vapor pressures of carbon and selected pure metals, as related to temperature, are shown in Fig. 1 and Table 2.

Table 2 Vapor pressures of various elements

Element	Vapor pressure at				
	0.013 Pa	0.13 Pa	1.3 Pa	13 Pa	1.0×10^5 Pa

Note: The vapor pressure of metals is fixed with probable values at a given temperature, and the temperature at which the solid is in equilibrium with its own vapor descends as the pressure to which it is exposed descends. For example: iron must be heated to 2735 °C (4955 °F) at atmosphere before its vapor pressure is greater than atmosphere (760 mm Hg); this point is reached at 1311 °C (2390 °F) at a pressure of 130 mPa (10^{-3} mm Hg).

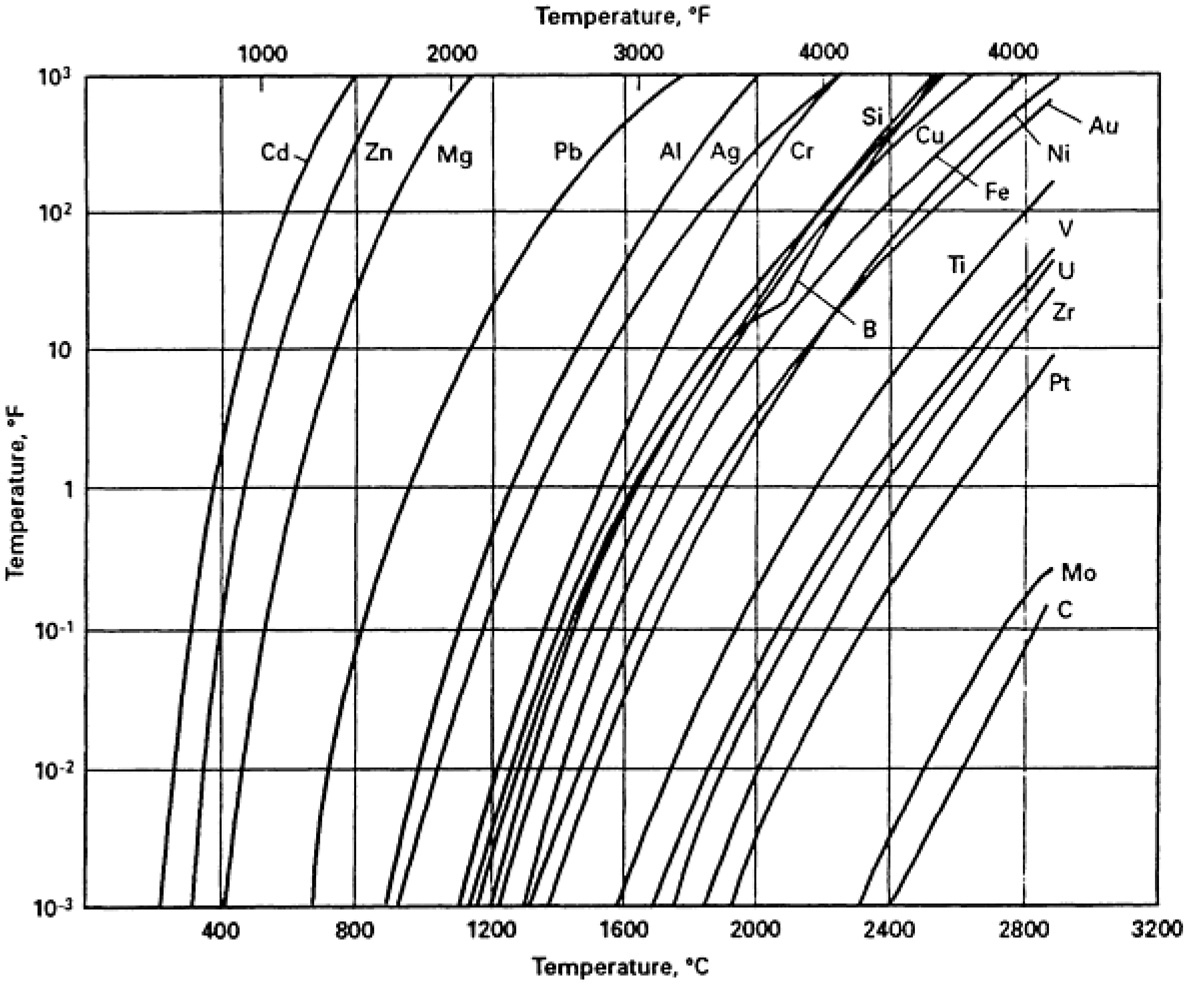

Fig. 1 Vapor pressure versus temperature for carbon and various pure metals

Alloy Vapor Pressures. The vapor pressures of pure metals are constant, well-established values. The vapor pressure of a given alloy varies according to conditions. The vapor pressure of an alloy is governed in part by a law analogous to Dalton's law of partial pressures: The total vapor pressure of an alloy, under ideal conditions, is equal to the sum of the partial vapor pressures of its constituents. However, the partial pressure of each element in the alloy is lower than its normal vapor pressure and is proportional to its concentration.

In processing at temperatures where the vapor pressures of more volatile minor constituents are still in the micron range, alloys behave in accordance with Dalton's law. For example, if pure manganese is heated to 790 °C (1455 °F), its vapor pressure will reach 13 mPa (0.1 μm Hg), making it impossible to evacuate to lower pressures without evaporating all of the manganese. However, when manganese is alloyed with other elements, as a solid solution in iron, for example, its effective vapor pressure is lowered. The total vapor pressure for the alloy is the sum of vapor pressures of the individual elements multiplied by their concentrations in the alloy. The vapor pressure of manganese in a 1% Mn alloy at 790 °C (1455 °F) is about 0.13 mPa (10^{-6} mm Hg). When alloys such as stainless steel are processed at high vacuum levels (theoretically exceeding the vapor pressures of some of its pure metal components), the volatilization is only a few molecules thick. This volatilization tends to draw the stable elements with it in a complex molecular destabilization that results in a surface chemistry similar to that of the core material. It is this molecular surface activity that can remove thin film oxides even though their theoretical combined vapor pressure has not been exceeded.

Many metals form compounds by reaction with oxygen, hydrogen, and nitrogen. These reactions are usually exothermic, and the possibility for dissociation of the resulting compound increases with higher temperatures. Some oxides, such as water, vaporize at temperatures so low that dissociation occurs only in the vapor phase. For an oxide, nitride, or hydride that remains a solid over a wide range of temperatures, a dissociation pressure exists at any temperature that represents an equilibrium between the compound, gas, and the metal.

All metallic compounds decompose into constituent elements when heated to sufficiently high temperatures. However, many of the metal oxides are quite stable, requiring low pressures at high temperatures to effect dissociation. It is impractical to dissociate many of these compounds because of the combination of vacuum level and temperature required. When a metal oxide dissociates, the metal remains and the oxygen is evacuated.

For example, chromium oxide will dissociate in a 1.3 mPa (10^{-5} torr) vacuum at 1300 °C (2370 °F). The dissociation of a metal oxide usually depends more on temperature than on pressure. Most oxides can be dissociated under normal operating vacuum levels at approximately their reduction temperature in a highly reducing hydrogen atmosphere.

The nitrides and hydrides often have higher dissociation pressures, making many of them unstable when heated in a vacuum. For this reason, vacuum heat treating can be used both to dissociate these compounds and to remove the evolved gas without disturbing the base metal.

It is believed that when oxidized surfaces brighten during vacuum heat treating, the mechanism involved is not simply thermal dissociation of the oxide. Bright surfaces do not discolor, or become brighter, when they are exposed to a vacuum atmosphere that is theoretically oxidizing. A metal surface can be maintained almost free of visible oxidation at a partial pressure several decades higher than that suggested by theoretical calculations. The following theories have been proposed to explain this apparent anomaly:

- The solution and diffusion rate for oxygen exceeds its surface absorption rate
- Oxide nucleation occurs at discrete sites rather than as a continuous film
- The effective concentration of oxygen is reduced by carbon and hydrogen in the solid metal and by the vacuum atmosphere

Heat Treating in Vacuum Furnaces and Auxiliary Equipment

Revised by the ASM Committee on Vacuum Heat Treating*

Vacuum Furnace Design

Although conventional atmosphere furnaces can be adapted for vacuum heat treating by adding a vacuum-tight retort connected to a suitable pumping system, furnace equipment developed especially for vacuum heat treating is generally used. There are two distinctly different types of vacuum furnaces: hot wall (no water cooling of the exterior walls) and cold wall (water-cooled walls).

Vacuum furnaces can be grouped into one of three basic designs:

- Top-loading, or pit, furnaces
- Bottom-loading, or bell, furnaces
- Horizontal-loading, or box, furnaces

Furnace designs can be varied to fit a wide variety of processing requirements by changing the chamber length or by adding internal doors, circulating fans, recirculating gas systems, and/or internal quenching systems.

Every vacuum furnace, regardless of its end use and basic hot- or cold-wall design, requires:

- Heating elements controlled to generate proper processing temperatures and cooling rates
- Suitable vacuum enclosures with access openings
- Vacuum pumping system
- Instrumentation to monitor and display critical processing data

Production furnaces may be single-chamber units, batch-type units, or multichamber, semicontinuous units.

Hot-Wall Vacuum Furnaces

Vacuum furnaces are classified according to the location of the heating and insulating components. Hot-wall furnaces were the first type to be designed. Because of the demand of the heat-treating industry for higher temperatures, lower pressures, rapid heating and cooling capabilities, and higher production rates, hot-wall vacuum furnaces have become essentially obsolete--with the exception of low-pressure chemical vapor deposition (LPCVD) and ion-nitriding processes--and have largely been replaced by cold-wall vacuum furnaces.

The entire vacuum vessel is heated by external heating elements in the hot-wall construction. The heat is contained by insulation materials similar to the materials used in electrically heated heat-treating furnaces. Hot-wall furnaces have limited use because of slow heating and cooling capabilities. They are also limited in temperature because the strength of materials is reduced at elevated temperature. However, hot-wall equipment is readily adaptable to low-temperature operations not exceeding 980 °C (1800 °F), with moderate-sized chambers.

The double-pump modification of the hot-wall furnace permits the construction of larger vessels and the use of operating temperatures approaching 1150 °C (2100 °F). This system incorporates a second vacuum vessel outside the vacuum retort to maintain a roughing vacuum during the heating cycle. This removes the stress of the atmospheric pressure on the heated retort or vacuum vessel.

Bell-Type Furnace. A bell-type hot-wall furnace is shown in Fig. 2. The workload is placed on an elevated refractory metal hearth that rests on an insulated base clad with an alloy plate material. A water-cooled circumferential flange and vacuum gasket are located on the vacuum-tight base cover adjacent to the heated zone but in an unheated area. A retort made with a heavy-walled heat-resisting alloy covers the work load. A flange at the bottom of the retort fits on top of the base gasket to provide a vacuum-tight enclosure. The bell-shaped furnace equipped with internal electrical heating elements is lowered into position over the retort by a vertical hoist. The vacuum pumping system is connected through the insulated base.

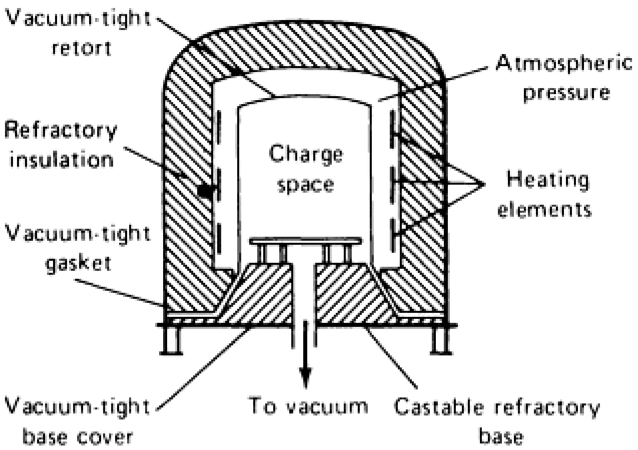

Fig. 2 Bell-type hot-wall vacuum furnace

Because this furnace cannot be heated or cooled rapidly, even when the bell-shaped vessel is removed, production rates and the number of thermal cycles within a given time period are limited. Moreover, because the hot retort must support the entire pressure of the external atmosphere, its wall must be quite heavy. Practical operating temperatures for a furnace of this type are generally limited to approximately 925 °C (1700 °F).

Pit-Type Furnace. Figure 3 shows a pit-type hot-wall furnace. The work load is placed in a top-loading muffle or retort made from a heat-resisting alloy. The upper end of the retort is provided with a water-cooled flange and vacuum gasket that interlock with a flange on the upper part of the furnace above the heated zone. The muffle is lowered into the furnace by an overhead hoist, providing vacuum connections for the furnace and retort.

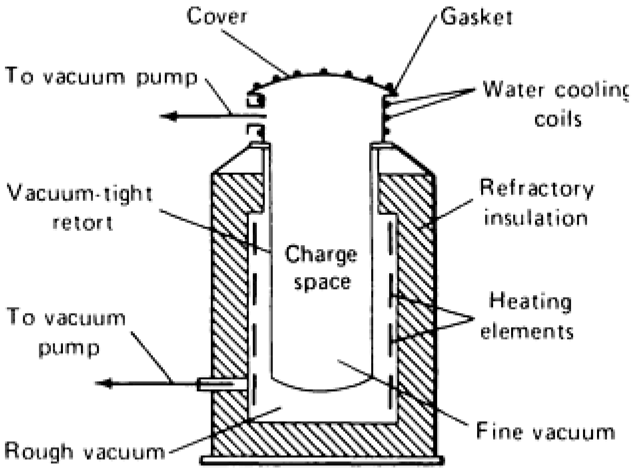

Fig. 3 Pit-type hot-wall vacuum furnace

With this construction, the space between the muffle and heating furnace can be evacuated by a roughing pump so that the pressure at the exterior surface of the muffle is essentially 0. This evacuation permits the use of a muffle with a much thinner wall and raises the maximum operating temperature of the system to approximately 1175 °C (2150 °F). When the heating cycle is completed, inert gas is bled into the retort, and air is bled simultaneously into the heating furnace so that the pressures remain balanced on both sides of the retort. The retort then can be removed from the furnace to a cooling stand, and another retort can be inserted in the hot furnace. This construction increases heating and cooling flexibility, which in turn increases cycle frequency and production.

Horizontal and vertical two-zone hot-wall vacuum furnaces are shown in Fig. 4 and 5. In both types, the heat-resisting alloy muffle is extended much further beyond the heating section of the furnace. This extended section has a water-cooled jacket to provide accelerated cooling. In the horizontal furnace, the charge is carried on an alloy hearth that can be moved in and out of the heated zone by a push rod extending through a seal in the outer fixed end of the muffle. This hearth has vertical heat baffles or multiple radiation shields at each end to confine the heat to the heated portion of the muffle. An equivalent means of transferring the work load is necessary in the vertical furnace as well, although this is not shown in Fig. 5. By using this technique, the charge can be cooled much faster because it is necessary to remove the heat from the hearth and work load only, not from the hot end of the muffle. This increased cooling rate permits the hardening of air-hardening steels and is adaptable to certain solution treatments not possible with other hot-wall furnaces.

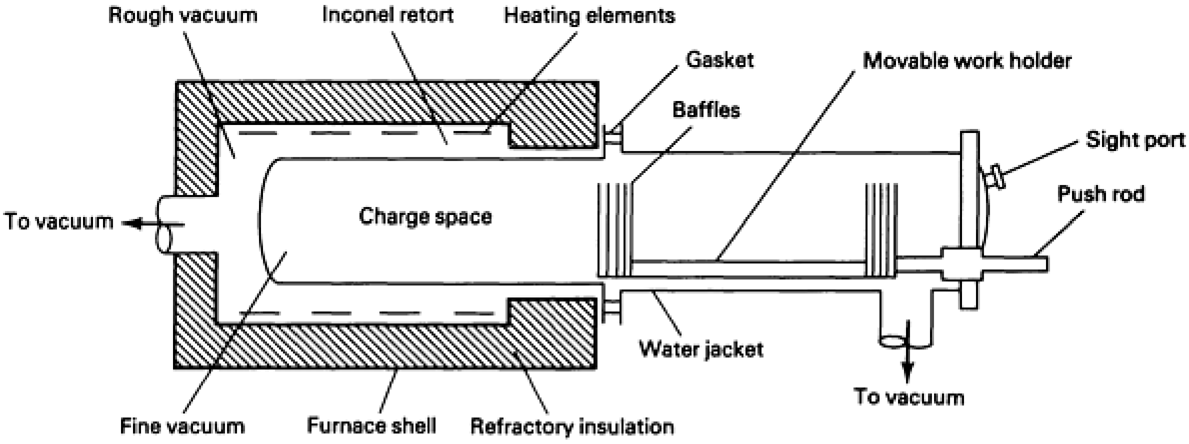

Fig. 4 Horizontal, two-zone, hot-wall vacuum furnace

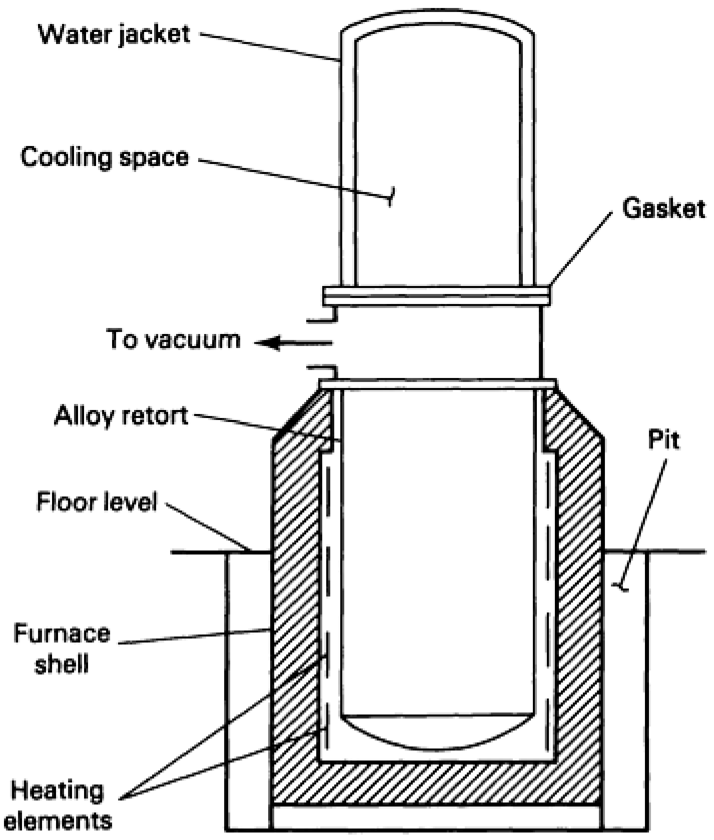

Fig. 5 Vertical, two-zone, hot-wall vacuum furnace

Cold-Wall Vacuum Furnaces

By far the most widely used, practical cold-wall furnace units consist of a water-cooled vacuum vessel maintained near ambient temperature during high-temperature operations. Consequently, because the operating temperature does not affect the strength of the vessel material, large units can be constructed for use at high operating temperatures.

In the cold-wall design, the water-cooled vacuum vessel contains and supports the internal insulation, the electrical heating elements, and the hearth upon which the work load rests. The vacuum acts as:

- A substitute for the normal heat-treating atmosphere to protect the work load
- An insulating medium in the furnace because the thermal conductivity of a vacuum is essentially 0
- An effective protective coating around the heating elements, heat shields, and supporting hearth

There are three forms of heat transfer in a furnace--radiation, conduction, and convection--but the only effective method of heat transfer in a vacuum is radiation. Heat transfer by conduction or convection is negligible because little or no gas is generated.

The use of a vacuum as the insulating medium has permitted the use of multiple radiation shields of very low mass or special lightweight ceramic, graphite laminate, or felt insulations that facilitate rapid heating and cooling. Rapid rates of heating and cooling are important because usually each treatment cycle is started at ambient temperature and must be cooled to near ambient temperature at completion. As the protective medium, vacuum has permitted the use of materials such as graphite, tungsten, molybdenum, and tantalum for heating elements and hot furnace structures. Such materials normally cannot be used in other furnace constructions without more elaborate, expensive, and sometimes hazardous protective-atmosphere environments.

Cold-wall vacuum furnaces can be classified as either batch vacuum furnaces or semicontinuous vacuum furnaces. In a batch operation, the work load remains stationary inside the furnace during heating. On the other hand, in semicontinuous

vacuum furnaces with multiple chambers, the work load is moved within the vacuum usually after completion of a processing step or segment.

Batch Vacuum Furnaces. By using high melting-point materials in furnace structures, extremely rapid rates of heating and high temperatures can be attained in batch furnaces. Heat is transferred to the work load almost entirely by radiation.

Radiation cooling in a hot batch vacuum furnace is extremely slow, however. To reduce furnace time and shorten quenching time, pressure in the vacuum chamber is usually increased to either just below atmospheric pressure or up to six times the atmospheric pressure by introducing a pure inert gas such as nitrogen or argon. This gas is rapidly recirculated within the furnace and then through cooling coils or through an external heat exchanger and back into the furnace, with high-powered large-capacity gas pumps.

The advantages of batch cold-wall vacuum furnaces over atmosphere furnaces include:

- Reliability
- Repeatability
- Cleanliness
- Bright, oxide-free treatment of most metals and alloys
- Outgassing and purging of entrapped volumes of gas
- Retained surface finish
- Removal of surface volatiles
- No heat added to local environment
- No chemical effect on furnace or work during treatment
- Easy control of furnace environment by controlling backfill gases
- Highest-quality workpiece produced
- No furnace conditioning
- Instant pushbutton start from cold
- Low pollution
- Wide operating temperature range in one unit
- Easy maintenance
- Safe operation
- Fully automatic processing
- Wide range of programmable heating and cooling rates
- Minimal distortion of treated work
- High heating rates and temperatures resulting from use of high-melting-point materials
- Complete shutdown when not in use; no need to maintain heat to maintain low dew point
- Blanketing gas usually not required during heating

Disadvantages of batch cold-wall vacuum furnaces over atmosphere furnaces include:

- Large amount of floor space required in relation to load size
- Lower productivity
- Longer cycle times
- Furnace must withstand atmospheric pressure and be free of leakage
- High capital cost
- High maintenance cost

Semicontinuous furnaces are constructed of modular units of three or more vacuum chambers. The heating chambers can be maintained at heat as required during loading and unloading. Each unit has a work carrier transfer system, an internal assembly of heating elements and shield package, pumping system, and temperature-controlled power system. Isolation locks or doors at each end of the vacuum heating or brazing environment separate these modular units from the entry and exit vacuum vestibules. These vestibules, in turn, have doors for access to and from atmospheric

pressure and other assembly operations. Usually included with the furnace are fans for fast cooling at the exit end of the furnace and an overhead conveyor system to transfer work carriers from the exit to the furnace entrance. Work carrier loading and unloading stations are incorporated in the external overhead conveyor system. A high-volume-production semicontinuous vacuum furnace is shown in Fig. 6. These furnaces are used for the fluxless brazing of aluminum heat exchangers at production rates of 100 to 250 parts per hour.

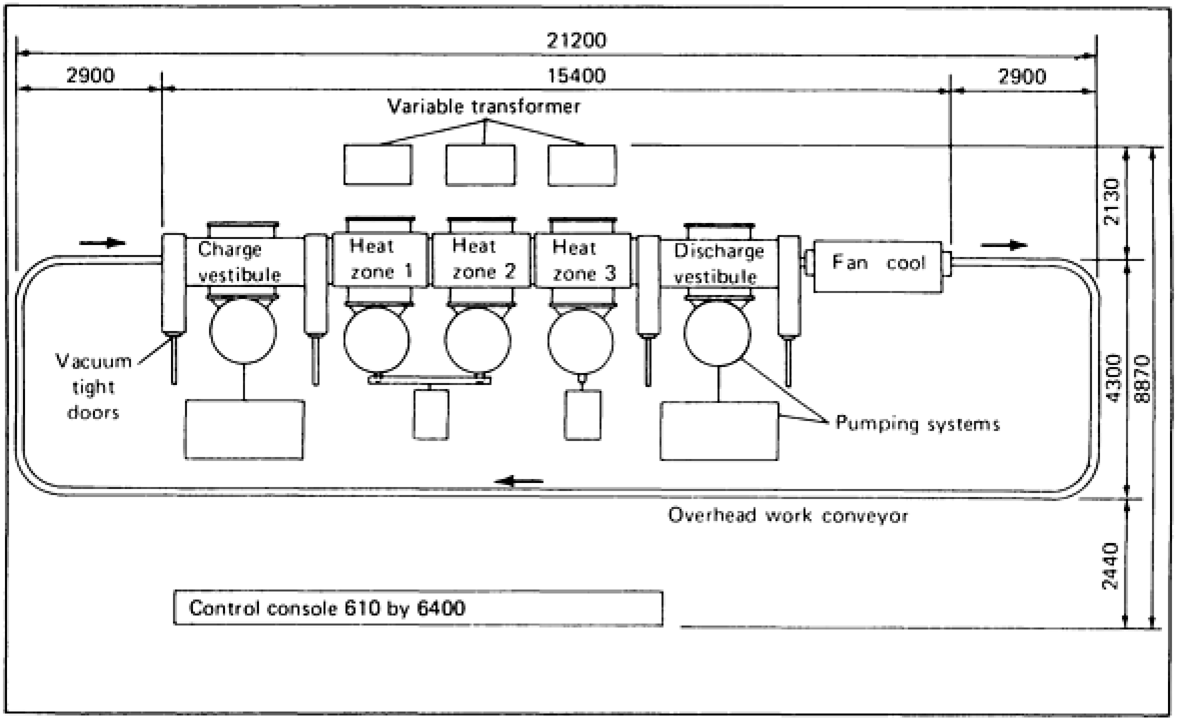

Fig. 6 Automatic vacuum furnace for fluxless aluminum brazing. Dimensions given in millimeters

For high-volume production and easy flow of work loads, semicontinuous vacuum furnaces are equipped with electrical controls that can also be computer programmed for automatic operation. The internal and external work carrier transfer systems, door operations, pumping systems, heating systems, gas backfill, and external cooling, loading, and unloading stations are all electrically interlocked and controlled for completely automatic operation. Automatically controlled mechanical loading and unloading of the work carriers can also be incorporated into the complete system.

Types of Cold-Wall Vacuum Furnaces. Cold-wall vacuum furnaces can be divided into bottom-loading, top-loading, and horizontally loading types.

Bottom-Loading Furnaces. As shown in Fig. 7, the furnace is stationary and elevated well above floor level. The bottom descends to floor level for ease of loading. The work is loaded on trays that are placed on the hearth by a fork lift when the bottom is in the lowered position. Such furnaces are built to handle large, heavy loads and are cooled rapidly by a high-velocity internal or external circulating-gas system.

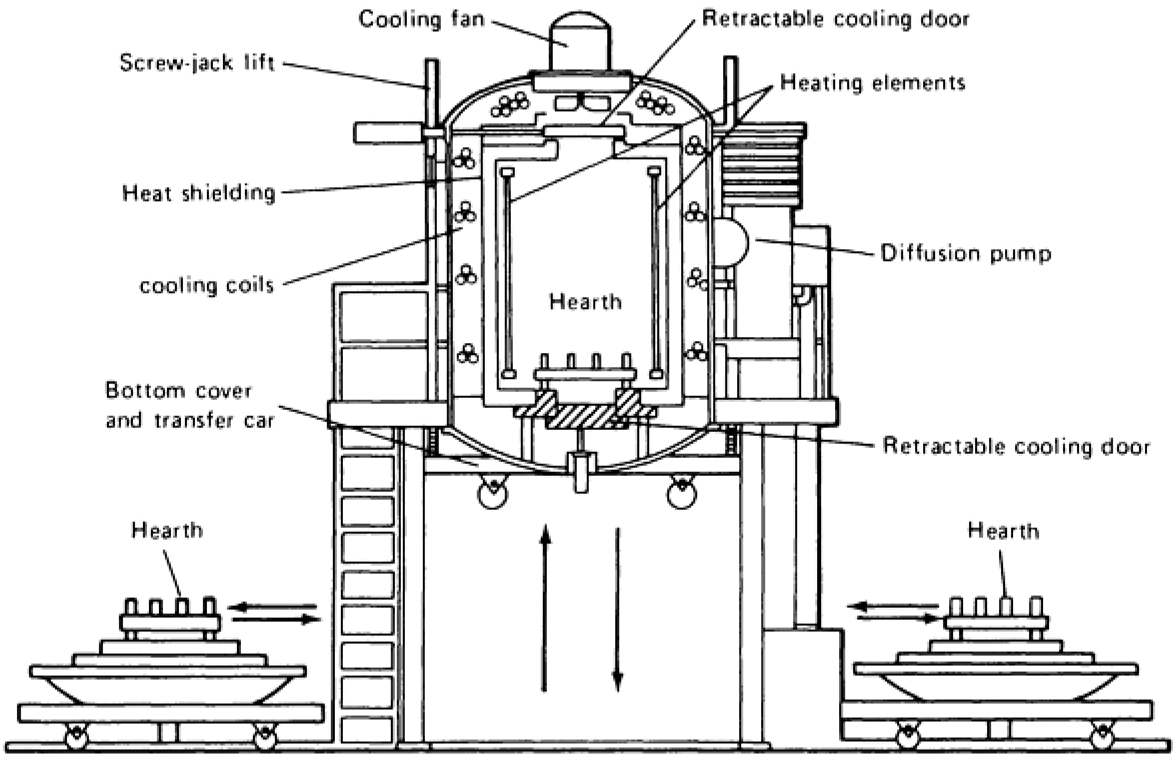

Fig. 7 Bottom-loading cold-wall vacuum furnace

Top-loading furnaces, as shown in Fig. 8, are not as widely used as bottom-loading furnaces. However, they are useful in processing long and relatively thin workpieces such as slender shafts. The workpieces are suspended vertically from hangers attached to the removable top of the furnace or placed on the hearth in the base. Adequate head room and a vertical hoist are required. These furnaces are cooled in the same way as bottom-loading units.

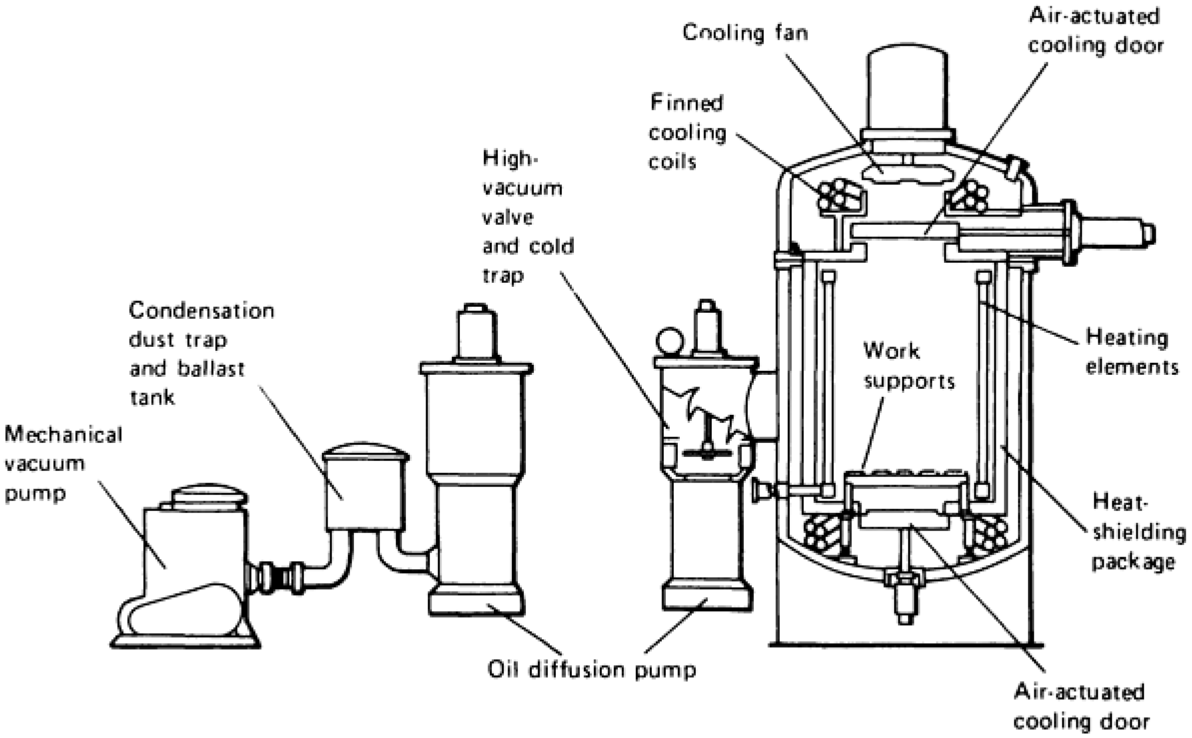

Fig. 8 Top-loading cold-wall vacuum furnace

Horizontally Loading Furnaces. A box-shaped or rounded design horizontally loaded furnace consists of a cylindrical shell free of gas leaks, with circular convex end plates or doors (Fig. 9). In some designs, both of the end plates are hinged to permit easy access to the furnace interior. Furnaces are also constructed with a stationary rear plate or with a second hinged access door at the front that is smaller than the main front plate. The cylindrical shell and the end plates are water cooled by copper coils soldered to the exterior surface or through the use of double-walled construction. The gastight shell is made of stainless or carbon steel, depending on the intended use. The movable end plates are sealed by O-rings at the end faces of the cylindrical section. The pressure of the outside atmosphere on the convex ends supplies the pressure for vacuum sealing. Usually, auxiliary clamps are provided to supply sealing pressure and to prevent the door from becoming unsealed when positive pressure inside the furnace is used during inert-gas quenching.

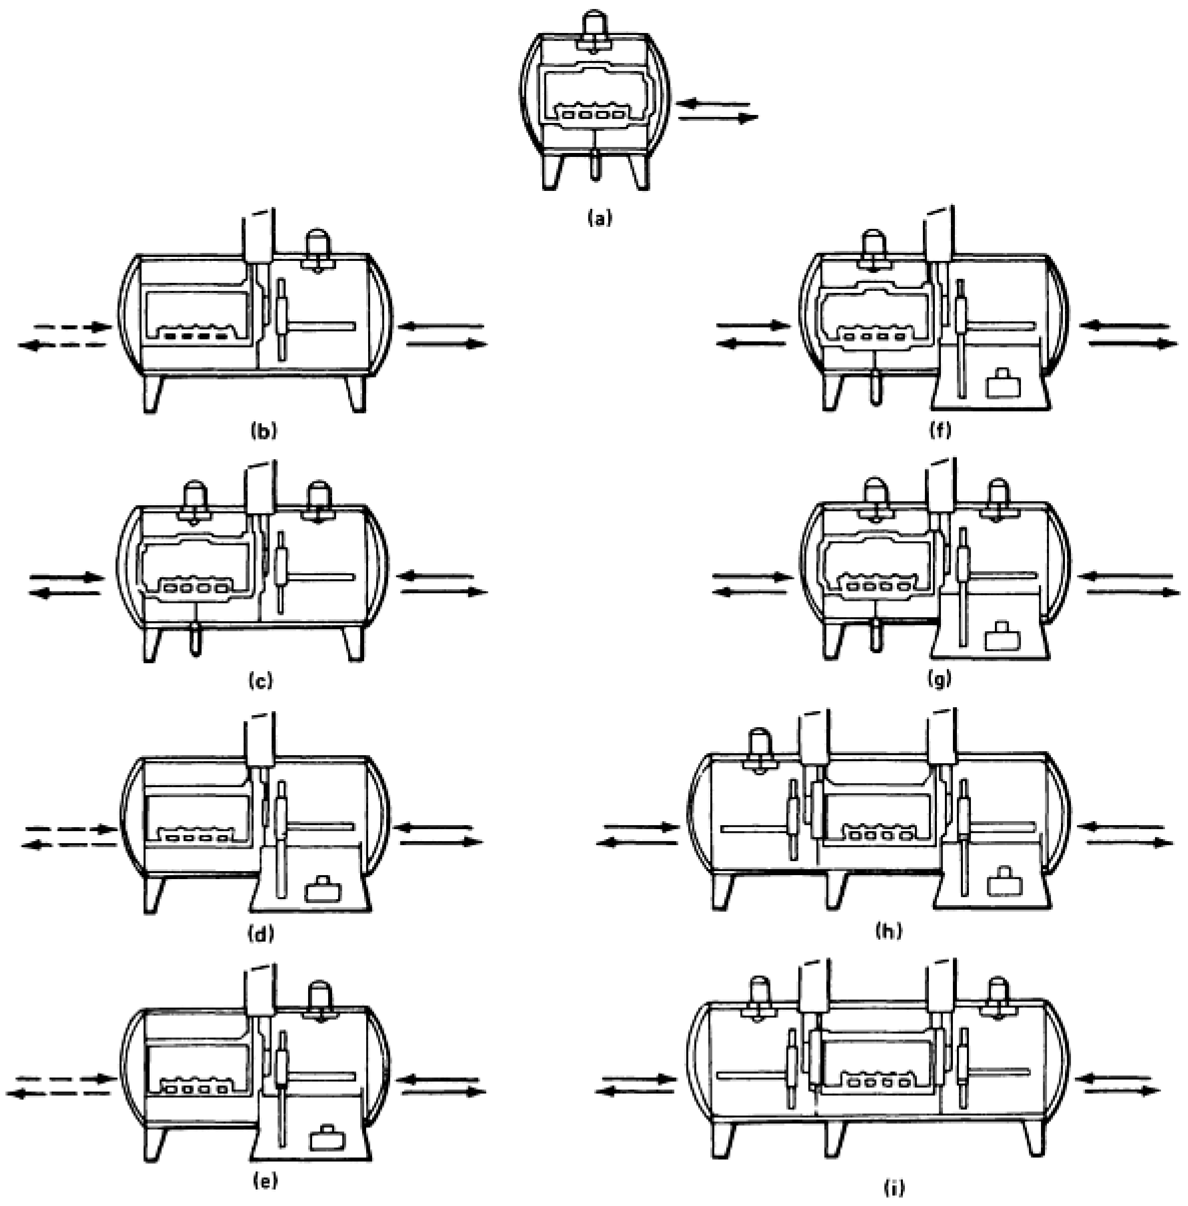

Fig. 9 Horizontal vacuum furnace configurations. (a) Single-chamber vacuum furnace with gas/fan quenching. (b) Two-chamber vacuum furnace; one chamber for heating, with integral second chamber for gas/fan quenching only and mechanism for internal in-and-out transverse movement of work load to and from heat chamber. Unit can be loaded and unloaded only from cooling or quenching chamber. (c) Same as (b) but gas/fan cooling is also included in heat chamber and unit can be loaded or unloaded from either chamber. (d)

Two-chamber vacuum furnace; one chamber for heating, with integral second chamber for oil quenching only and mechanism for internal movement of work load to and from heat zone. Unit can be loaded/unloaded from oil-quenching zone only. (e) Same as (d) but gas/fan cooling is also included only in quenching or cooling chamber. (f) Same as (d) but gas/fan cooling is also included only in the heating chamber and unit can be loaded or unloaded from either chamber. (g) Same as (d) but gas/fan cooling is included in both chambers and unit can be loaded or unloaded from either chamber. (h) Three-chamber vacuum furnace; middle chamber is for heating only. One end chamber contains gas/fan quenching only and internal mechanism for work movement to and from heat zone. Other end chamber contains oil quenching only and an internal mechanism for work movement to and from heat zone. Unit can be loaded or unloaded from either end chamber. (i) Three-chamber vacuum furnace with middle chamber for heating only. End chambers both contain gas/fan quenching only and internal mechanisms for workload movement to and from heat zone. Unit can be unloaded or loaded from either end.

Many horizontally loading furnaces are equipped with a special lifting and transfer truck that is stationed in front of the furnace. Frequently, this truck rolls on a track so that it is permanently aligned with the heating chamber. A hydraulic fork lift raises the work basket, and the truck moves forward to transfer the basket into the furnace, where it is lowered onto the hearth or work pedestal. This mechanism avoids damage to the interior of the furnace, which could occur if the transfer were attempted without controlled movement.

Horizontally loading furnaces may have several chambers, depending on the heat-treating operation to be performed (Fig. 9). Special systems have been designed to transfer work loads inside these furnaces. The conveyor, walking beam, roller-hearth, and pusher-type furnace designs can be adapted for vacuum furnaces.

The hearth is supported on wheels that roll on rails that are installed below and outside the heated zone and are protected by movable heat baffles. The longitudinal motion can be supplied by a sealed push rod extending through the furnace wall to an air or hydraulic cylinder or by an internal chain-driven conveyor in the cool area.

Another method of work transfer within a horizontally loaded furnace uses an internal rack-and-pinion drive. An overhead chain-driven conveyor can also be used. The work trays may also be transferred longitudinally to the second chamber hearth by a lifting mechanism installed in the unheated chamber that is exposed to the furnace heat only during the short transfer time. Rack-and-pinion drives and pneumatic cylinders are often used to execute vertical elevator movements into and out of liquid quench tanks, as well as to open and close internal heat shields and vertical doors.

A horizontally loaded vacuum furnace equipped with radiation shields is shown, in a vertical section, in Fig. 10. The work load is exposed directly to radiation from the electrical heating elements. The multiple radiation shields are made of thin sheets of heat-resisting material, such as molybdenum, in parallel layers between the heating elements and the chamber shell. An alternative construction using thermal insulating material instead of radiation shields is shown in Fig. 11. This insulation may be a fiber fill, graphite felt, or special low-density fiber ceramic material.

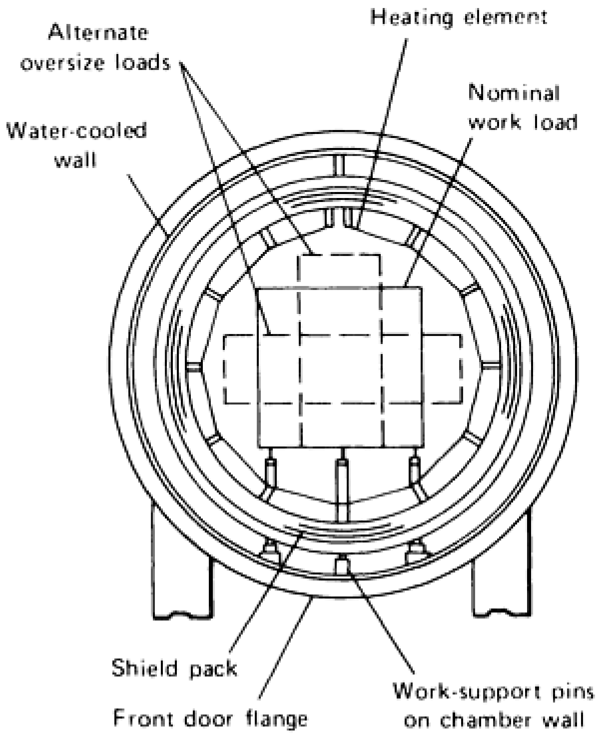

Fig. 10 Radiation shield cold-wall vacuum furnace

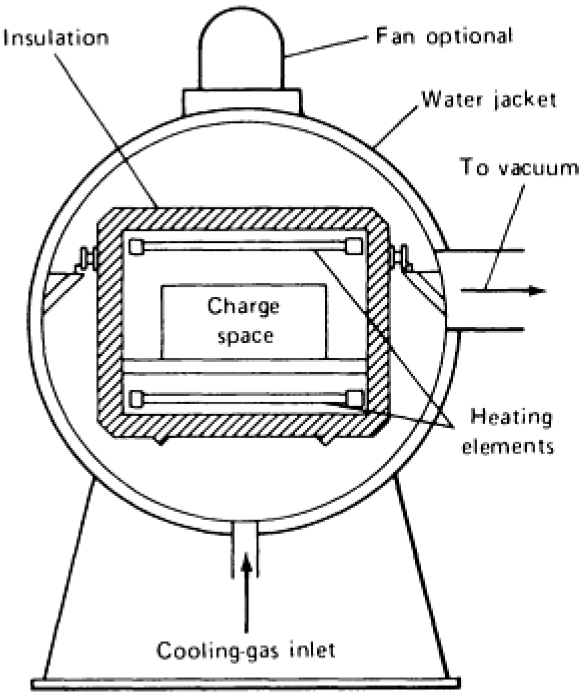

Fig. 11 Insulated cold-wall vacuum furnace

Cross-sectional views of a three-chamber oil quench furnace are shown in Fig. 12. The front chamber is equipped with internal cooling coils and a circulating fan for accelerated gas cooling. The center chamber is the heating chamber, which can be sealed at both ends during the heating cycle by internal moving heat shields and doors equipped with O-rings. The third chamber contains the oil quench and the vertical transport system required to immerse the work in the circulated quenching oil.

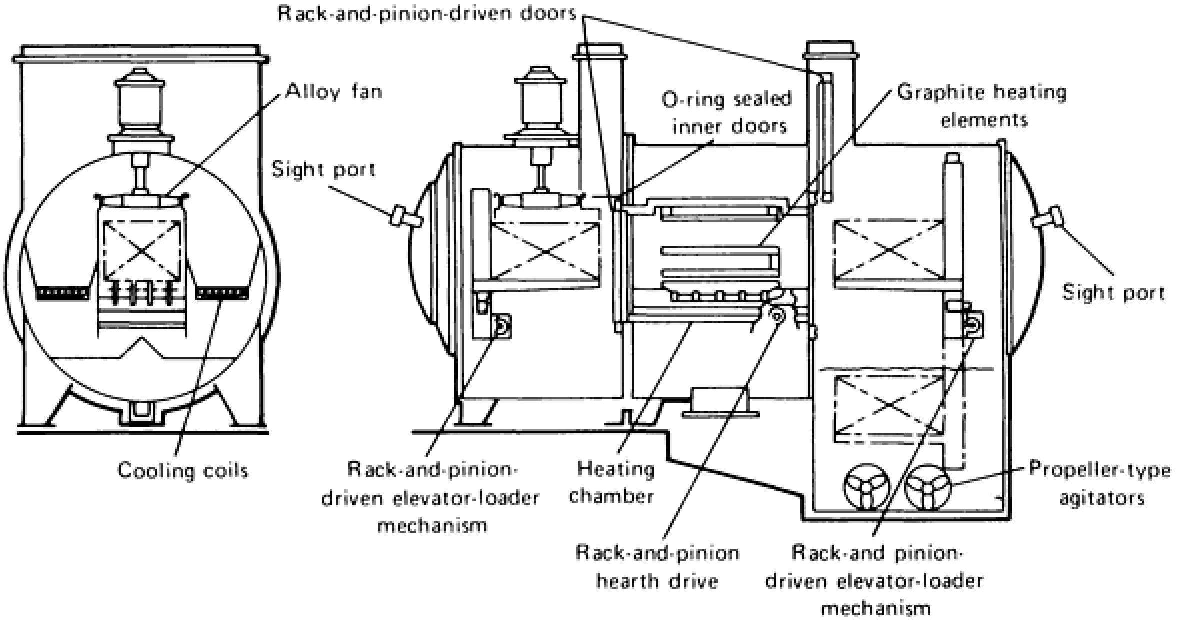

Fig. 12 Three chamber vacuum oil quench furnace

Two-chamber oil quench furnaces are also common. One chamber is used for heating, and the other for loading and oil quenching. A double high elevator in the quench chamber allows loading from either end of the unit.

Heating Elements

Resistance heating and induction heating were formerly the two most commonly used methods of heating within the cold-wall furnace; induction heating is now rarely used. When vacuum furnaces are heated inductively, a graphite cylinder is used as a susceptor; the graphite is heated by induction and radiates the heat to the work inside the cylinder. When heating is provided by the more common resistance elements, the heat transfer is also completed by radiation; therefore, the active heating surface should be large enough to effect a rapid and uniform transfer of heat.

Essentially all vacuum furnaces use three-phase 60 Hz power supplies. Three types of power supplies and controls are used:

- Controllable variable reactance transformers
- Saturable core reactors
- Silicon-controlled rectifiers

Low voltage (generally, <70 V or a maximum of 100 V at a pressure of 13 Pa, or 100 μm) should be used in the vacuum chamber because a high electrical potential can produce short circuiting of the elements by ionizing the residual gases within the chamber.

Resistance heating elements operating in a vacuum do not require oxidation-resistant properties equal to those required in oxidizing atmospheres. To improve operating efficiency, resistance heating elements are heated to higher temperatures than are the elements used in conventional furnaces because the transfer of radiant energy is proportional to the fourth power of the absolute temperature. Higher temperatures require heating elements with low vapor pressures to ensure long life. Materials meeting these requirements are:

- Refractory metals, such as tungsten, molybdenum, and tantalum
- Pure solid graphite in the form of bar, rod, or tube
- Pure graphite cloth woven from fine filaments of pyrolyzed graphite

- Chromium-nickel elements for operating temperatures of less than 980 °C (1800 °F)

Properties of these materials are compared with those of iron in Table 3.

Table 3 Characteristics of heating elements used in vacuum furnaces

Material	Melting point		Upper operating temperature limit		Vapor pressure at			
					1600 °C (2910 °F)		1800 °C (3270 °F)	
	°C	°F	°C	°F	Pa	torr	Pa	torr
Molybdenum	2617	4743	1705	3100	1.3×10^{-6}	10^{-8}	1.3×10^{-4}	10^{-6}
Tantalum	2996	5425	2500	4530	1.3×10^{-9}	10^{-11}	1.3×10^{-7}	10^{-9}
Tungsten	3410	6170	2800	5070	1.3×10^{-11}	10^{-13}	1.3×10^{-9}	10^{-11}
Graphite	3700	6700	2500	4530	1.3×10^{-11}	10^{-13}	1.3×10^{-8}	10^{-10}

Refractory Metals. The high melting points of tungsten, molybdenum, and tantalum make these metals ideal for use as heating elements in vacuum furnaces.

Tungsten is capable of withstanding higher operating temperatures than the other refractory metals (see Table 3). As a heating element material, it is used as wire or rod, thin sheet, or sections of woven wire screen. Wire screen is less likely to be damaged from thermal stresses that occur during heating or cooling.

Molybdenum in the form of solid rod, strip, or thin sheet material is the most widely used metallic element. Material in sheet form is normally preferred because the electrical power density (watts per square inch of radiating surface) is low compared to that of cylindrical rod, resulting in lower operating temperatures and thus longer service life for the elements. Also, thermal expansion and contraction and the resulting stresses are handled more easily from a design standpoint. However, thin sheets are subject to mechanical damage. Hangers and supports for metallic heating elements must have good insulating properties and must be chemically stable at the temperatures and pressures encountered in service. Heating elements must not be restrained by the support system from free movement during the thermal cycle.

Molybdenum exhibits extremely brittle characteristics at low temperatures after being in service. If deformed at low temperatures, molybdenum heating elements can fail because of the brittle nature of the metal.

Molybdenum undergoes a large change (500% increase) in electrical resistance between room temperature and the normal operating temperatures; consequently, the power supply must control the current during the early stages of heating to avoid damaging the elements, as well as the furnace heating systems.

Solid Graphite Heaters. All metals lose some strength when heated, whereas crystalline carbon in the form of graphite increases in strength as the temperature increases. Pure graphite in the form of flat bar or rod is less expensive than other high-temperature metallic resistors. Graphite also has a much lower heat expansion coefficient and is more resistant to thermal shock than most metallic materials.

As shown in Table 3, graphite also has a high melting point and a low vapor pressure; thus, it is an excellent choice for a vacuum furnace heating element material. In processes in which possible minute concentrations of carbonaceous material in the vacuum atmosphere will not have an adverse effect on workpieces, such as in the processing of the refractory alloys, where the use of graphite is not recommended (forbidden by most specifications), graphite resistors are commonly chosen. Moreover, the presence of incandescent carbon may provide additional cleansing or gettering action with respect to oxygen or water molecules in the residual vacuum atmosphere. This subtle action is not provided by any of the metallic resistors. The replacement of graphite resistors may be less expensive than the replacement of metallic ones because often graphite elements can be replaced without disturbing the surrounding insulation and because electrical connections are mechanical and require no welding.

Graphite has up to a 20% decrease in resistance as it heats, requiring wiring and power sources to be sized to handle the increased amperage should full power be applied to the cold elements.

Graphite Cloth Heaters. A third type of material used for vacuum heating elements is a cloth composed of fine graphite fibers. This material is made from rayon cloth pyrolyzed at high temperature to convert the carbon in the rayon to crystalline graphite. The cloth is strong and very flexible. It can be cut with ordinary scissors to the desired size and shape. Because the cloth is flexible, the supporting system can be considerably simplified. The ends are usually clamped in graphite electrodes. This graphite cloth is also available as a hollow cylinder with solid graphite ends of high electrical conductivity, forming a self-supporting electrode with a large radiating surface area.

The direction of the weave of cloth used in making elements is a critical factor in determining the resistance and voltage values of the graphite cloth. In most weave patterns, the fibers in one direction are straight, and those in the other direction are woven over and under the first. The actual cloth resistance obtained will exceed the calculated resistance value because the over-and-under cut length will exceed the straight cut length of the cloth.

Heat Insulation

Part of the insulation in a cold-wall vacuum furnace is provided by the vacuum itself. Where space is essentially void, there can be virtually no heating by convection or conduction. Radiant energy emitted by the resistors in all directions is generally confined to the desired heating zone by one of four designs of radiation shielding.

Metallic Shielding. Multiple concentric layers of thin heat-resisting sheet metal reflect the energy back into the heating chamber of the furnace. Approximately 6 mm ($\frac{1}{4}$ in.) spacing is maintained between these sheets. Thin wire coil springs are sometimes used as spacers between adjacent surfaces. Inner shields are sometimes fabricated from molybdenum because of its superior heat-resisting qualities; the next two layers may be stainless steel, and the outer layers are composed of nickel steel or plain carbon steel, depending on the maximum operating temperature of the furnace. As the number of shield layers (N) increases, the efficiency of the shielding increases; however, the insulating effect of each added shield decreases. Consequently, no more than five or six shields or layers are used. Approximately 85% efficiency can be achieved in this manner, even with a material of 0.5 emissivity. The effect on efficiency of the number of insulating layers and the emissivity of the sheeting material is shown in Fig. 13. Efficiency declines as the originally bright, clean metal surfaces become affected by the deposition of oxide or sooty films. This decline must be considered during the design of the furnace system.

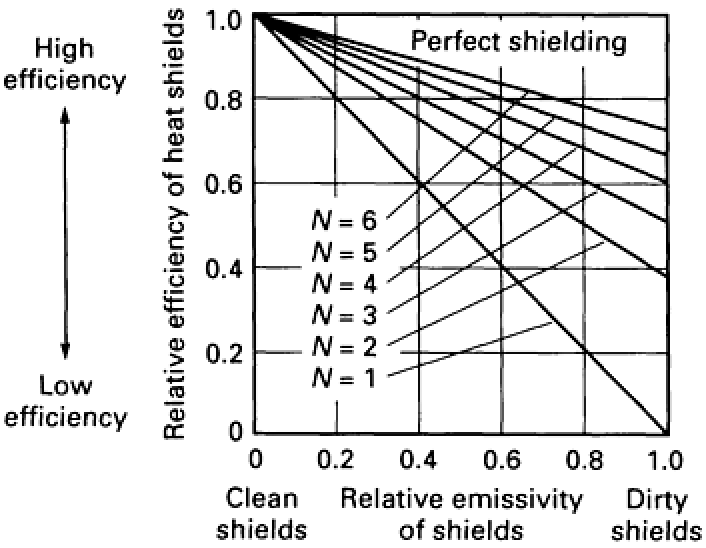

Fig. 13 Relationship between heat shield efficiency and emissivity of sheet metal for various numbers (*N*) of sheets

Slightly faster evacuation rates, higher ultimate vacuum levels, and cleaner work products are usually obtainable with designs incorporating radiation shields. These advantages are realized only if the furnace is subsequently used for a singular process application or is scrupulously maintained. These advantages readily revert to disadvantages when radiation-shielded units are used for multiprocess purposes or are not cleaned.

Sandwich construction, which resembles the wall of a conventional low-temperature furnace, has proved to be an efficient design. One or more layers of graphite felt or high-temperature refractory fiberfill are placed between the inner and outer sheet metal walls. For instance, the inner wall may be molybdenum, and the outer wall stainless steel. A vacuum between the fibers reduces the thermal conductivity of the wool packing to a fraction of the thermal conductivity in any atmosphere. Thermally insulated cold-wall vacuum furnaces are better suited to conventional vacuum heat treating involving multiple process and temperature requirements.

Pump rates for sandwich construction furnaces are slower than for conventional heat-treating multiple-process furnaces. Ultimate vacuum levels are not as high. The residual-gas load is not as clean as with radiant-shield designs because of higher internal outgassing loads. However, for most vacuum processing, thermally insulated vacuum furnace design is adequate. It is certainly less expensive in original cost, maintenance, thermal efficiency, and power consumption than conventional vacuum heat-treating multiple-process furnaces. Typically a radiant shield furnace with identical pump system runs a decade vacuum level lower than does a similar insulated furnace, that is, 1.3 mPa (1×10^{-5} torr) compared to 13 mPa (1×10^{-4} torr).

Multilayer Graphite. In this design, multiple layers of high-purity graphite felt are fastened to an outer cage of refractory metal by molybdenum clips. This material has a density of only about 0.08 g/cm^3 (0.003 lb/in.^{3}), and it functions as a thermal insulator in much the same way as refractory fiber fill. Because it is a felted material with inherent cohesion, it does not require support by sheet metal walls, as does the fiber-fill. Its emissivity is near unity--about 0.98 or better. Graphite felt is more economical than molybdenum and is easy to replace. This method, like sandwich construction, relies on an insulating material with low conductivity in a wall heated from one side.

Carbon-Bonded Carbon Fiber. This insulation material uses blocks or molded cylinders to form a structural lining. It has a density of approximately 0.19 g/cm^3 (0.0069 lb/in.^{3}) and is used to make a refractory lining that minimizes the use of molybdenum and is resistant to high-velocity erosion in gas quenching applications.

Insulation Maintenance. All types of insulation are subject to accidental contamination. In many cases, foreign materials, such as lubricants used in deep-drawing operations, volatile metals, or even cotton gloves, may be inadvertently carried into vacuum furnaces with the workload. Contamination can result in extensive damage to radiation shields and

considerable down-time if it necessitates the mechanical cleaning of the shields. In an insulated furnace that does not depend on reflectivity, a thorough outgassing normally returns the furnace to operating condition within several hours.

The efficiency of multiple radiation shields decreases rapidly as the shields become dirty and nonreflective and as emissivity increases. One method of cleaning molybdenum shields consists of heating the furnace to above the operating temperature after backfilling with dry hydrogen to a pressure of 130 Pa (1 torr).

An effective method of protecting the innermost radiation shield is to overlay the molybdenum with a layer of graphite foil. This material is essentially pure graphite that has been rolled into a thin sheet by a special process with dry hydrogen. It is held in place by mechanical fasteners. Any contamination from the splattering of brazing filler metal or the evaporation of volatile materials is deposited on this inert material rather than on the molybdenum shield. Graphite foil can be applied to almost any other metal lining surface as well.

Gas Quenching

The inability to obtain the high cooling rates necessary for many metallurgical operations proved to be a severe limitation to early hot-wall vacuum furnaces. The development of a retort that could be transferred from the hot furnace to a special cooling stand provided a somewhat inconvenient solution.

With the development of the cold-wall vacuum furnace, the cooling problem has been overcome to some extent by radiation shielding made of multiple thin metal sheets, thermal insulation of very low mass such as refractory fiber, special foam refractory brick, or graphite fiber felt. Because of the low heat content of these insulating media, most of the heat to be dissipated is contained in the work load itself. Cooling the work continues to be quite a slow process because of the absence of convective heat transfer in a vacuum. Backfilling the chamber with an inert gas is necessary to promote the conductive transfer of heat from the work to the water-cooled shell. Fans made from stainless steel or other heat-resisting alloys can be installed above the insulated work area to promote the convective circulation of the backfill atmosphere. Usually baffles or bungs of insulating material must be moved from above and below the work load to improve the access of the cooling atmosphere to the hot work. Finned copper coils cooled by circulating water can be installed between the insulating medium and the shell of the furnace to facilitate heat transfer, to avoid total reliance on the cold furnace shell as the transfer surface.

Circulation by an internal fan is often used because it provides the fastest gas cooling, but it is not as likely to provide uniform cooling throughout the load.

Cooling rate uniformity is not entirely due to the system used. It also depends on the size, shape, quantity, and distribution of the load being processed. Care must be exercised when loading a furnace to optimize the placement of parts for heating and cooling.

An inert-gas circulating system with an internal manifold is shown in Fig. 14. To increase the rate of heat removal, the mass-flow coefficient must be increased. Mass flow is the product of the mass of gas moved times its velocity. To increase this coefficient, either the velocity of the gas circulating through the load or the gas pressure in the system can be increased so that a greater number of gas molecules are present per unit volume.

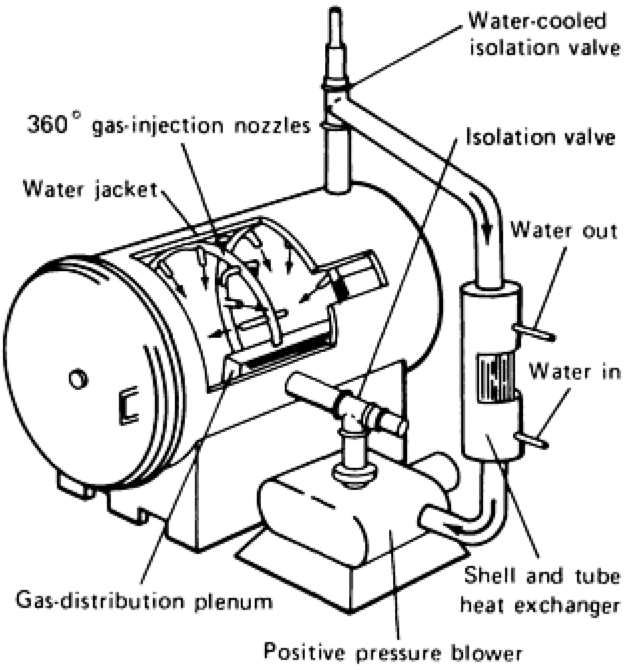

Fig. 14 Inert-gas recirculating system

Internal pressures used during inert gas quenching range from 13 to 86 kPa (100 to 650 torr) on furnaces that do not have positive-pressure clamps on the doors. For even more rapid gas cooling with the proper furnace construction, positive pressure up to six times atmospheric pressure have been used.

Because of technical advances in fan motors, door-sealing methods, and related equipment, it has become common to cool loads with gas fans at pressures up to 170 kPa (1275 torr) in conventional units and up to several times atmospheric pressure in furnaces with turbine recirculation systems. Because the cooling rate is proportional to absolute pressure, it is increased considerably by positive-pressure cooling.

By backfilling to pressures above atmospheric pressure, for example, 70 kPa (10 psi) gage, rather than slightly below atmospheric pressure, the cooling time can be shortened by as much as 30% (see Fig. 15). This development has greatly enhanced the use of vacuum equipment for air-hardening tool steels with decreased overall cycle time.

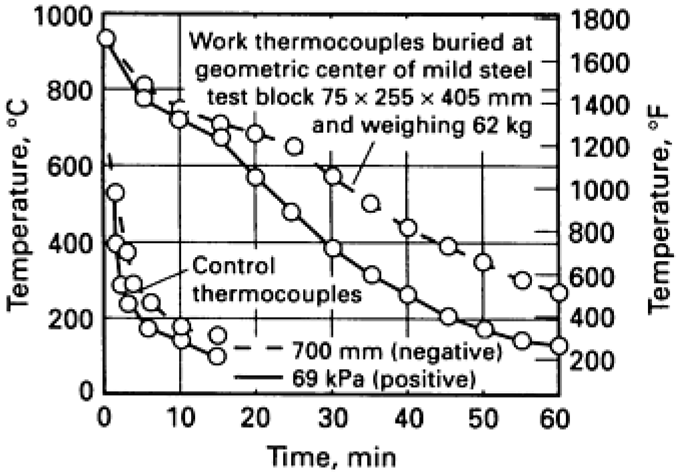

Fig. 15 Comparison of cooling rates and backfill pressures

The proportional increase of quenching speed with increasing gas pressure up to two times atmospheric pressure also applies to 500 kPa (5 bar) if the time delay in reaching this pressure and starting rapid gas circulation is minimal. Fast backfilling is promoted by a compact design and a special turbine system that builds up the forced circulation very rapidly. Figure 16 shows the effect of pressure on quenching speeds from a hardening temperature to 1010 °C (1850 °F). An increase in pressure from 100 to 200 kPa (1 to 2 bar) will decrease cooling time by 60 s, or 50%. An increase from four to five times atmospheric pressure would give a cooling-time decrease of 6 s, or 20%.

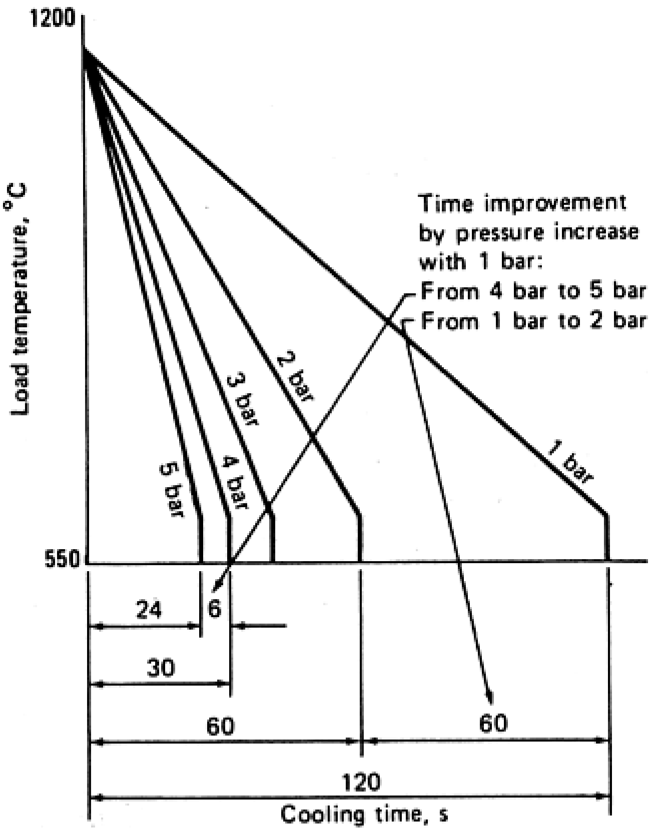

Fig. 16 Relationship between gas pressure and quenching rate

Liquid Quenching

When even faster cooling rates are needed, furnaces with liquid quench capabilities may be used. This usually requires an arrangement in which the quenching is done in a chamber isolated from the heating chamber. In one such design, a horizontal loading furnace has a rear heating chamber and a forward cooling chamber, with a vacuum sealing door between them. When the heating cycle is completed, the work is transferred to the front chamber. After the sealing door is closed, the work load is lowered into the quench tank by an elevator. The quenching liquid is agitated vigorously by propellers, and the heat absorbed by the quenching medium is removed by a heat exchanger similar to that used in many atmosphere heat-treating furnaces. The chamber that houses the quench tank can also be equipped with a circulating fan and cooling coils to provide forced convection gas cooling or liquid quenching. Quenching is usually completed at slightly below atmospheric pressure within an inert-gas backfill.

Precautions must be taken to ensure that the trays and fixtures that carry the work load into the heating chamber are degreased before reuse. Organic residues on trays and work load will outgas and make the pump-down time longer and give the interior of the furnace, and possibly the work, an undesirable appearance.

Gases Used for Backfilling

Gases used for backfilling vacuum furnaces are argon, nitrogen, helium, hydrogen, and natural gas. Argon and nitrogen can be obtained as compressed gases or as condensed liquids stored in cryogenic containers. Helium and hydrogen are readily available only as compressed gases. If appreciable amounts of argon or nitrogen are to be used, it is much less

expensive to purchase the gas in liquid form. Very high-purity gases are available, and some typical analyses of these gases are listed in Table 4.

Table 4 Typical analysis of backfill gases

Gas	Purity, %	Impurity, ppm							Dew point		Thermal conductivity (*k*) at 0 °C (32 °F)		Relative cooling rate[(a)]
		O_2	N_2	CO_2	CO	H_2	Hydro-carbons	Carbon-aceous gas	°C	°F	W/m · K	Btu · in./ft^2· h · °F	
Argon	99.9995	2	2	1	. . .	. . .	1	. . .	-79	-110	5.77	32.3	0.74
Nitrogen	99.9993	3	. . .	. . .	. . .	. . .	. . .	1	-79	-110	8.65	48.4	1.0
Helium	99.998	1	10	. . .	. . .	1	1	. . .	-62	-80	49.0	274	1.03
Hydrogen	99.9	10	1500	1	2	. .	25	. . .	-	-75	60.6	339	1.4

(a) Relative to nitrogen as 1.0

When a gas is purchased in a liquid state, it is stored under pressure in a large tank with a safety pressure relief value that allows gas to escape to the atmosphere if the internal pressure exceeds a set value. Liquid gas leaves the tank through a vaporizer, where ambient heat supplies the necessary heat for vaporization. Frequently, this vaporizer is a series of finned coils used to increase heat transfer. Because of the excellent insulation provided for the tank, usually very little gas is lost by venting. Sometimes a reservoir or storage tank of appreciable volume is used to store the vaporized gas at a nominal pressure to avoid sudden surges of pressure in the cryogenic system and to ensure that sufficient volume is available when backfilling is in progress.

Work Load Support

The work load in most vacuum furnaces is placed on a tray or in a basket to facilitate loading. Because such fixtures are heated and cooled at fairly rapid rates during processing, the material and design must allow for the cycles of thermal stresses. Molybdenum is often used for these support fixtures. If moderately high temperatures are used, as with many tool and die steels, austenitic stainless steel trays may be used. However, work baskets of Inconel alloys are often used in the processing of high-speed tool steels.

The work-supporting tray usually rests on a graphite or metallic hearth. Frequently this hearth consists of three or four horizontal molybdenum or graphite bars supported by heat-resisting piers from the furnace shell below. Some hearths use ceramic bars, and others use ceramic alumina wheels on which the work tray can be rolled.

It is essential that possible reactions between the hearth support and the work baskets be taken into consideration. Graphite hearths react with stainless steel and Inconel alloys to form a eutectic melting at approximately 1125 °C (2060 °F). To prevent a graphite hearth from reacting with a work basket or work load placed directly on the hearth, a thin sheet of a ceramic material capable of resisting high temperatures can be placed between the hearth and the workpiece. Some graphite hearth blocks have a longitudinal groove at the top. An alumina ceramic rod or tube is placed in the groove and supports the work or the work basket, thus separating the graphite and the metallic workpiece.

Molybdenum reacts with nickel to form a eutectic melting at approximately 1315 °C (2400 °F). Therefore, it is necessary to separate nickel-bearing alloys from a molybdenum hearth at this temperature. Slabs of honeycomb alumina ceramic are available for this purpose. Nickel and titanium form a eutectic melting at approximately 955 °C (1750 °F), and alloys of these metals must be kept separated if temperatures this high are contemplated. Table 5 is a listing of metal combinations and their compatibility.

Table 5 Maximum temperatures at which selected pure metals and metallic oxides are compatible in a 13 to 1.3 mPa (10^{-3} to 10^{-4} mm Hg) vacuum

Note: Although various materials may be compatible at a given temperature, a particular material may be unstable at this range of vacuum.

Vacuum Chambers

The prime requisites in the design, fabrication, and operation of a vacuum chamber are the prevention of leakage from the outside atmosphere and the assurance that the planned material processing will be completed without damage to the chamber or product. Leakage is a serious consideration even though the pressure within the vessel may be held at the required vacuum because the continual entrance of air into the evacuated chamber can be harmful to the product or internal components. If a high-capacity pump is used, the pump may well be able to maintain a low pressure inside the furnace regardless of a substantial air leak that causes a constant influx of oxygen, which can react with the surface of the work load. Many operators of vacuum equipment routinely conduct leak tests before energizing the heating elements. This is particularly useful when the work load consists of very expensive material. For example, a furnace is evacuated to 13 mPa (10^{-4} torr) for at least 1 h. The vacuum valve connecting the furnace to the pump is closed, and the rise in internal furnace pressure in a specified time interval is checked. It is difficult to set specific limits on leakage tolerance because this tolerance depends on the type of material being processed, the dew point of the air, and the length of time the furnace door is open. Common industrial practice with vacuum furnaces is to establish permissible leakage rates in terms of microns or micrometers per hour. A rate of rise between 1.3 and 3.3 Pa (10 and 25 μm Hg) per hour is generally an acceptable specification for most industrial work, but more stringent applications may require a lower rate. A more dependable method for discovering air leakage prior to or even during a run is to use a residual-gas analyzer. A residual-gas analyzer will indicate whether the leak is air, quench gas, water, solvent, or oil.

Generally, equipment manufacturers specify rate-of-rise measurements of 1.3 Pa (10 μm Hg) per hour or less for an empty, clean, cold, and thoroughly outgassed system. This measurement is usually obtained by checking the furnace after a gas cooling or vacuum cooling from a heat-up to a temperature sufficient to dry out or bake out the internal components. This procedure almost completely eliminates the out-gassing effects of work load and furnace components on rate-of-rise measurements.

Once a vacuum furnace has been properly installed and put into operation, the heat treater usually need only be concerned with preventing or correcting the leakage of air at seals around the doors, sight ports, pumping ports, electrical and water feed lines, mechanical rotating and sliding seals for introducing mechanical force and motion into the chamber, and any other point on the vessel that is subject to opening and closing.

Unless a vacuum furnace has been built for service at vacuum levels of 0.13 mPa (10^{-6} torr) or less, typical elastomer seals used in most applications will be worn out if subjected to overheating, to repeated openings and closings, or to rotating or sliding motions. When seals are replaced, all flanges must be properly aligned to ensure complete seating of the seal, and sharp edges or burrs must be removed to prevent physical damage. A good grade of vacuum grease lubricant should be used sparingly to facilitate placement of the seals and to obtain optimum sealing.

The best and most expensive vacuum chambers are constructed of an oxidation-resistant material such as a 300-series stainless steel. This material may be used for vacuum service at approximately 0.13 mPa (10^{-6} torr) pressure or less or when the vacuum chambers must operate as a hot-wall or retort unit. A less expensive carbon steel, adequately epoxy coated, is effective in cold-wall chambers for most heat-treating applications. However, unprotected carbon steel should not be used in the construction of a vacuum chamber. When carbon steel is exposed to a vacuum, it can be so thoroughly degassed that oxidation occurs very rapidly when reexposed to atmospheric conditions. Oxidation that occurs in a carbon steel chamber is permanent and progressive because the chamber is completely water-jacketed and does not achieve the temperatures necessary for surface cleaning.

The efficiency of the pumping system can be affected by the material used to build the vacuum chamber. For example, a stainless steel chamber with a total volume of 0.3 m^3 (10 ft^3) will require 10 min for evacuation to a pressure of 1.3 mPa (10^{-5} torr) by a 152 mm (6 in.) diffusion pump. A chamber with the same volume constructed of unprotected carbon steel can require evacuation times of up to 30 min to achieve the same pressure. If the carbon steel surfaces are oxidized, evacuation times of up to 2 h can be required.

Pumping Systems

Vacuum vessels are evacuated by various types of pumping systems that depend, to a great extent, on the pressure range needed for processing. An adequate vacuum pumping system must attain the specified pressure and must have sufficient capacity to handle the processing gas load, not only at the ultimate pressure but at all intermediate pressures during the pump-down cycle. Pumping systems are usually divided into two subsystems: the roughing pump and the high-vacuum pump. For certain requirements, a single pumping system is sufficient for the entire range and cycle. Pumps are usually

classified as mechanical or diffusion pumps. The choice of pump or combination of pumps depends largely on the pressure and gas volume or pumping rates required for a specific process and size of vacuum vessel. The vacuum system shown in Fig. 17 consists of a mechanical forepump that can be connected directly to the vacuum vessel by closing the high-vacuum valve, opening the roughing valve, and closing the foreline valve. This procedure isolates the diffusion pump from the rest of the system. The diffusion pump interior can then be pumped free of air by its mechanical holding pump.

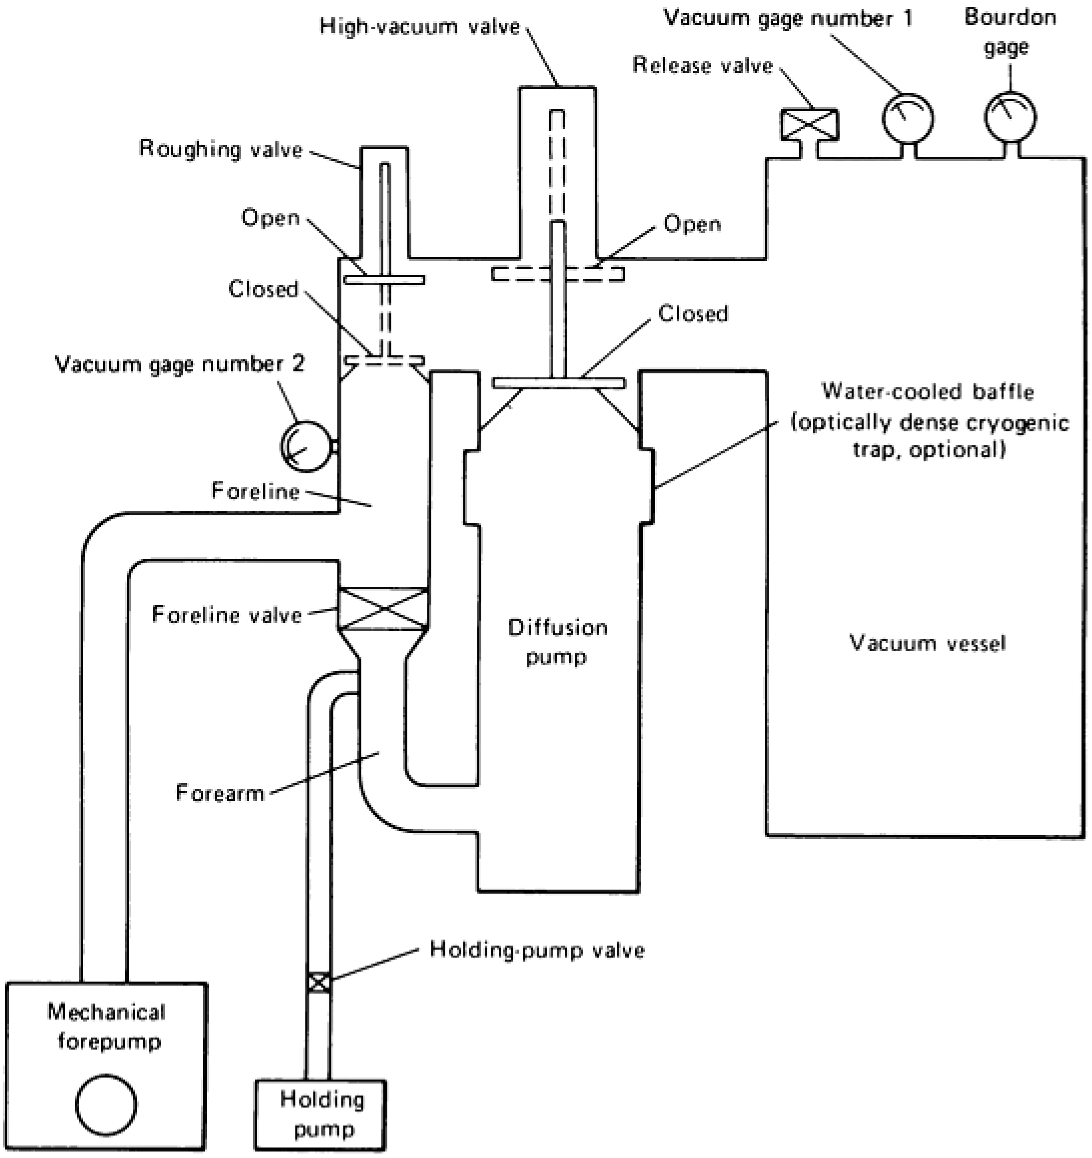

Fig. 17 Typical vacuum system containing mechanical and vapor pumps with interconnected valving and piping

When the pressure as shown on vacuum gage 2 has been reduced to a level at which the diffusion pump can operate efficiently, the roughing valve is closed and the foreline valve and high-vacuum valve are opened. The residual gas in the vacuum vessel can then expand continuously into the region of the diffusion pump, then through the foreline to the forepump, and finally to the atmosphere. The water-cooled baffle or other optically dense trap on top of the diffusion pump prevents diffusion pump oil from diffusing backward into the vacuum system. Vapors from the system are condensed in the liquid nitrogen cryogenic trap, if one is used, when a very high vacuum (very low pressure) of 0.13 mPa (10^{-6} torr) or below is desired. Vacuum gage 1 measures the pressure in the vacuum vessel. This gage should be more sensitive than vacuum gage 2. The release valve controls backfilling of the system to atmospheric pressure up to the high-vacuum valve.

Mechanical pumps operate on the fluid-flow principle and are primarily positive-displacement pumps with suitable seals to permit operation at low pressures. Piston pumps or rotary blowers in various pumping-speed ratings are available. Vacuum system levels down to 3.3 Pa (25 μm Hg) can be obtained with oil-sealed rotary mechanical pumps. Depending on the application, they may be called roughing or forepumps. They can discharge directly into the air against normal atmospheric pressure. A portion of air in the closed system expands into and is trapped within a chamber of the pump. This volume of air is then compressed by the movement of vanes or a piston in the interior of the pump and is expelled through a port equipped with a check valve. This process is repeated and, with each cycle, a portion of the remaining air volume in the closed system is expelled. When the back leakage through the pump or the leaks in the wall of the container equal the rate of air removal by the pump, the closed-vessel internal pressure remains constant.

A nonmechanical limitation on the ultimate pressure of a mechanical pump is the vapor pressure of the oil itself. Most commercial pump oils are controlled grades of petroleum type SAE 20, which have a vapor pressure of about 130 mPa (1 μm Hg).

When air containing moisture is compressed in the interior of the pump, water may condense and contaminate the oil, affecting the attainable ultimate pressure. One method used to prevent condensation is to introduce enough pure, dry air at the beginning of the cycle to ensure that the resulting moisture level of the trapped air is below the level at which compressive condensation can occur. Air is introduced during the pump compression cycle to prevent condensation of water vapor to water and to revaporize the water during the expansion cycle. During the expansion, the water may be pumped out as a vapor but not as a liquid. Called gas ballasting, this method alleviates the moisture condensation problem.

Diffusion Pumps. When the pressure in the vacuum chamber becomes so low and the molecules so few that the path typically traversed by a gas molecule exceeds the dimensions of the chamber, the remaining gas molecules collide more often with the walls than with each other. At higher pressures, the constant and frequent collisions of adjacent gas molecules and the resulting elastic rebounding effectively scatter and expand the gas such that it quickly fills any new volume created. At lower pressures, this effect nearly disappears, and the remaining gas is difficult to pump with fluid-flow positive-displacement mechanical pumps.

At these pressures, it is necessary to allow molecules to diffuse randomly into the throat of the pump, and to impart a preferred direction of motion to the molecules by momentum transfer. For pumping at a vacuum system level below 130 mPa (10^{-3} torr), a vapor diffusion pump is generally used. Pumping action is directed by a high-velocity stream of heavy molecules in the form of a pump fluid, usually oil. The heavy molecules strike the gas molecules and push them in the desired downward direction toward the outlet of the pump. To be effective, the inlet pressure of the diffusion pump should be below 130 mPa (1 μm Hg) so that the vapor stream is operating in nearly empty space except for the occasional diffusing gas molecule.

A diagram of a three-nozzle vapor diffusion pump is shown in Fig. 18. Vapor from a liquid held in a closed boiler heated at the bottom is forced upward inside the boiler. The vapor passes quickly at a downward angle through narrow, circumferential openings in the nozzles. Molecules of gas that stray from the vacuum chamber above the pump toward the vapor jet streaming from the nozzles encounter the downward-directed stream of heavy molecules. The overall effect is to compress the gas molecules and force them downward to a point at which they can be removed by the mechanical forepump.

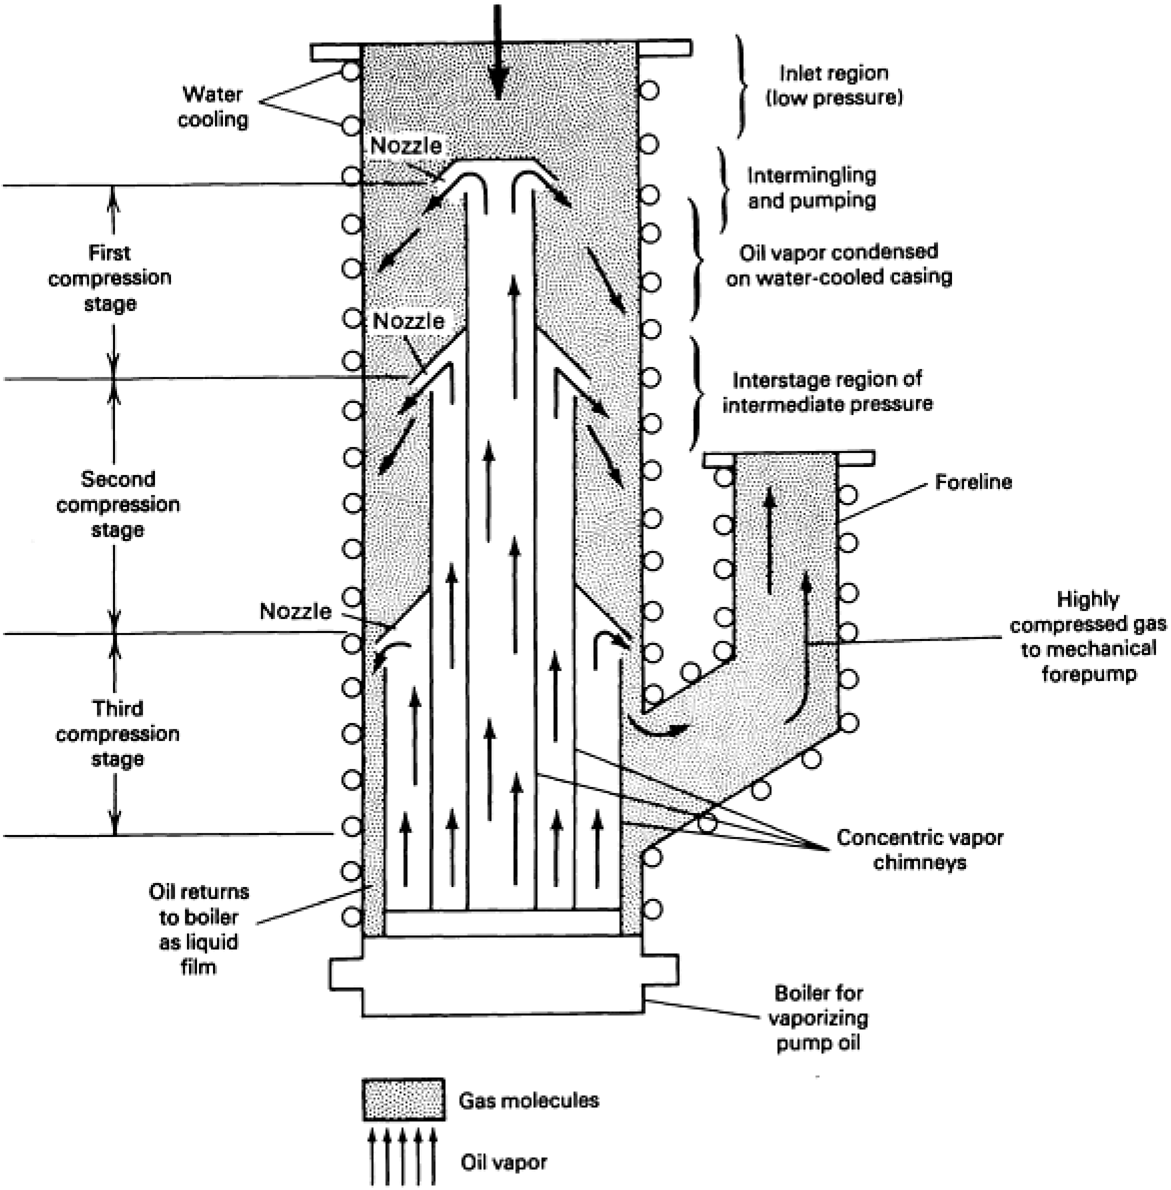

Fig. 18 Oil vapor diffusion pump

Pump vapor is condensed on the cooled inner walls of the pump and returns as a liquid to the boiler. Maximum velocity is imparted to the gas molecules by using a liquid composed of heavy molecules in the boiler. Efficiency is improved by using several nozzles in line, one above the other. Special highly stable liquids with very low vapor pressure are required for such diffusion pumps.

Backstreaming is the movement of the molecules of the pump fluid above the inlet flange of the diffusion pump and in the direction of the vacuum chamber. The rate of backstreaming increases rapidly as the inlet pressure exceeds 130 mPa (1 μm Hg) and depends on the size and type of diffusion pump. Backstreaming can also be caused by exceeding the fore pressure limit, which is about 65 Pa (500 μm Hg), of most diffusion pumps. Backstreaming can be reduced by interposing opaque baffles between the diffusion pump throat and the vacuum chamber. Most backstreaming originates at the top jet of the pump and can be reduced by placing a water-cooled cap above the jet. The oil vapor condenses on the cap and drips back into the pump.

By using a cold trap placed above the throat of the diffusion pump, it is possible to reduce oil backstreaming further. The cold trap consists of an arrangement of baffles and water-cooled or refrigerant-cooled walls that provide an opaque path through the trap. A refrigerant such as liquid nitrogen may be used. Molecules of oil condense on the surface of the cooled baffle and remain trapped. Such traps also attract condensable vapors that may be present in the vacuum chamber.

Water vapor, the most common contaminant present in high-vacuum systems, may be removed successfully in this way. The capability of the trap to serve as a pump for condensable vapors increases as the temperature of the refrigerant decreases.

Other Pumping Systems. Many types of vacuum pumps may be used, depending on the pressure to be maintained for a given vacuum process. The rotary mechanical pump and the oil vapor diffusion pump are typically used for most vacuum metallurgical processes. Other types of pumps include steam ejector, oil booster, liquid ring, turbomolecular, and cryogenic pumps. These pumps are used in vacuum processing for such functions as degassing and drying in conjunction with a rotary pump.

Steam ejector pumps have an operating range from 0.13 to 1.3 Pa (1 to 10 μm Hg). Although steam ejector pumps eliminate the need for a mechanical pump, they require a large volume of steam to operate. Because their principal advantage is the capability of removing large volumes of gas vapor at low vacuum levels, they are suitable for laboratory work and for very large vacuum vessels, especially if noxious vapors are to be pumped.

Oil booster pumps have an operating range from 130 to 0.13 Pa (1000 to 1 μm Hg) and require a backing pump. These pumps tend to introduce the excessive backstreaming of oil vapor into the vacuum vessel and are used mainly when high pumping capacities are desired above 1.3 Pa (10 μm Hg). They can be used in conjunction with an oil diffusion pump to achieve lower pressures while maintaining high pumping capacities.

Cryogenic pumps condense gas molecules on refrigerated surfaces at -195 °C (-320 °F) or lower. These pumps are regenerated periodically by heating the condensing surfaces to vent the accumulation of condensed gases. Cryogenic pumps are often used instead of diffusion pumps to pump high volumes of water vapor and other condensable gases in the 130 to 0.013 mPa (10^{-3} to 10^{-8} mm Hg) range. Cryogenic pumps capture the gas instead of pumping it. Consequently, they must be shut off occasionally for gas removal.

Gas Flow Valves. Gas flow of the vacuum pumping system is controlled by three specific types of valves, as shown in Fig. 19. High-vacuum valves isolate the oil diffusion pumps from the vessel, and butterfly and gate valves are used as roughing, foreline, and holding-line valves. All of these valves have apertures that provide minimal gas flow impedance and special seals for vacuum service.

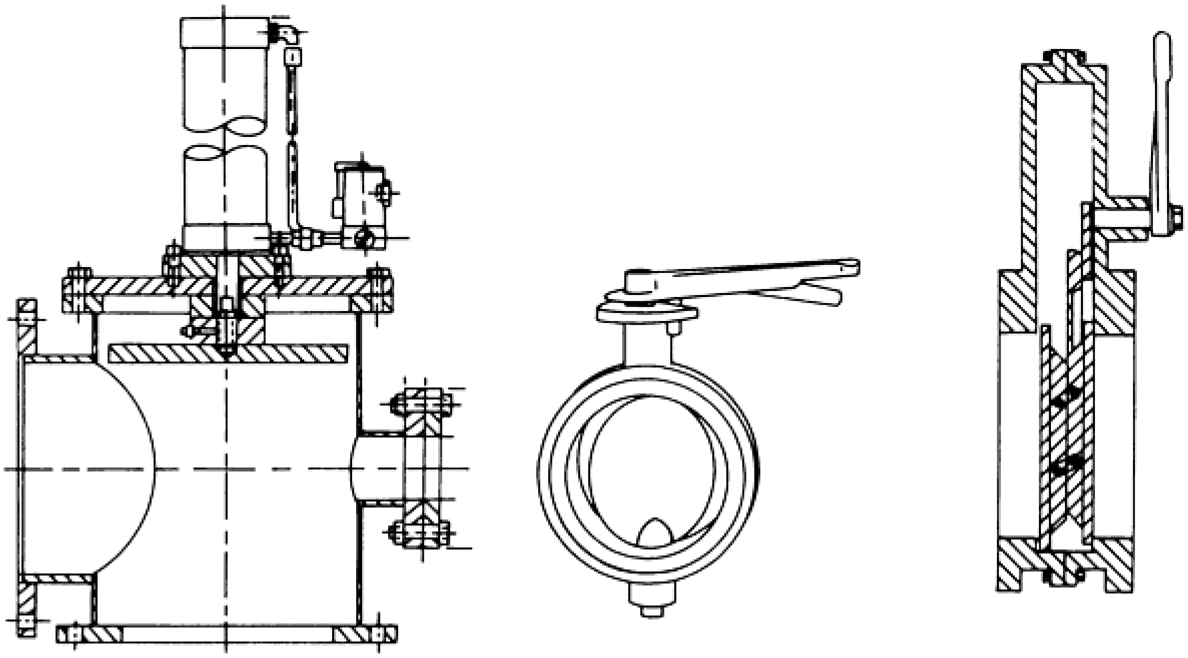

Fig. 19 Typical vacuum valves

Process Control Instrumentation

Except for vacuum-gaging instruments, the instruments used in vacuum equipment processing are similar to those used in other heat-treating operations. Once vacuum control has been attained, heating cycles can be initiated, either manually or automatically, by a temperature-sensing instrument.

Temperature Control Systems

Temperature control systems consist of a primary sensing device, the control instrument, and the final control element.

Pyrometers. The total radiation pyrometer is adaptable to automatic control, but its accuracy may be impaired by intervening media such as gas, smoke, or a discolored sight-glass window. Sublimation of materials within the furnace may cause the deposition of metallic vapors on the sight-glass window, thereby reducing the radiation reaching the detector.

Thermocouples are typically used as temperature-sensing devices, although their performance varies with the environment (from a vacuum to an oxidizing atmosphere). Unless the hot junction of the thermocouple is attached to the part being measured, heat transfer to the thermocouple is based almost completely on radiation. In air or other furnace atmosphere, a thermocouple receives heat by conduction and convection. For this reason, the response time of a thermocouple in a vacuum is slower than in air. A change in air gap of 0.03 mm (0.001 in.) between the hot junction of the thermocouple and the part being measured can change the response time of the thermocouple significantly.

Control thermocouples made from nickel-nickel molybdenum are satisfactory for many heat-treating applications up to 1290 °C (2350 °F) (see Table 6 and Fig. 20). Noble metal thermocouples such as platinum-platinum rhodium are used up to 1650 °C (3000 °F) (see Table 7 and Fig. 21). Refractory metal thermocouples such as those of tungsten-rhenium are used up to 2205 °C (4000 °F) (see Table 8 and Fig. 22). Thermocouples are sometimes used with unsheathed (bare wire) hot junctions, reducing lag time tremendously. In many applications, particularly with platinum, thermocouples are sheathed in an adequate ceramic or metal protection tube. Below 1095 °C (2000 °F), sheathed base-metal thermocouples can be used to measure different locations in the load.

Table 6 Properties of 19 alloy/20 alloy nonstandard thermocouple

Property	**Thermoelement**	
	Negative 19 alloy	**Positive 20 alloy**
Nominal composition	Ni-1Co	Ni-18Mo
Melting point, °C (°F)	1450 (2640)	1425 (2595)

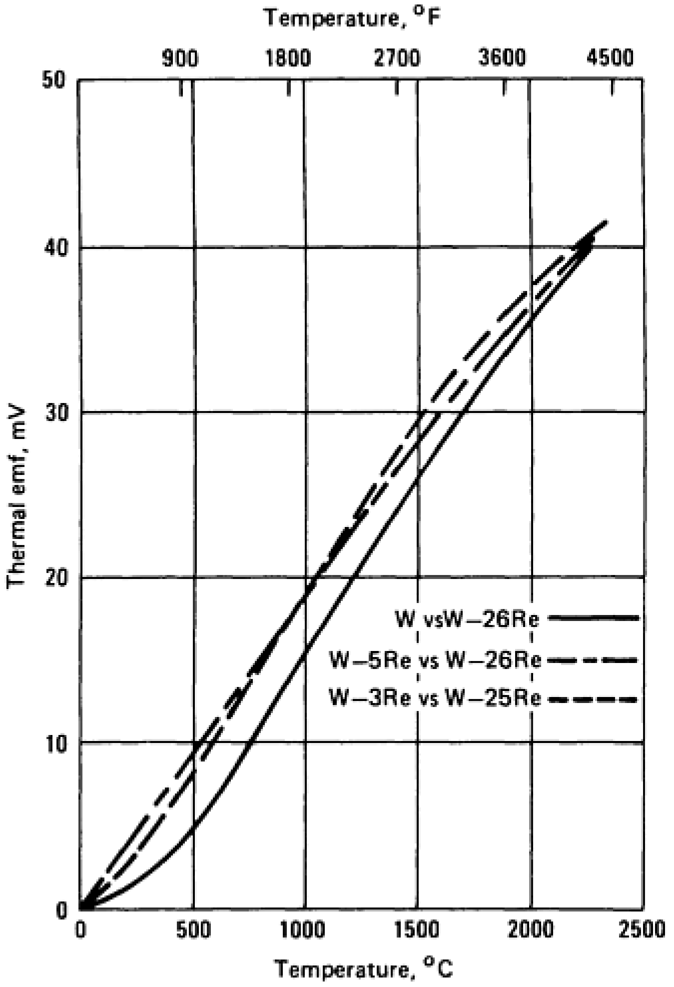

Fig. 22 Thermal emf of tungsten-rhenium thermocouples

Because rapid heating rates can be achieved in most vacuum furnaces, it is important to determine temperatures at various locations in the work load. For instance, a large die may overheat in certain locations within the furnace. Information on heating uniformity is also required when processing smaller parts loaded in baskets.

To bring thermocouple lead wires through the exterior shell of the furnace, special feed-through fixtures are provided. These fixtures are electrically insulated and vacuum tight, and they constitute a permanent portion of the furnace. The ends of the lead wires inside the furnace have ceramic-insulated quick-disconnecting terminals to which workpiece thermocouples can be connected. Type K chromel-alumel thermocouples are often used to monitor workpieces if the temperature to be measured is not above 1175 °C (2150 °F) and the time at temperatures above 980 °C (1800 °F) is not excessively long (see Table 7 and Fig. 21).

Additional information is available in the article "Furnace Temperature Control" in this Volume.

Pressure Control Systems

Instruments used to measure and record the pressure inside a vacuum processing chamber fall into two classifications: those that measure the pressure hydrostatically, and those that sense some physical characteristic of the gas that bears a definite relationship to the pressure.

Hydrostatic Measuring Devices. The Bourdon pressure gage and the McLeod gage are two hydrostatic measuring devices.

The Bourdon gage (Fig. 23) accurately and continuously indicates the pressure from 100 kPa (1 atm) to approximately 1 kPa (0.01 atm) and can be used effectively to monitor the roughing cycle and the performance of the roughing pump.

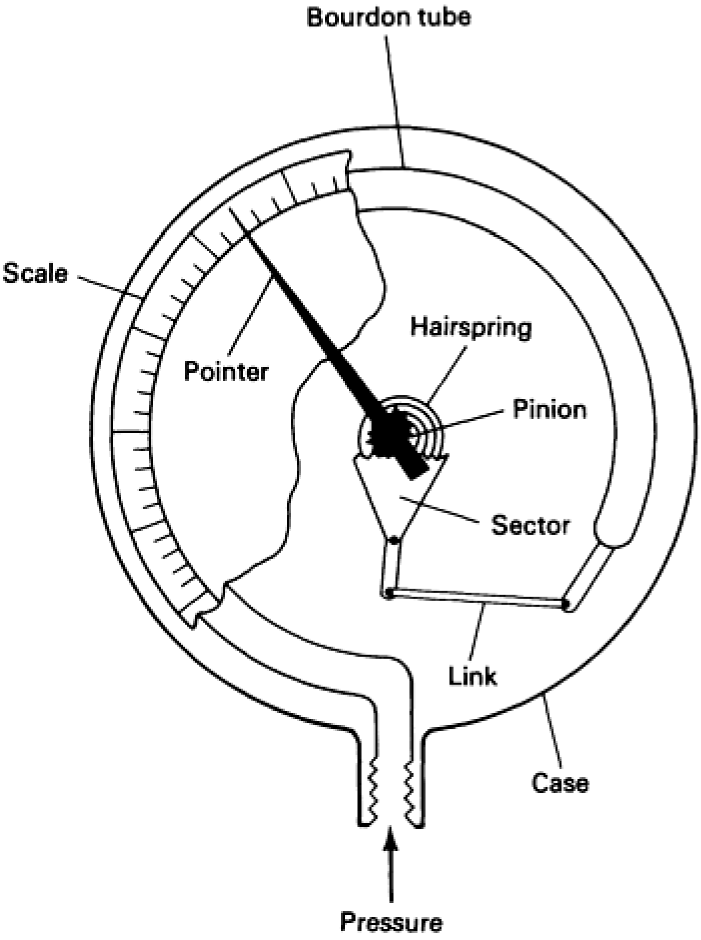

Fig. 23 Spriral Bourdon tube gage

McLeod Gage. Special, expensive diaphragm gages are available for measuring pressures continuously from atmospheric pressure down to approximately 13 mPa (10^{-4} torr). Pressures from a few torr down to 13 mPa (10^{-4} torr) can be measured periodically with a McLeod gage (Fig. 24), which samples the gas and compresses it to a small, calibrated volume. It then registers the ratio of the initial and final volumes, and this ratio is an indication of the pressure at which the gas sample was taken. McLeod gages are manual units that are usually used to monitor the accuracy of other gages.

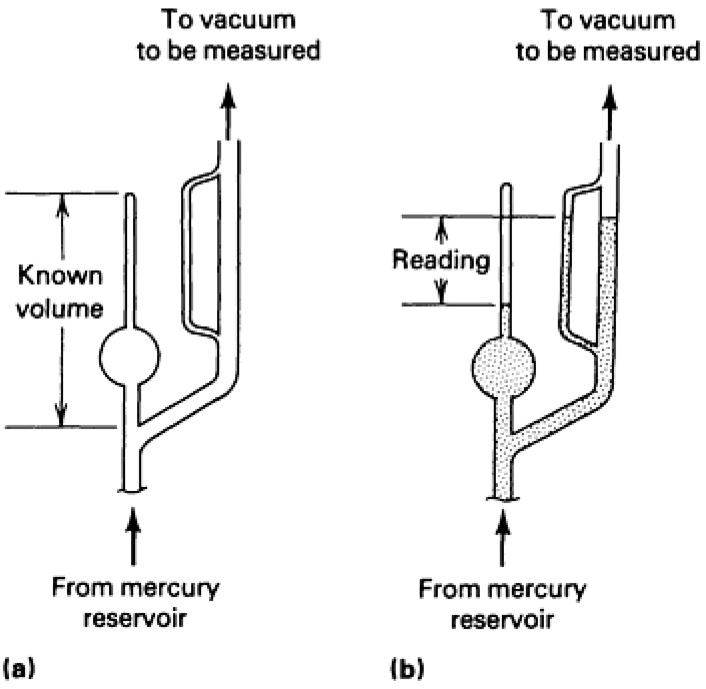

Fig. 24 McLeod gage. (a) In filling (charging) position. (b) In measuring position

Thermal and Electrical-Conductivity Measuring Devices. The second classification of gages includes those that sense the thermal and electrical conductivity of the gas. These physical characteristics bear a direct relationship to pressure and to the specific type of gas.

The thermal-conductivity gages are widely used for most vacuum metallurgical processing because they are relatively inexpensive and can continuously monitor vacuum levels between 130 and 0.13 Pa (1 and 10^{-3} torr). The thermal conductivity, or convective heat transfer, of a gas is essentially constant as pressure is reduced until a pressure of about 130 Pa (1 torr) is reached. From that point, the conductivity declines until, at a pressure somewhat less than 0.13 Pa (10^{-3} torr), there is almost no heat transfer by the gas molecules to the surface of the gage walls, and thermal conductivity becomes virtually 0. This trend is shown for a typical common gas in Fig. 25.

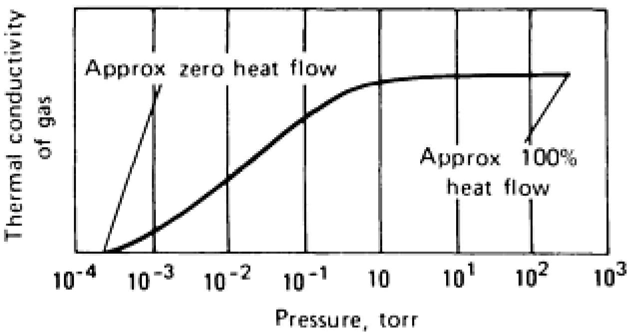

Fig. 25 Relationship between the thermal conductivity of gas and pressure

Thermal conductivity varies considerably from 0.13 to 130 Pa (10^{-3} to 1 torr), but varies little above that pressure; this behavior constitutes the operational principle of the thermal-conductivity gage. Two gages use this principle, the thermocouple and the Pirani.

The radiation or thermocouple gage is based on the principle that, as the amount of gas in a vessel decreases, the temperature of a constantly heated wire increases because less heat is radiated to the surrounding environment. The thermocouple gage is the most commonly used measuring device used with vacuum furnaces.

Wire temperature is measured by a fine wire thermocouple attached to the midpoint of the heated wire. The maximum temperature of the wire is about 115 °C (240 °F), a temperature reached at pressures of 130 mPa (1 μm Hg) or less. A typical thermocouple gage is shown in Fig. 26. Advantages of this gage are:

- Circuitry and tubes are comparatively inexpensive
- It samples temperature continuously
- Because of the relatively low wire temperature, it can be exposed to air for years without damage or danger of burnout
- The signal can be used to activate relays or other remote controls

Disadvantages of this gage are:

- Because different gases have different thermal-conductivity values, the gage requires calibration for each type of gas
- The scale is markedly nonlinear; at low pressures, the marks on the scale are spread widely; in higher ranges, the marks are closely spaced (Fig. 25)
- Output depends somewhat on the ambient temperature of the tube
- The useful range is from 0.13 to 130 Pa (1 to 1000 μm Hg)

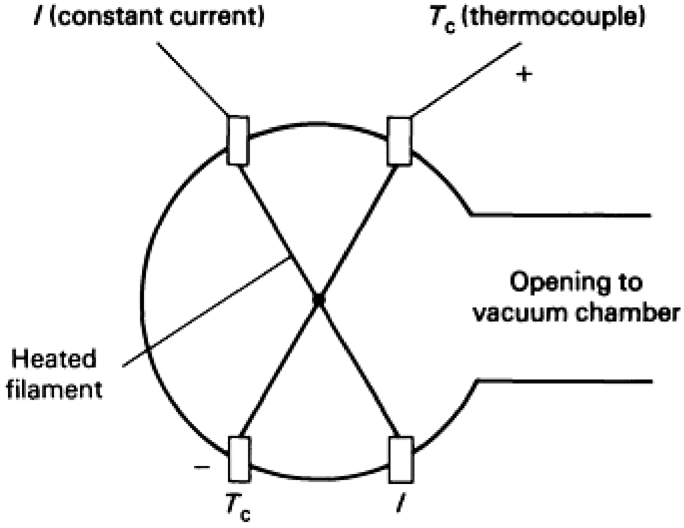

Fig. 26 Thermocouple-type thermal-conductivity vacuum gage

The Pirani gage (Fig. 27) uses the same thermal conductivity principle as the radiation or thermocouple gage. Operation is based on the change of heat conductivity of a gas with pressure and the change of electrical resistance of a wire with temperature. When the wire is electrically heated with a constant current, its temperature changes with pressure, producing a voltage across the bridge network. The compensating cell corrects for changes in room temperature. The vacuum pressure is thus measured in terms of the bridge imbalance. The system is somewhat more expensive and complicated than the thermocouple gage, with essentially the same advantages and disadvantages.

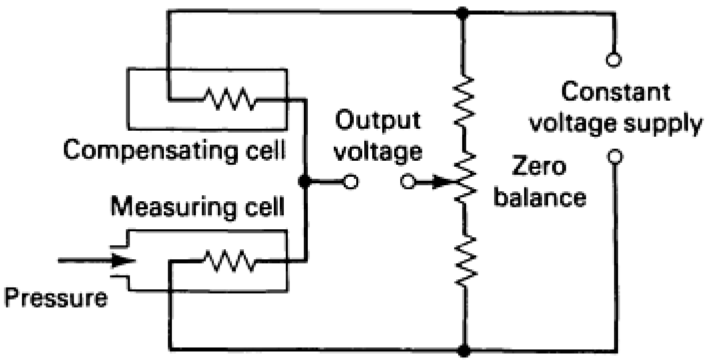

Fig. 27 Schematic of a Pirani gage

Hot-Filament Ionization Gage. The thermocouple and Pirani gages do not measure pressures of less than 0.13 Pa (1 μm Hg); therefore, a different type of gage is necessary for systems operating below this level. For vacuums from 130 mPa to 0.13 μPa (10^{-3} to 10^{-9} torr), the hot-filament ionization gage can be used. The sensing element of the gage resembles a triode vacuum tube. Figure 28 shows the three elements of a hot-filament ionization gage. A heated filament emits electrons that are attracted to the loosely wound and positively charged grid. The electrons strike residual molecules of gas in the vacuum. These collisions may remove an electron from the gas molecule, resulting in a positively charged gas ion, which is attracted to the collector. The positive ion current flow from the collector to ground is a measure of the gas pressure or vacuum.

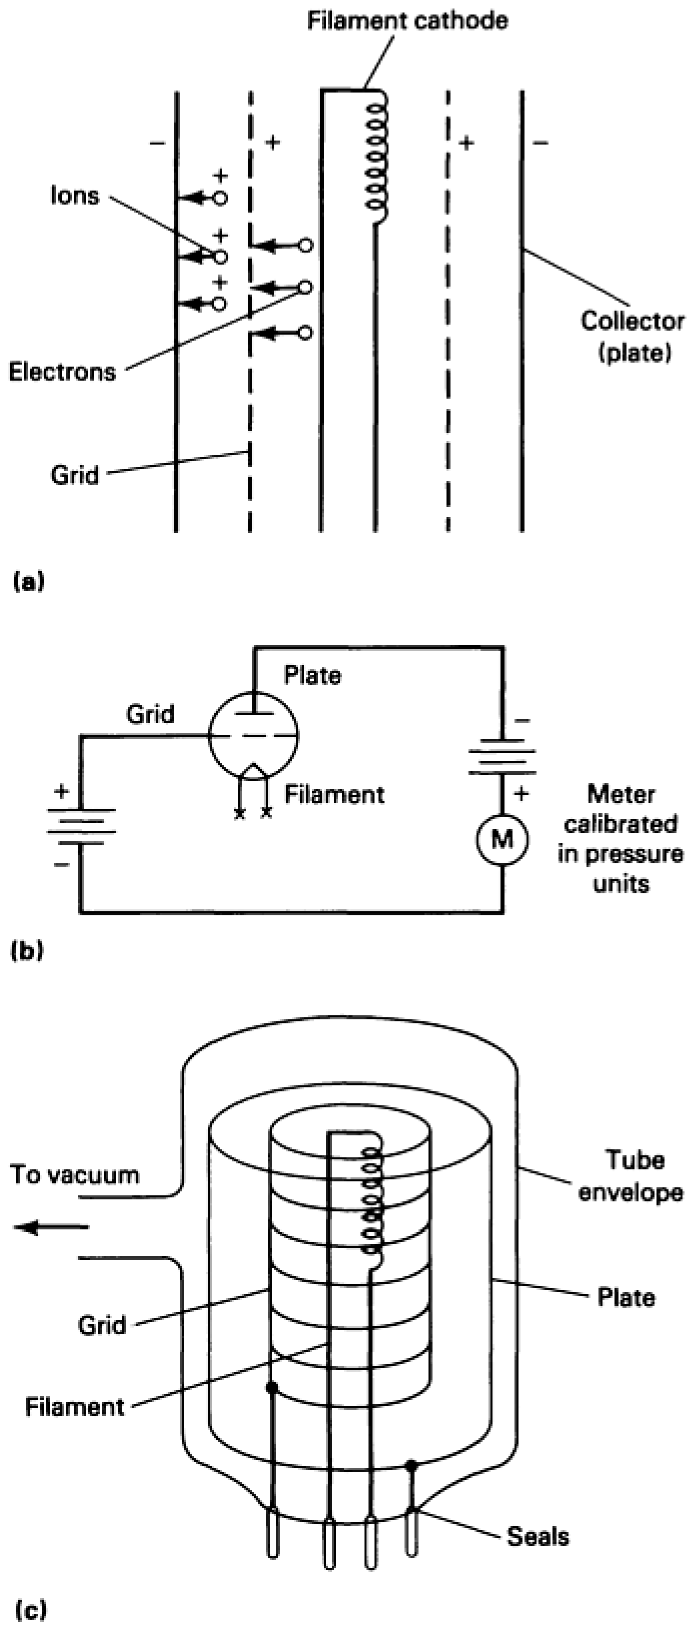

Fig. 28 Components of a hot-filament ionization gage. (a) Movement of electrons and ions in relation to filament cathode. (b) Simplified electrical circuit of the device. (c) Typical gage construction. A tungsten or thoria-coated filament cathode emits a current of approximately 5 mA. The electrons are accelerated toward a cylindrical grid operated at approximately 150 V.

The glass ionization gage, which originated in the radio tube industry, is usually calibrated with dry nitrogen. Its response varies slightly with other gases, and this must be considered when great accuracy is required. The filament can deteriorate, with a resulting loss of accuracy and subsequent burnout.

Cold-Cathode Ionization Gage. Another type of ion gage is the cold-cathode gage (Fig. 29), which depends on the measurement of an ion current produced by a high-voltage discharge. The cathode in the sensing element releases electrons that spiral through a magnetic field toward the anode. This spiralling motion lengthens the distance that electrons travel between cathode and anode, increasing the probability of collision with gas molecules and the formation of positive ions. The formation of ions varies linearly with pressure, and the ion current indirectly indicates the pressure. These rugged gages are well suited for production applications. They cannot be degassed as easily, however, and they are more readily contaminated and less accurate than hot-filament gages. Output is linear below 130 mPa (10^{-3} torr), and the usable range for measuring vacuum is between 1300 and 0.13 mPa (10^{-2} and 10^{-6} torr).

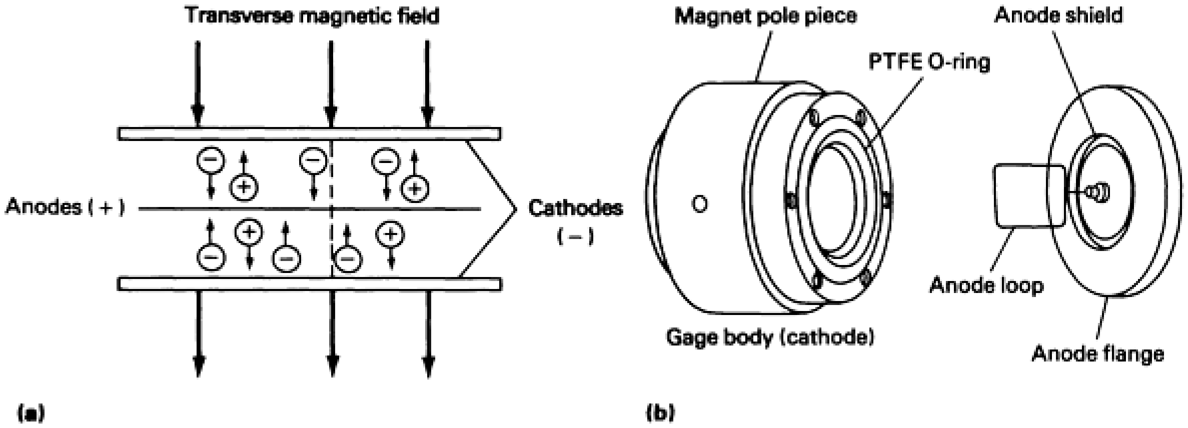

Fig. 29 Components of a cold-cathode discharge gage. (a) Movement of electrons in relation to magnetic field. (b) Typical gage construction showing cathode body and anode flange. PTFE, polytetrafluoroethylene

Whether the ionization gage is the hot-filament or the cold-cathode type, vacuum gas is used for vacuum pressures below 130 mPa (10^{-3} torr).

Heat-Resistant Materials for Heat-Treating Furnace Parts, Trays, and Fixtures

Revised by G.Y. Lai, Haynes International, Inc.

Introduction

TRAYS AND FIXTURES made of heat-resistant alloys are among the many parts used in industrial heat-treating furnaces that operate at temperatures from 540 to 1200 °C (1000 to 2200 °F). Coverage of heat-resistant structural materials may be found in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*, together with room-temperature and high-temperature mechanical properties.

Basic Metallurgy and Product Forms

A partial list of typical products can be divided into two categories: The first consists of parts that go through the furnaces and are therefore subjected to thermal and/or mechanical shock; these include trays, fixtures, conveyor chains and belts, and quenching fixtures. The second comprises parts that remain in the furnace with less thermal or mechanical shock; these include support beams, hearth plates, combustion tubes, radiant tubes, burners, thermowells, roller and skid rails, conveyor rolls, walking beams, rotary retorts, pit-type retorts, muffles, recuperators, fans, and drive and idler drums.

These heat-resistant alloys are supplied in either wrought or cast forms. In some situations, they may be a combination of the two. The properties and costs of the two forms vary, even though their chemical compositions are similar. Because

there are many foundries and fabricators experienced in the design and application of these products, it is important to seek their advice when purchasing high-alloy parts.

Five types of heat-resistant alloys are listed in Vol 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*:

- Iron-chromium alloys
- Iron-chromium-nickel alloys
- Iron-nickel-chromium alloys
- Nickel-base alloys
- Cobalt-base alloys

The great majority of heat-treating furnaces use only the second and third types because the iron-chromium alloys do not have sufficient high-temperature strength to be useful. Some iron-chromium alloys (more than 13% Cr) are susceptible to so-called 475 °C (885 °F) embrittlement. Because of increasing temperatures (for example, >980 °C, or 1800 °F), more and more applications use nickel-base alloys because of their improved creep-rupture strengths and oxidation resistance. Cobalt-base alloys are generally too expensive except for very special applications. Therefore, this discussion will be limited to the use and properties of the iron-chromium-nickel, iron-nickel-chromium, and nickel-base alloys.

Room-temperature mechanical properties have limited value when selecting materials or designing for high-temperature use, but they may be useful in checking the quality of the alloys. These properties are shown in Vol 1 and also may be found in ASTM specification A 297. The useful high-temperature properties of these alloys are summarized in Table 1 for castings and Table 2 for wrought products. The tables include nominal composition of the alloys and the stress required to produce 1% creep in 10,000 h and rupture in 10,000 h and 100,000 h, at temperatures of 650, 760, 870, and 980 °C (1200, 1400, 1600, and 1800 °F). A design stress figure commonly used for uniformly heated parts not subjected to thermal or mechanical shock is 50% of the stress to produce 1% creep in 10,000 h, but this should be used carefully and should be verified with the supplier.

In general, these materials contain iron, nickel, and chromium as the major alloying elements. Carbon, silicon, and manganese also are present and affect the foundry pouring and rolling characteristics of these alloys, as well as their properties at elevated temperature. Nickel influences primarily high-temperature strength and toughness. Chromium increases oxidation resistance by the formation of a protective scale of chromium oxide on the surface. An increase in carbon content increases strength.

Since the mid to late 1970s, a number of heat-resistant wrought alloys have been developed and are now being used in the heat-treating industry. Some of these alloys, such as Haynes alloys 230 (UNS N06230) and 556 (UNS R30556) and Inconel alloy 617 (UNS N06617), were originally developed for gas turbines, which require alloys with high creep-rupture strengths, good oxidation resistance, good fabricability, and good thermal stability. These alloys, commonly

referred to as solid-solution-strengthened alloys, use molybdenum and/or tungsten for strengthening. The alloys are also strengthened by carbides. Another high creep strength alloy, originally developed for gas turbine combustors, is Incoloy alloy MA 956, which is strengthened by oxide dispersion. This alloy is produced by a mechanical alloying process, using the high-energy milling of metal powders. These wrought heat-resistant alloys, along with chemical compositions and major characteristics, are tabulated in Table 3.

All of the alloys commonly used in castings for furnace parts have essentially an austenitic structure. The iron-chromium-nickel alloys (HF, HH, HI, HK, and HL) may contain some ferrite, depending on composition balance. If exposed to a temperature in the range of 540 to 900 °C (1000 to 1650 °F), these compositions may convert to the embrittling σ phase. This can be avoided by using the proper proportions of nickel, chromium, carbon, and associated minor elements. Chromium and silicon promote ferrite, whereas nickel, carbon, and manganese favor austenite. Use of the iron-chromium-nickel types should be limited to applications in which temperatures are steady and are not within the σ-forming temperature range. Transformation from ferrite to σ phase at elevated temperature is accompanied by a change from ferromagnetic material and from a soft to a very hard, brittle material. All heat-resistant alloys of the iron-nickel-chromium group are wholly austenitic and are not as sensitive to composition balance as is the iron-chromium-nickel group. Also, the iron-nickel-chromium alloys contain large primary chromium carbides in the austenitic matrix and, after exposure to service temperature, show fine, precipitated carbides. The iron-nickel-chromium alloys are considerably stronger than the iron-chromium-nickel alloys and may be less expensive per part if the increased strength is considered when designing for a known load.

The life expectancy of trays and fixtures is best measured in cycles rather than hours, particularly if the parts are quenched. It may be cheaper to replace all trays after a certain number of cycles to avoid expensive shutdowns caused by wrecks in the furnace. Chains or belts that cycle from room temperature to operating temperature several times a shift will not last as long as stationary parts that do not fluctuate in temperature. Parts for carburizing furnaces will not last as long as those used for straight annealing.

Finally, alloy parts represent a sizable portion of the total cost of a heat-treating operation. Alloys should be selected carefully, designed properly, and operated with good controls throughout to keep costs at a minimum.

Material Comparison for Heat-Resistant Cast and Wrought Components

The selection of a cast or fabricated component for furnace parts and fixtures depends primarily on the operating conditions associated with heat-treating equipment in the specific processes, and secondarily on the stresses that may be involved. The factors of temperature, loading conditions, work volume, rate of heating, and furnace cooling or quenching need to be examined for the operating and economic trade-offs. Other factors that enter into the selection include furnace and fixture design, type of furnace atmosphere, length of service life, and pattern availability or justification.

Some of the factors affecting the service life of alloy furnace parts, not necessarily in order of importance, are alloy selection, design, maintenance procedures, furnace and temperature control, atmosphere, contamination of atmosphere or work load, accidents, number of shifts operated, thermal cycle, and overloading. High-alloy parts may last from a few months to many years, depending on operating conditions. In the selection of a heat-resistant alloy for a given application, all properties should be considered in relation to the operating requirements to obtain the most economical life.

If either cast or wrought alloy fabrications can be used practically, both should be considered. Similar alloy compositions in cast or wrought form may have varying mechanical properties, different initial costs, and inherent advantages and disadvantages. Castings are more adaptable to complicated shapes, and fabrications to similar parts, but a careful comparison should be made to determine the overall costs of cast and fabricated parts. Initial costs, including pattern or tooling costs; maintenance expenses; and estimated life are among the factors to be included in such a comparison. Lighter-weight trays and fixtures will use less fuel in heating. Cast forms are stronger than wrought forms of similar chemical composition. They will deform less rapidly than wrought products, but may crack more rapidly under conditions of fluctuating temperatures. Selection should be based on the practical advantages, with all facts considered.

General Considerations. Both cast and wrought alloys are well accepted by the designers and users of furnaces requiring high-temperature furnace load-carrying components. Heating elements are also manufactured in either cast or wrought form (Fig. 1).

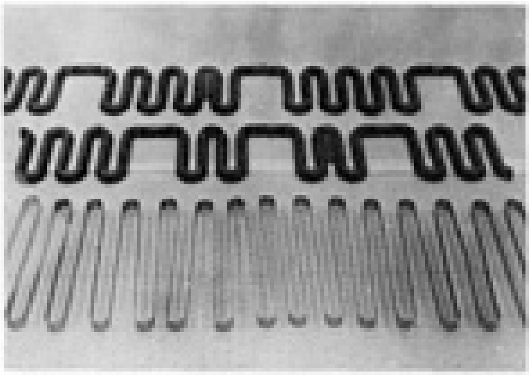

Fig. 1 Cast grid heating element (top) and ribbon heating element (bottom). Courtesy of the Electric Furnace Company

There are certain advantages for each type of manufactured component; often, the compositions are similar, if the carbon and silicon levels in the castings versus the wrought material are ignored. In general, the specifications of the wrought grades have carbon contents below 0.25%, and many are nominally near 0.05% C. In contrast, the cast alloys have from 0.25 to 0.50% C. This difference has an effect on hot strength. The difficulty in hot working the higher-carbon alloys accounts for their scarcity in the wrought series. Castings and fabricated parts are not always competitive; each product has advantages, which include:

Advantages of cast alloys

- *Initial cost:* A casting is essentially a finished product as-cast; its cost per pound is frequently less than that of a fabricated item
- *Strength:* Similar alloy compositions are inherently stronger at elevated temperatures than are wrought alloys
- *Shape:* Some designs can be cast that may not be available in wrought form; also, even if wrought material is available, it may not be able to be fabricated economically
- *Composition:* Some alloy compositions are available only in castings; they may lack sufficient ductility to be worked into wrought material configurations

Advantages of wrought alloys

- *Section size:* There is practically no limit to section sizes available in wrought form
- *Thermal-fatigue resistance:* The ductility of the fine-grain microstructure of wrought alloys may promote better thermal fatigue resistance
- *Soundness:* Wrought alloys are normally free of internal or external defects; they have smoother surfaces that may be beneficial for avoiding local hot spots
- *Availability:* Wrought alloys are frequently available in many forms from stock

Shape, complexity, and number of duplicate parts (eventually affecting cost) usually determine the choice between casting or wrought part. Where section thickness and configuration permit, castings are usually cheaper. The cost per pound of the casting metal is comparable to that of a fabricated part. The total projected cost of the fabrication is usually higher because the cost of forming, joining, and/or assembling must be added to the cost of the material. However, when only one or two types of parts are to be made, the pattern cost precludes the use of a casting.

In energy-intensive heat-treating industries, the use of wrought fabrications allows fuel savings through reduced heat-treating time cycles. At the present level of energy costs, wrought fabrications may be economically preferable because of improvements in thermal efficiency.

Fabrications are preferred for thin sections and for parts where less weight or greater heat transfer may be required. Where thick walls are necessary for strength or where heavy loads are transported or pushed, the cost of fabricated sections may be prohibitive. Wrought materials have a greater degree of acceptance in fabricated baskets used under carburizing or carbonitriding conditions.

A factor that must be considered in evaluating castings and fabrications is the importance of good welding techniques, particularly for parts that are used in case hardening atmospheres. Castings have replaced fabricated products because of weld failures in multiwelded fabrications.

Although cast alloys exhibit greater high-temperature strength, it is possible to place too much emphasis on this characteristic in materials selection. Strength is rarely the only requisite and frequently is not the major one. More failures are due to brittle fracture from thermal fatigue than from stress rupture or creep. However, high-temperature strength is important where severe thermal cycling is required.

Specific Applications. Recommended alloy applications for parts and fixtures of various types of heat-treating furnaces, based on atmosphere and temperature, are summarized in Tables 4, 5, and 6. Where more than one alloy is recommended, each has proved adequate, although service life varies in different installations because of differences in exposure conditions.

(1850-2400 °F)			

Note: Where more than one material is recommended for a specific part and operating temperature, each has proved satisfactory in service. Multiple choices are listed in order of increasing alloy content (except ceramic parts).

(a) A series of alloys generally of the 35Ni-15Cr type or modifications that contain from 30 to 40% Ni and 15 to 23% Cr and include RA 330, 35-19, Incoloy, and other proprietary alloys.

(b) Immersed electrode furnaces only.

(c) Low-carbon steel is recommended for completely submerged electrodes only.

Typical Applications

Trays and Grids. Many parts to be heat treated are irregular in shape and as such must be conveyed through the continuous-heat-treating furnaces or loaded and unloaded from the batch furnaces on grids or trays (Fig. 2). These trays or grids must withstand exposure to the same furnace conditions as the product: They are subjected to repeated heating and cooling, as well as repeated compression and tensile loading. Heat-resistant alloys are used extensively for these parts, although there are instances in which dispensable carbon or low-alloy-steel fabricated trays are employed. In such instances, the choice is based on the economics of the particular situation, taking into account the cost of materials and the expected service life.

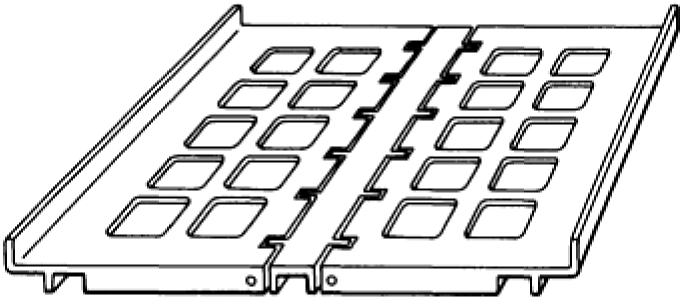

Fig. 2 Articulated tray for roller rail furnace

Two-thirds of the approximately 15 common heat-resistant alloy compositions find application in the heat-treating industry. Of these, half are recommended for use in trays and grids. The particular alloy chosen should be selected on the basis of required strength at temperature, ductility, and oxidation corrosion resistance.

Trays and grids made of austenitic stainless steels containing approximately 10% Ni may find an application at furnace temperatures of 650 to 870 °C (1200 to 1600 °F), but as the service temperature goes up, for example, to 1040 to 1150 °C (1900 to 2100 °F), an alloy with twice as much nickel would probably be selected. If the tray or fixture is to be subjected to the thermal shock of rapid heating and cooling, an even higher nickel content would probably be selected. The particular atmosphere surrounding the trays necessitates the consideration of varied amounts of chromium addition to enhance resistance to oxidation or high-temperature corrosion. If trays are to be used in an atmosphere with very high sulfur, an alloy with rather high chromium and moderate nickel would be selected. Some alloys contain relatively large amounts of silicon to fortify against carburization in carburizing applications (Fig. 3).

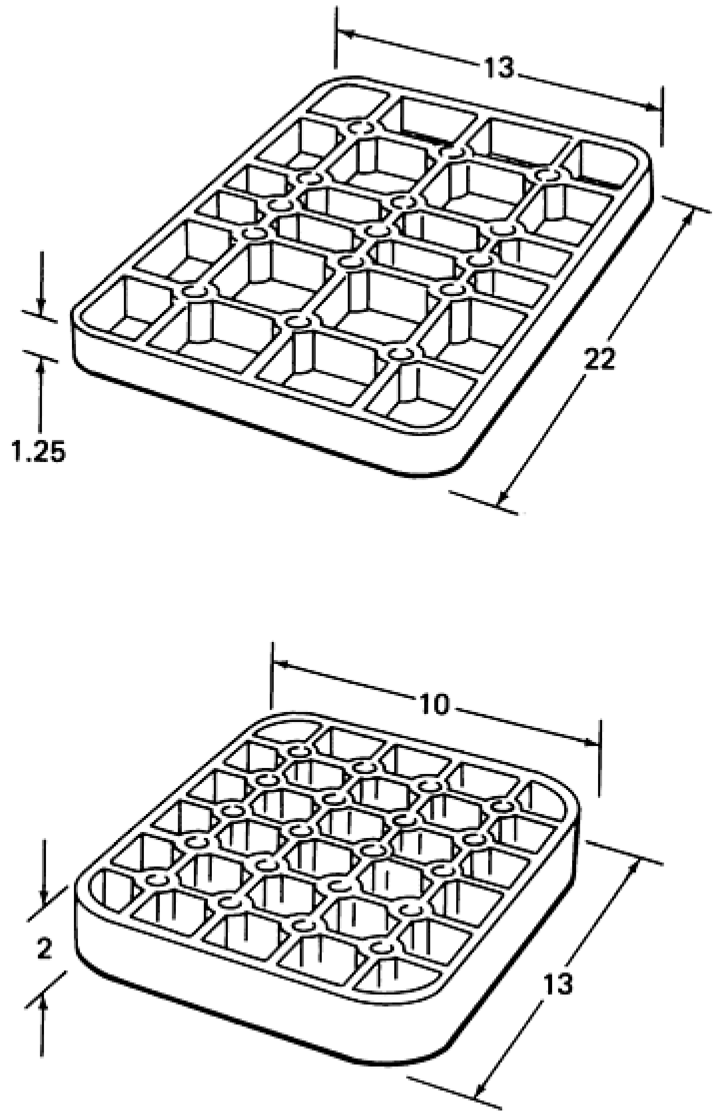

Fig. 3 Typical HT alloy carburizing furnace trays. Dimensions given in inches

Families of commercially available heat-resistant alloys provide sufficient selection so that an alloy that is optimized for each application and use can be specified. Alloy producers as well as vendors of trays and grids, both cast and fabricated, are an invaluable source of information regarding service life, design considerations, and fabrication. Generally, a tray or grid should be of sufficient section size to provide reasonable service life under specified loading conditions. An overly heavy tray may prolong service life, but the added energy cost to heat the tray through each cycle may offset any cost savings realized through added life. It is sometimes possible to combine materials in trays to provide sufficient strength yet maintain minimum weight. For example, in an articulated tray used in an extremely long pusher furnace, the tray grid that is subjected to the compressive force of the pusher bar is of a higher nickel content than are the vertical load supports that must bear the compressive load on a per-tray basis. This dual-alloy tray represents a compromise between weight, cost, and service life. In addition, service life is greatly affected by the tray-cooling process, and, in general, uniform section size throughout the tray is highly desirable to minimize thermal contraction/expansion stresses during cooling and heating.

All service conditions should be considered when selecting an alloy for trays and grids. Unlike furnace structural parts, a tray is subject to alternate heating and cooling during each cycle. The cooling can be rapid, as in quenching, or relatively slow, as in furnace-cooling applications. The selection of a proper alloy ensures adequate service life if all service conditions are known and considered.

Baskets and Fixtures. In many situations, parts being heat treated are of a size that does not permit them to be loaded directly on a furnace hearth, tray, or grid. They require some type of container, such as a basket. The design of these baskets varies because each product is developed for a specific application and loading and must function with a specific type of furnace equipment.

Baskets and fixtures can be produced from cast or wrought alloys. Fabricated parts are used in light-to-medium loading applications, intricate designs, complex shapes, and generally with lighter metal sections. Typically, these include the bar frame-type basket (Fig. 4) or corrugated box or shroud. In applications involving heavy loading and/or simple shapes and designs, cast alloys are commonly selected; typically they are large-pit-furnace baskets (Fig. 5).

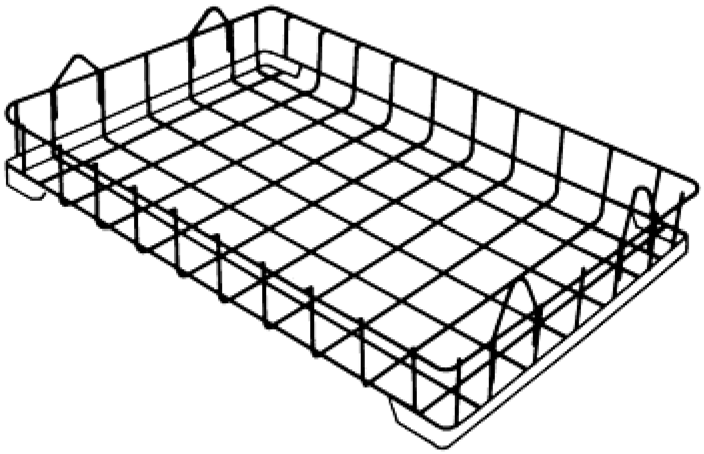

Fig. 4 Bar frame-type basket

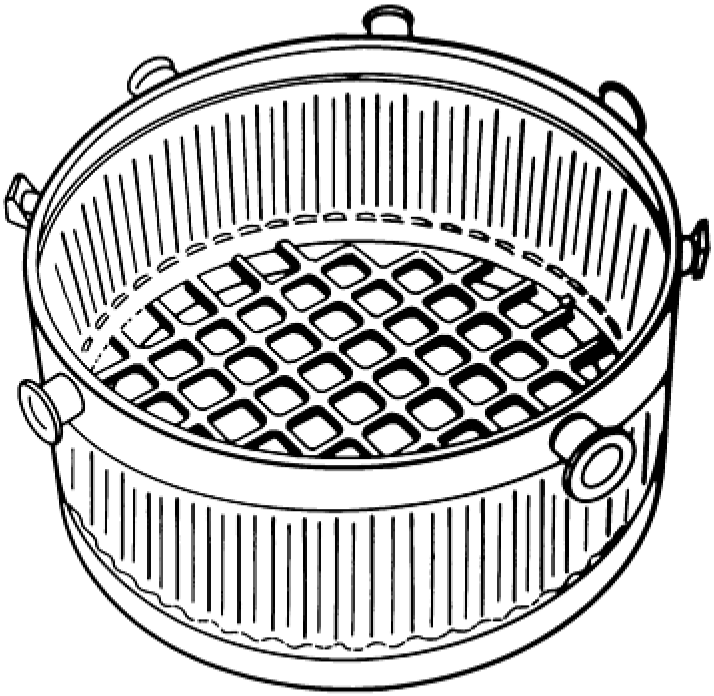

Fig. 5 Large-pit-furnace basket

In specific applications, a part may require special positioning. This is accomplished by using a fixture that is generally adaptable to an existing tray or grid or, in some instances, placed directly into a basket or container. These components can range from simple shapes, such as round, square, rectangular, or fluted bars, to extremely intricate shapes. Figures 6,

7, and 8 are examples of such fixtures. Figure 6 is a tray/fixture assembly used for carburizing pinions. Figure 7 was designed for heat treating lawn mower blades, and Fig. 8 was designed for heat treating shafts.

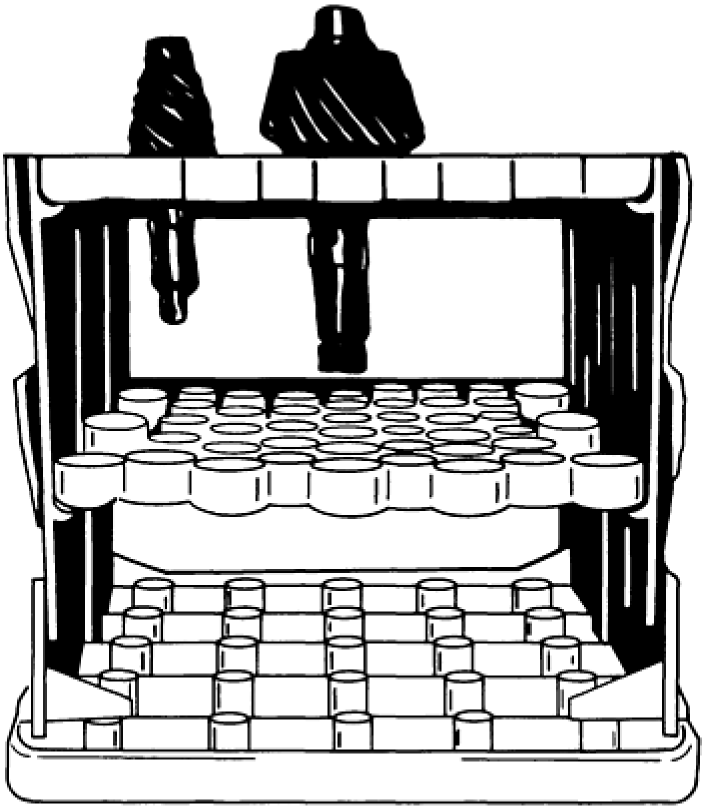

Fig. 6 Tray/fixture assembly for carburizing pinions

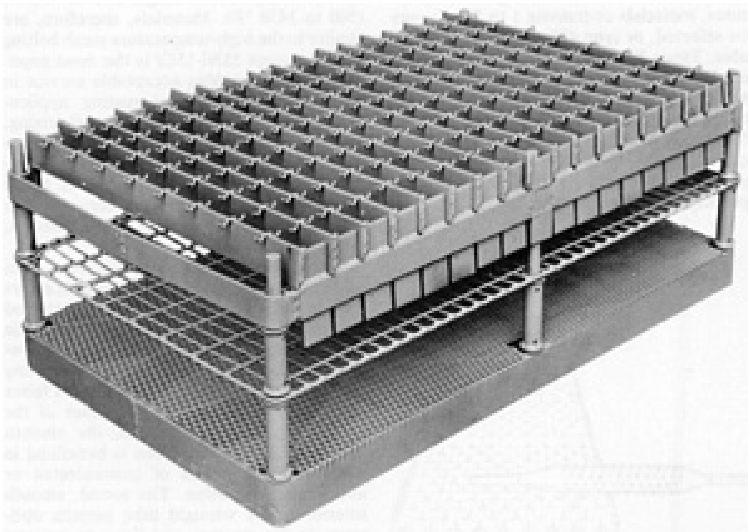

Fig. 7 Fixture designed for heat treating lawn mower blades

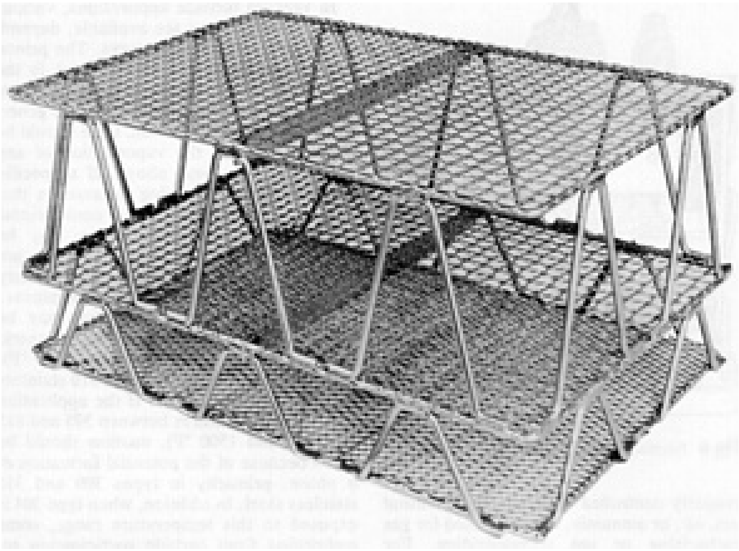

Fig. 8 Fixture designed for heat treating shafts

In most applications involving operating temperatures of 790 to 1010 °C (1450 to 1850 °F), the product is generally manufactured with a material having a nominal composition of 35Ni-15Cr, which provides a fully stable austenitic structure virtually free from any embrittling phases. In addition, it provides a reasonable cost-to-life ratio in applications involving endothermic, exothermic, and inert atmospheres even with properly controlled enrichments of natural gas, air, or ammonia, typically used for gas carburizing or gas carbonitriding. For quenching, a 35Ni-15Cr alloy provides acceptable life; however, in applications of severe quenching, higher-nickel alloys may be considered, depending on the cost-to-life ratio of the product. If applications involve higher temperatures, excessive oxidation, or carburization, consideration should be given to increasing the nickel-chromium content of the alloy. For nitriding, a higher nickel content provides the best cost-to-life ratio.

In vacuum furnace applications, various heat-resistant alloys are available, depending on operating temperatures. The principal controlling factor in this case is the creep-rupture strength of the alloy. A combination of distortion and warpage is generally the major failure mode. Care should be taken to prevent the vaporization of any element within these alloys. If a specific application has operating parameters that will not allow the use of a conventional alloy, molybdenum fabrications may be used, providing that air and oxygen are absent because catastrophic oxidation may become significant at higher temperatures.

For baskets and fixtures that may be restructured to lower-temperature operations of 260 to 595 °C (500 to 1100 °F), materials such as 304, 309, and 310 stainless steel may be acceptable. If the application involves temperatures between 595 and 815 °C (1100 and 1500 °F), caution should be taken because of the potential formation of σ phase, primarily in types 309 and 310 stainless steel. In addition, when type 304 is exposed to this temperature range, some embrittling from carbide participation results. Therefore, if the operating temperature is between 595 and 815 °C (1100 and 1500 °F), iron-nickel-chromium alloys, such as 35Ni-15Cr and 35Ni-20Cr, are generally suitable.

It should be noted that in the applications of baskets and fixtures, periodic straightening and rewelding can greatly enhance product life and improve the cost-to-life ratio.

Skid Rails, Hearth Components, and Rollers. Certain furnace parts are subjected to an additional service condition that must be considered when opting for a particular design or alloy selection. This group of parts includes components of the conveyance system in a continuous furnace that is subjected to wear as a result of interfacing with product or trays. Furthermore, this interfacing or wear occurs at elevated temperatures where alloy strength is diminished. The proper selection of an alloy for a specific high-temperature service involves consideration of many factors. One important factor is to avoid selecting the same composition for components that have sliding or rolling contact in order to minimize the possibility of galling or seizing. For example, when selecting an alloy to make skid rails (Fig. 9), it is necessary to consider whether the rail will be cooled and, if so, by what method; whether adequate expansion space has been specified; the amount of contact area present at the interface; and how the rail will be supported and at what

intervals. Thus, it can be inferred that the design of skid rails and selection of the alloy are an integral part of furnace design; the same principles apply to rollers and hearth components.

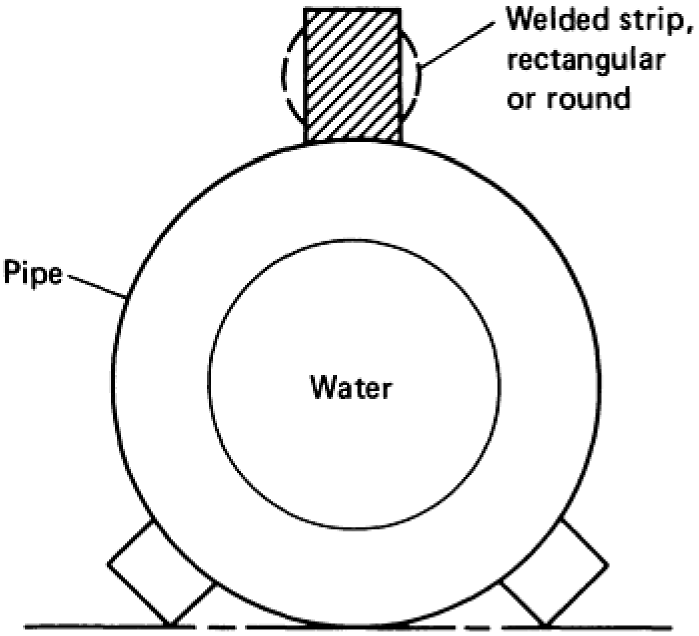

Fig. 9 Water-cooled skid pipe with welded strips

Perhaps the greatest single factor affecting a roller in a heat-treating-furnace application is the actual bearing or roller support of the roller. In roller hearth furnaces, the rollers protrude through the furnace walls, and the roller bearing can operate in a relatively reduced ambient temperature (Fig. 10). However, in some roller tray furnaces, the individual rollers operate within the furnace heated area, and the roller spindle or shaft must rotate on a roller support without aid of a precise, lubricated bearing. Hearth components are usually nonrotating or nonmoving parts and, in most situations, are well supported by refractory piers and/or ledges. Hearth components are almost always subjected to compressive loading, although they could on occasion be subjected to lateral thrust and/or bending. When selecting an alloy for these applications, it is necessary to consider the elevated-temperature mechanical properties required for the anticipated loading.

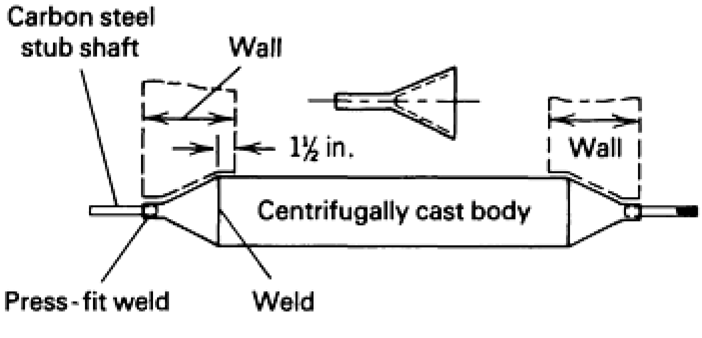

Fig. 10 Thin-walled furnace roller

Belting. Conveyor belts are used extensively in the design of furnaces used for the brazing, sintering, and hardening of carbonitriding applications. Woven belts or mesh belts are commonly used for light-duty loading, whereas cast link belts are designed for heavy-loading requirements. Figure 11 shows an assembled conveyor belt with a 100 mm (4 in.) pitch and the drive drum ready for installation.

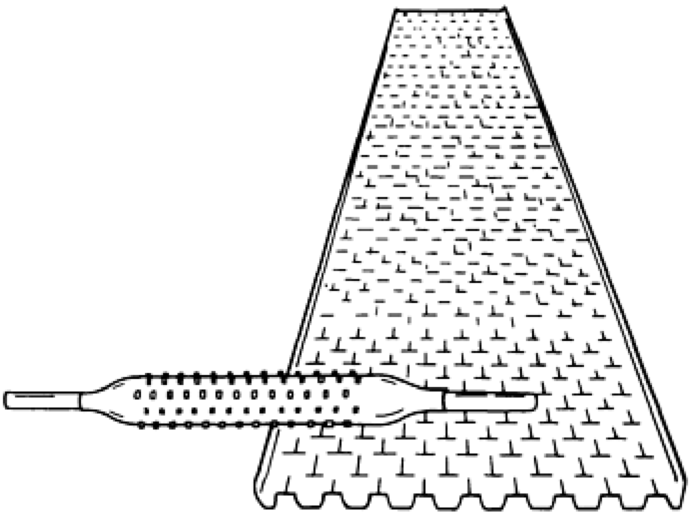

Fig. 11 Conveyor belt assembled with 100 mm (4 in.) pitch and drive drum ready for installation

When mesh belting is required for applications between 260 and 790 °C (500 and 1450 °F), medium-carbon steel (grades 1040 and 1055) can be selected for application up to 540 °C (1000 °F). For higher temperatures, materials containing 1 to 5% Cr may be selected, or type 430 stainless is acceptable. Types 304, 309, and 316 stainless steel tend to be susceptible to carbide participation or the formation of σ phase within this temperature range and therefore are not frequently selected. If stainless steel is required, type 347, which is stabilized with niobium and virtually free from carbide participation, may be selected.

Alloys commonly used for mesh belts in the temperature range of 790 to 1205 °C (1450 to 2200 °F) are 35Ni-15Cr; 80Ni-20Cr; type 314 stainless steel; and alloy 600, alloy 601, and 214 alloy, with the latter three nickel-base alloys servicing the high end of the temperature range (that is, 980 to 1205 °C, or 1800 to 2200 °F) The selection of the proper alloy is based on temperature, atmosphere, possible process contaminants, and cost-to-life ratios of the application. In addition to material selection, other key considerations for mesh belt applications are belt support, drive system, proper tension, and control of side travel.

In applications involving heavier loading, the cast link belt is often used. These applications tend to be in the temperature range of 790 to 1095 °C (1450 to 2000 °F) and not in the low-temperature range, 260 to 790 °C (500 to 1450 °F). Materials, therefore, are similar to the high-temperature mesh belting alloys, except 35Ni-15Cr is the most popular alloy. It provides acceptable service in most conventional heat-treating applications, such as hardening, gas carburizing, and gas carbonitriding. The cast links are generally assembled using a wrought 35Ni-15Cr alloy with a higher carbon level. In the application of cast link belts, consideration should be given to support, drive systems, tension, and side travel.

Radiant tubes can be manufactured from cast alloys or fabricated with wrought alloys and, in most applications, can be selected interchangeably depending on cost-to-life ratios. Fabrications may be selected because of the direct savings in fuel resulting from reductions in weight (fabricated tubes can weigh as much as one-quarter of the equivalent cast tubes). Also, the smooth surface of a fabricated tube is beneficial in avoiding focal points of concentrated or accelerated corrosion. The sound, smooth interior of the wrought tube permits optimum design stresses and helps to prevent the buildup of soot deposit. Figure 12 shows a typical U-shaped radiant tube used in carburizing furnaces. Some furnaces use a straight radiant tube.

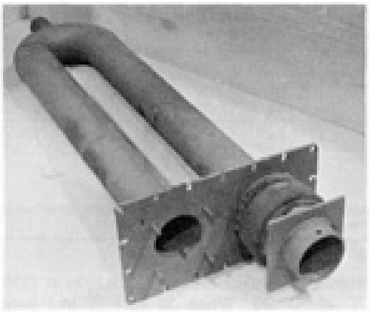

Fig. 12 U-shaped radiant tube

Wrought alloys for radiant tubes include type 309, type 310, RA 330 alloy, alloy 800H, alloy 601, 230 alloy, and 214 alloy. Most radiant tubes are fired with natural gas in the inner diameter. The inner diameter of the radiant tube is subject to oxidation. The outer diameter of the tube is exposed to the furnace atmosphere; thus, the furnace atmosphere can also influence the selection of alloys. For example, nickel-base alloys are preferred for nitriding atmospheres. However, nickel-base alloys are not recommended for use with gases having a high sulfur content.

In addition to temperature and atmosphere, consideration should be given to tube design for proper expansion and contraction, support for horizontal mounting, and burner positioning to prevent flame impingement. These considerations, as well as dissipation rates, affect service life as severely as the material selection.

Pots. Furnace design is the most important consideration in the selection of material for pots holding molten lead or salt. Externally heated pots act as a muffle or barrier between the heating and work zones. This type of service is severe because of the great difference between outside and inside temperatures, especially while the furnace is being heated to the operating temperature, when the outside of the pot is subjected to maximum heat input and the lead or salt it contains is still solid.

When the furnace is heated by immersed or submerged electrodes, the pot is completely sealed from the outside air, and the inside of the pot is protected by the molten bath. A pot in this type of installation lasts much longer than an externally heated pot. For environmental reasons, salt operations, such as those using cyanide salts, have diminished greatly. The most popular operations remaining generally involve neutral salt and lead. The specific alloy selected for pots used in salt operations is directly related to salt composition.

Pots are available in both cast alloys and fabricated wrought alloys. However, because the availability of cast pots has become somewhat limited, fabricated pots are more widely used. Carbon steel pots can be used within a temperature range of 260 to 540 °C (500 to 1000 °F). For applications between 540 and 815 °C (1000 and 1500 °F), type 309 stainless, 35Ni-15Cr, and higher-nickel alloys can be applied.

Electrodes. The choice of heat-resistant alloys used for electrodes depends chiefly on the type of furnace in which they are used. The most popular alloy for neutral salt pot electrodes is type 446 stainless steel. Immersed electrodes deteriorate rapidly along the line where the surface of the salt bath comes in contact with them. This is known as air-line attack. Submerged electrodes, entering the bath through the side of the furnace, are never exposed to air and last much longer. This type of electrode is used only with ceramic pots.

Electrodes deteriorate badly at the salt line during the start-up period. Better service is obtained by maintaining them at a temperature just above the freezing point of the salt during short pauses in operation. This practice not only prolongs the life of electrodes, but also eliminates the tedious task of starting a cold bath. Very little power is required to hold a well-insulated, unused furnace at about 700 °C (1300 °F).

Retorts and muffles are used in heat-treating furnaces to separate materials being heated from the products of combustion and, in some instances, to contain atmospheres that would otherwise escape through more porous containment vessels. In most situations, a muffle may be made either of metallic or nonmetallic materials. A typical D-shaped muffle with internal hearth is shown in Fig. 13.

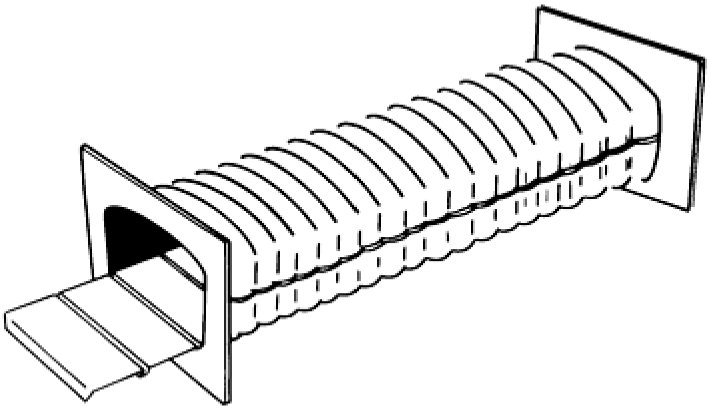

Fig. 13 Typical fabricated D-shaped muffle with internal hearth

Muffles are treated as a separate category of HT alloy applications. An important and different set of constraints apply because the heat necessary to raise the inside of a muffle to the proper process temperature is applied from without. Materials and designs must be selected that will not only withstand the rigors of furnace temperature and corrosion conditions, but will also not significantly prevent heat transfer. Designs must provide for expansion and contraction, be atmosphere tight, and provide maximum area for radiating surfaces because most muffles do not include internal recirculation features. For this reason, many cast or fabricated muffles are corrugated in design. This corrugated construction increases the radiating area while assisting in accommodating expansion and contraction as the muffle is cycled to and from operating temperature. Heat is transmitted by conduction to the inner-wall radiating surface of a muffle. In order to transfer heat, there must be a temperature drop across the wall of the muffle. The temperature drop is directly proportional to the thickness of the muffle wall. With heavy wall construction, the outside temperature must be raised to effect a given temperature within the muffle. Muffle material should be selected to provide a balance between alloy content (which represents strength), cost, and wall thickness.

Cost of any specific furnace part or fixture increases as the alloy content increases, although not necessarily in the same proportion as the base cost of the alloy. Some cost items will be approximately the same regardless of the type of alloy used.

To be meaningful, computations of cost for furnace parts and fixtures must be based on the number of hours of operation. In many instances, the more expensive alloys prove to be more economical. For example, service comparisons show that HU may be less expensive than HT for oil-quenched carburizing trays, and HW may be less expensive than HT for oil-quenched carburizing fixtures. On the other hand, some examples, such as brazing belts, show that the alloy of lower initial cost may also be less expensive when judged by cost per service hour.

From a practical standpoint, even cost-per-service hour data may be incomplete. Other factors should be considered for some components, notably the labor cost of replacement, the loss of productivity during downtime, and the possibility of damage to other components when failure occurs.

Nonmetallic Material Radiant Tubes (Ref 1, 2)

Silicon-silicon carbide composite radiant tubes having a density of 2.80 g/cm^3 (0.088 lb/in.^{3}) have undergone field trials in gas-fired indirect heating applications in a variety of atmospheres. One manufacturer installed these composite tubes in a pusher-type carburizing furnace in place of previously used mullite tubes in 1988 and the silicon-silicon carbides tubes were still operational after 26 months of continuous operation (24 1-h cycles/day at 980 °C (1800 °F). Another manufacturer indicates that the life expectancy of the silicon-silicon carbide tubes averaged 16 months while the life expectancy of the mullite tubes averaged 1 month.

These ceramic radiant tubes have been used in the following heat-treating processes:

- Annealing

- Carburizing
- Carbide solution treating
- Neutral hardening
- Carbonitriding
- Ferritic nitrocarburizing

Furnace atmospheres have included:

- Endothermic (both lean and rich)
- Carbon-enriched gases
- Ammonia-enriched gases
- Nitrogen
- Mixed endothermic and ammonia (50/50)

The composite radiant tubes are produced by using a moving hot zone (induction coil) to progressively melt the silicon and cause the particulate silicon to infiltrate the coarse-grained silicon carbide. The end product is a material that contains reaction-bonded silicon carbide grains in a silicon matrix. Tube composition is 53 wt% C and 47 wt% Si. An exothermic chemical reaction yields a composite material tube having excellent oxidation resistance, creep resistance, thermal shock resistance, and heat transfer properties.

Figure 14 demonstrates the results of a compression creep test run on tube sections of the silicon-silicon carbide composite material and a Ni-Cr-Fe alloy (8.51 g/cm^3, or 0.307 lb/in.^{3}, density). The Inconel 600 tube section actually melted after 1 h at 1350 °C (2460 °F) while the composite material showed no effect even after 2 weeks at 1350 °C (2460 °F). When 50 mm (2 in.) long samples of both materials were tested in compression for 2 weeks at 1200 °C (2190 °F), Inconel 600 showed 1.6% (0.79 mm, or 0.031 in.) creep while the silicon-silicon carbide composite creep was negligible at <0.03 mm (<0.001 in.).

Fig. 14 Comparison of high-temperature (1350 °C, or 2460 °F) creep testing of radiant tube sections. (a) Silicon-silicon carbide composite after 360 h. (b) Ni-Cr-Fe alloy after <1 h

Table 7 provides strength and fracture toughness data for the silicon-silicon carbide composite material at selected temperatures.

Table 7 Strength and fracture toughness properties of silicon-silicon carbide composite for radiant tubes used in gas-fired indirect heating applications

Temperature	Strength[a]		Fracture toughness

Energy-Efficient Heat-Treating Furnace Design and Operation

S. Lampman, ASM International

Introduction

ENERGY EFFICIENCY AND COST of heat-treating operations are related concerns that are substantially affected by the method of converting stored energy into molecular kinetic energy (temperature) of the workpiece(s). In electric furnaces, for example, high relative efficiencies between 85 and 100% are feasible, but the cost of electric energy has a substantially higher rate than that of fuels such as natural gas. Consequently, gas-fired furnaces are often more economical than electric heating, even though their efficiencies (which can range from 5 to 70% depending on operating temperatures and furnace design) are generally lower than electric heating methods.

The sources of heat loss in fuel-fired furnaces result from flue losses and furnace losses (Fig. 1). Flue losses, which can be the most significant component of energy inefficiency, occur from either incomplete combustion or the loss of sensible heat due to the discharge of hot flue gas. Furnace losses depend on the particular furnace design and method of operation. For example, batch processing can be less efficient than continuous processing because the heating and cooling cycles require expenditure of unused energy. Other typical types of furnace losses are illustrated in Fig. 1. All forms of heat loss become more significant as furnace temperature increases.

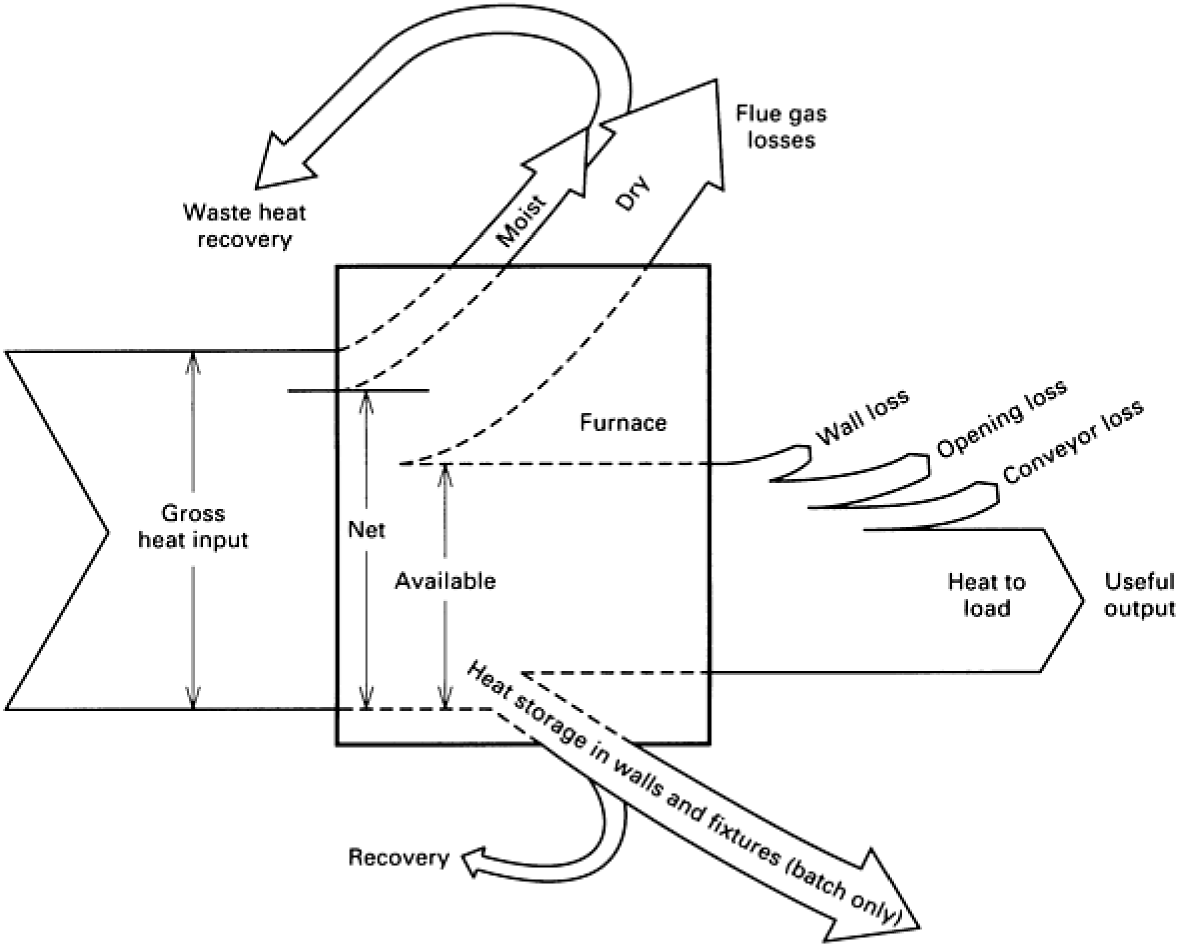

Fig. 1 Sankey diagram of heat loss in a fuel-fired furnace

This article briefly reviews some of the methods used to improve the efficiency of gas-fired furnaces. The methods are classified into three areas:

- Combustion control
- Waste-heat recovery
- Furnace design and operation

Of these methods, recovery of flue gas heat can have a significant impact on efficiency, particularly at higher temperatures. For example, if flue gases are discharged at 1300 °C (2400 °F) from a natural gas burner, about 70% of the energy input is lost in flue discharge. If incomplete combustion or an improper air/gas ratio occurs, then losses will be even higher. These losses can be reduced by recovery of heat from flue gases and/or improved combustion control.

At high furnace temperatures (≥ 1040 °C, or 1900 °F), electric heating may also become more effective because electric heating elements may require less maintenance than metallic radiant tubes. The higher relative efficiency of electrical heating may also be an advantage at higher temperatures. However, with advances in the technology of gas-fired heating, gas is becoming more competitive at higher temperatures. In particular, ceramic radiant tubes (reaction-bonded SiC) with recuperative burners can operate up to 1200 °C (2200 °F) with efficiencies of about 60%. High-alloy metallic tubes with regenerative burners also can provide economic life-cycle costs at higher temperatures.

Combustion Control

Combustion control is a basic factor in reducing flue losses, which are closely related to the fuel/air ratio prior to combustion. Too much excess air decreases efficiency because the energy expended to heat this air is wasted up the stack. Too little excess air results in fuel being unburned and also wasted up the stack. Consequently, the best efficiency theoretically occurs when the fuel/air ratio is closest to stoichiometric combustion conditions. In practice, however, some level of excess air is required to completely burn the fuel because of imperfect fuel/air mixing conditions in any commercial burner.

In most processes, efficiency is lost because the fuel/air ratio is too lean (too much excess air). The effect of this type of loss is shown in Fig. 2 in which the percent fuel required is plotted as a function of excess oxygen for several values of exhaust gas temperature. It is clear from this figure that the potential savings are greatest in high-temperature processes. For example, a reduction of excess oxygen from 6 to 5% for a process with 815 °C (1500 °F) exhaust gases produces a fuel savings of more than 5%.

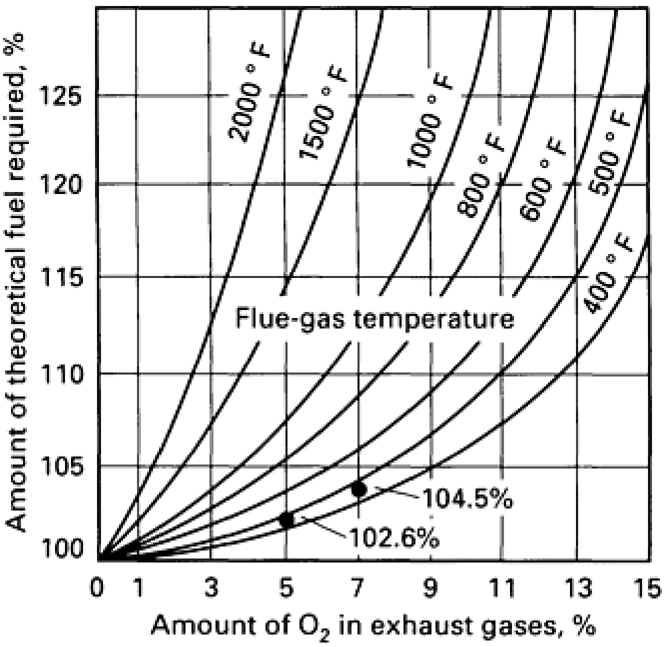

Fig. 2 Efficiency losses due to excess air in a typical gas-fired combustion process. Source: Ref 1

Control of Fuel/Air Ratio. There are two well-known methods of determining fuel/air ratios in gas-fired furnaces:

- Metering of gas and air flow rates into the furnace or burner unit
- Determining O_2 and CO content of flue gases

Currently flue gas analysis is becoming increasingly attractive with the availability of lower cost instruments, particularly oxygen analyzers. The sensor most widely favored for measuring O_2 uses a solid electrochemical zirconium oxide cell, which has an output directly related to the product of the absolute temperature and the logarithmic difference in the partial pressure of O_2 across the cell. One side of the cell is connected to a reference air supply that provides a quantified supply of oxygen ions. There are several methods of determining CO content, including a catalytic method that can be incorporated into the same assembly as the O_2 sensor. Because O_2 sensors have been prone to maintenance problems, flue gas analyzers are often supplemented with flow meters for backup.

The control of fuel/air ratios depends, in part, on whether the furnace provides direct heating of the workpiece or indirect heating with radiant tubes. Because direct heating involves the exposure of workpieces to the hot flue gases, the control of fuel/air ratios in direct heating furnaces may be slightly on either the oxidizing side or the reducing side of stoichiometric conditions depending on the application. In the iron and steel industry, for example, slab reheating furnaces are supposed to be run at about 1% excess oxygen to avoid tight scaling on the surface. Other processes must be run slightly on the

reducing side to avoid oxidation. For heat treating of steel and copper, direct heating furnaces are controlled at or near stoichiometric conditions to avoid oxidation.

Depending on the specific combustion process, the optimum oxygen content in terms of efficiency is 1 to 3% excess O_2. The optimum value of CO is in the range of 200 to 250 ppm. (As a regulated pollutant, however, 60 ppm of CO is an industry standard.) For combustion on the reducing side, efficiency drops off more rapidly than for combustion on the oxidizing side for an equal change in the fuel/air ratio (Fig. 3). Therefore, if a reducing atmosphere is required, then indirect heating with radiant tubes may be more efficient because the combustion process could be run more efficiently near the oxidizing side of stoichiometric conditions.

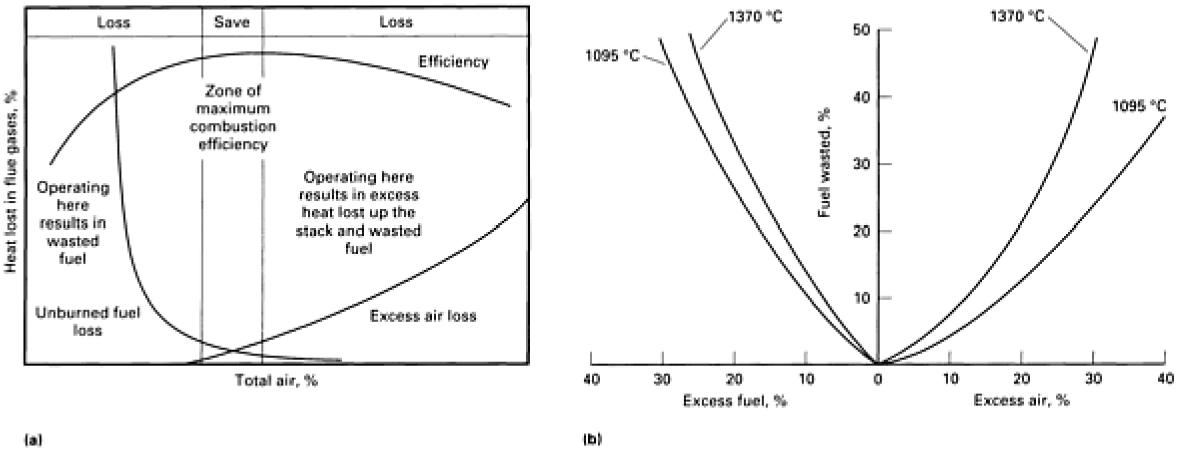

Fig. 3 Effects of excess air or fuel on combustion efficiency. (a) General effect on efficiency. (b) Effect on percent of fuel wasted

Heat transfer from the combustion flame is due to a combination of convection and radiation in the flue gases. With natural gas flames, for example, heat transfer by radiation is low because of the transparent nature of natural gas flame. Therefore, convection of flue gases is an important factor in both direct-fired and indirect-fired gas furnaces. Efforts to increase the heat transfer of combustion flames also include increasing the flame temperature with a preheat of combustion air (see the sections on recuperators and regenerative burners in this article).

High-velocity burners represent a recent development to improve convective heat transfer in direct-fired furnaces. The use of high-velocity burners create vigorous circulation of gases in the furnace and thereby promote uniform heat transfer. A small number of high-velocity burners therefore provides an efficient alternative to burner arrays, which require individual adjustment of a large number of burners so as to achieve uniform heating.

A potential limitation of high-velocity burners is that the circulating flow diminishes when the burners are turned down. Using excess air (to reduce temperature and increase the velocity of circulating) also leads to a reduction in thermal efficiency. Therefore, pulse firing can be useful in achieving lower temperatures and adequate circulation without resorting to the use of excess air (see the section "Pulse Firing" in this article).

Heat Transfer in Radiant Tubes. When a controlled furnace atmosphere is required, indirect heating is performed with radiant tubes. Inside the tube, heat transfer to the tube surface is governed by radiation and convection. Improvements in heat transfer inside radiant tubes can be attained by the use of axial fins (Ref 2).

Pulse techniques include two distinct methods known as pulse firing and pulse combustion. Pulse firing involves on-off cycling of burners, while pulse combustion is a resonant technique that depends on oscillations in a suitably designed combustion container.

Pulse firing is a method of controlling temperature by cycling the fuel or fuel/air supply so that a burner is either off or operating at full capacity. Temperature is thus controlled by varying the frequency of the on-off cycle, which typically has a period of about 3 to 6 s. This method of frequency modulation differs from conventional combustion control, which involves the control of heating by varying the amplitude of the flame.

Pulse firing has several advantages such as:

- Improved efficiency because fuel burns more effectively with maximum flame velocity
- Turndown ratios as high as 20:1 or even 30:1 as compared to a typical turndown ratio of 8:1 in an amplitude controlled system
- Improved convective heat transfer from the turbulence created by pulsing

Pulse firing also has other potential benefits, depending on the particular firing practice and furnace. In direct-fired furnaces, for example, pulse firing allows the reduction in the operating temperature of high-velocity burners without the addition of excess air. Pulse firing thus allows improved energy efficiency, which is the main motivation for its use in high-velocity burners.

In other applications, pulse firing can have other advantages that are more important than improved energy efficiency. In radiant tubes, for example, the pulsing provides more uniform heating of the tube and promotes the extension of tube life. The high turndown ratios also provide better furnace control. If energy efficiency of radiant tubes is a concern, pulse firing can be incorporated with regenerative burners (see Example 1 in this article).

Pulse Combustion. The basic principle of pulse combustion involves the enhancement of heat transfer by creating oscillation of gas flow within the combustion system. This oscillation follows a pattern of periodic combustion, which in many cases can have a cycling frequency up to 150 Hz. Specific advantages of pulse combustors include: ability to burn various fuels; high combustion intensities; low NO_x formation; low excess air requirements; and self aspiration, which eliminates the need for compressors or fans to pump the air and combustion products through the system. Additionally, the presence of pulsations in the exhaust flow enhances the rates of mass, momentum, and heat transfer in the process.

To date, pulse combustors have been utilized in such applications as drying, steam raising, water heating, and domestic space heating (Ref 3). In heat treatment furnaces, however, there are some potential drawbacks of pulsed combustion. One disadvantage is that the furnace (or combustion chamber) must be designed around the burner so that oscillations are sustained adequately. The heat-transfer enhancement resulting from the pulsations will also decrease as distance from the pulse combustor discharge is increased. The greatest heat transfer enhancement occurs within the combustor and is related to the acoustic intensity. The pressure and velocity fluctuations decrease as the gases expand outward from the discharge of the system. There is not an extensive body of data on the pressure and velocity fluctuations downstream from the combustor, but there are some indications that the pressure levels may decease by 3 to 5 dB within 3 m (10 ft) of the outlet (Ref 4).

Nevertheless, radiant tube burners might be a potential application of pulse combustion technology. In this application, the benefit of pulse combustion would be to improve convective heat transfer from the burner to the tube. A theoretical estimate relates heat transfer enhancement with tube efficiency (Ref 5). Another possible advantage is reduced NO_x emissions, which may be a more important factor with future environmental restrictions.

Recovery of Waste Heat

Recovery of waste heat is a basic objective that can be implemented in a variety of ways. Waste heat can be used to heat water, or it can even be used to generate electricity. The main objective, however, is the most efficient utilization of the waste heat for the given energy needs of a particular plant.

This section focuses exclusively on the use of recuperators and regenerative burners for the preheating of combustion air with hot flue gases. Preheating combustion air improves combustion efficiency (Fig. 4) and is common to many fuel-fired furnaces. Other recovery methods depend on the specific plant operations. For example, the heat stored in a batch furnace can be partially recovered to preheat another batch furnace or another load.

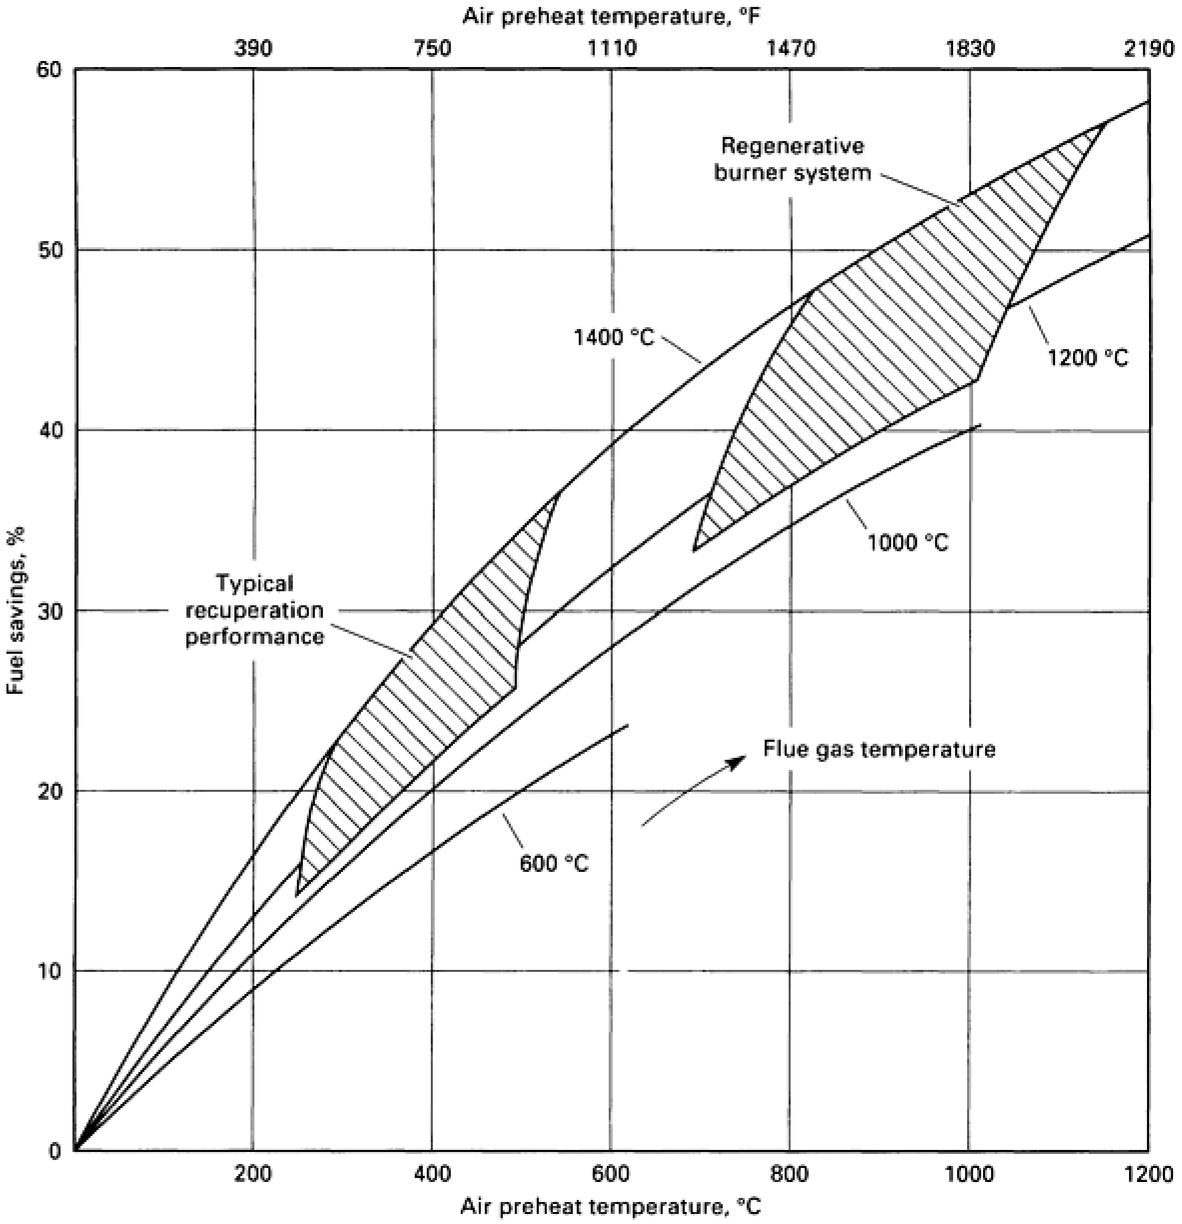

Fig. 4 Effect of air preheat on conbustion efficiency. Source: Ref 6

Recuperators preheat combustion air by transferring heat from the hot flue gases to the inlet air. In a direct-fired furnace, for example, tubes can carry the combustion air directly through the main flow of flue gases. This type of recuperator design transfers heat by convection. Convective recuperators, which are typically used with flue temperatures up to about 1000 °C (1850 °F), can preheat combustion air up to about 450 °C (850 °F). This would provide a fuel savings of about 25% (Fig. 4).

Conventional recuperators are also designed with inlet air passages placed alongside flue ducts (Fig. 5). Conventional recuperators, which can be based on metallic or ceramic tube design, are used with flue temperatures up to about 1500 °C (2700 °F) with ceramic materials (Ref 7). Wrought metallic radiant tubes with recuperation can be used up to about 1000 °C (1850 °F), but the tube life is limited to less than six months at these temperatures. Cast radiant tubes, which do not require a tradeoff between strength and workability, can operate satisfactorily at temperatures in excess of 1200 °C (2200 °F) (Ref 8).

Fig. 5 Radiant tube recuperator systems. (a) External recuperation with U tubes. (b) Single-ended recuperation with inner and outer tubes made of reaction-bonded silicon carbide

The amount of air preheat from conventional recuperation depends on the design of the heat exchanger and flue gas temperatures. For an external recuperator (Fig. 5a) with wrought metallic radiant tubes, the combustion air is commonly preheated up to about 590 °C (1100 °F). A single-ended ceramic tube with recuperation (as shown in Fig. 5b), which has a maximum operating temperature of 1260 °C (2300 °F), can preheat combustion air to 650 °C (1200 °F) (Ref 9). A special two-stage recuperator with a metallic stage and a ceramic stage (Ref 10) preheated combustion air up to 1100 °C (2000 °F). This can provide fuel savings comparable to that of regenerators (Fig. 4).

Self-Recuperative Burners. Because conventional recuperators (Fig. 6) are generally large and confined to large-scale plants, self-recuperative burners have been developed. Self-recuperative burners are compact units that combine the function of burning and recuperation into a single integral unit (Fig. 6).

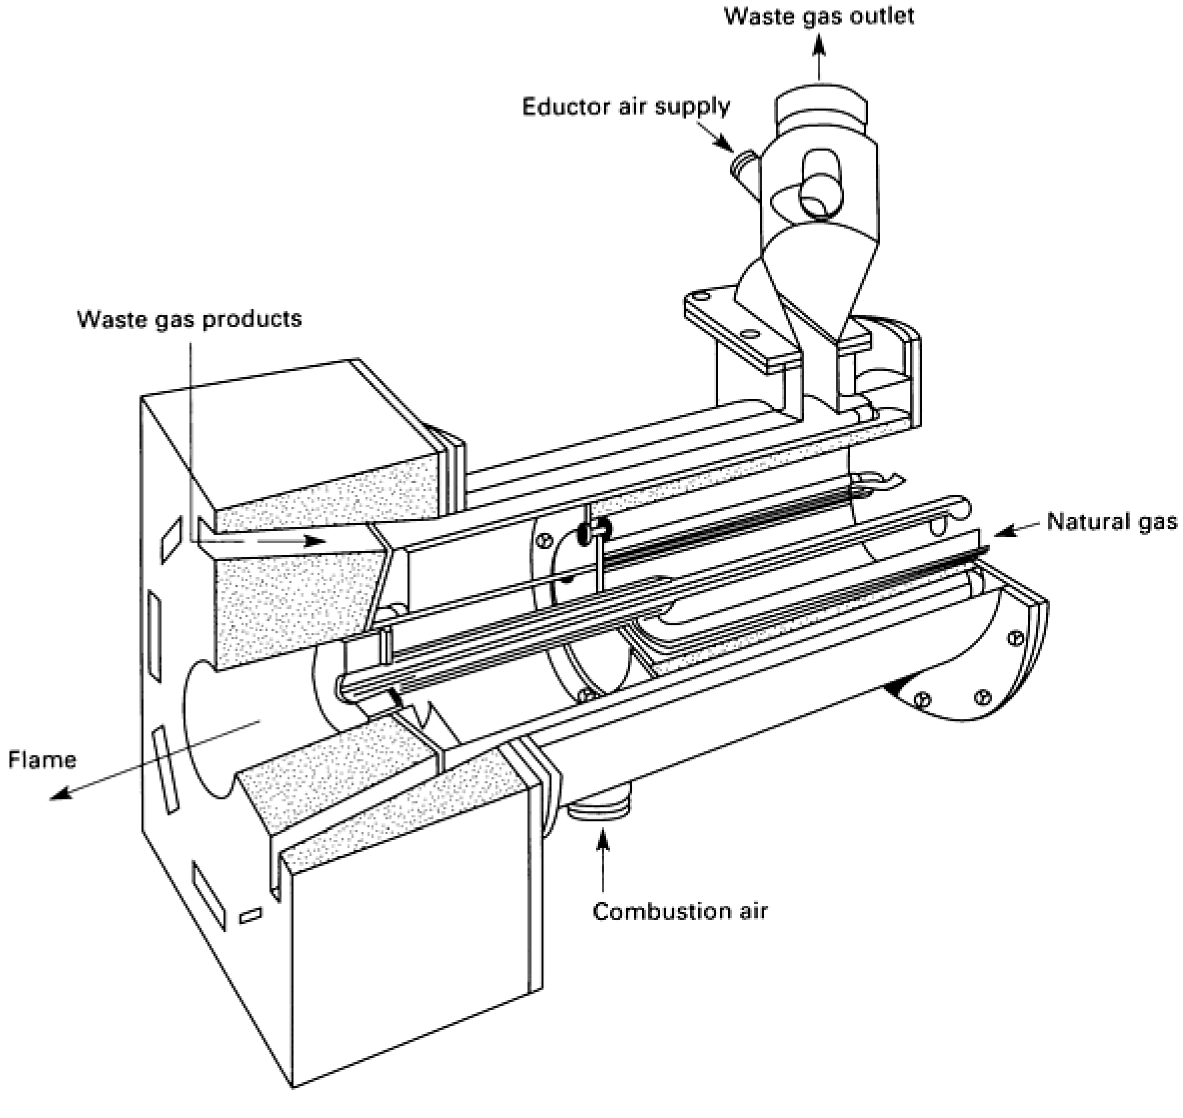

Fig. 6 Self-recuperative burner system

Self-recuperative burners are widely used in Europe and can provide fuel savings up to about 30% as compared to cold-air combustion. In a furnace with direct heating, the waste gases are drawn from the furnace through a series of ports that surround the burner quarl by means of an air ejector. The arrangement obviates the need for insulated hot air mains and

simplifies the necessary control system. Self-recuperative burners are also used successfully with radiant tube burners for indirect heating.

Regenerative burners, which operate on the same principle as the large regenerators used in steel and glass industries since the 1850s, provide a second method of preheating combustion air with hot flue gases. Regenerative burners typically operate at higher temperatures than recuperators and thus provide larger improvements in fuel savings (Fig. 4). Regenerative burners are also more reliable than recuperators when dirty fuel is used.

A regenerator basically consists of two chambers, each containing a permeable storage bed constructed of firebrick or another refractory shape. Flue gas gives up its heat to the refractory as it flows through one chamber, while combustion air flows through the other chamber, absorbing the heat stored in it during the preceding half of the "regenerative" firing cycle. After a certain length of time--about 20 min in a traditional system--the flows are switched.

Traditional regenerators often are larger than the furnaces they serve, and they also require large exhaust fans. To create a combination burner-regenerator compact enough to be mounted on a furnace, changes in bed material and cycle timing have been made. The surface-to-volume ratio of the refractory was increased 100-fold by switching to a granular refractory, which results in a large increase in heat-storage capacity per unit volume. Adoption of microprocessor-based controls shortens the switching time from 20 min to 20 s, which reduces the amount of heat that needs to be stored during each cycle. The regenerator bed is composed typically of ceramic spheres. Advantages of metals over ceramics in this application include higher thermal conductivity and density.

Regenerative burners are used on direct-fired furnaces and indirect-fired furnaces. In direct-fired units, exhaust fans draw flue products to the regenerator bed. In an indirect-fired unit, regenerative burners are placed at each end of a radiant tube (Fig. 7). While the regenerative burner at one end of the radiant tube is firing, the flapper valve, or damper, on its eductor is closed, which forces air through the hot refractory bed and into the burner for combustion. At the same time, the flapper of the other burner is open, which causes hot exhaust gases to be sucked through the refractory bed of the burner. Eductor suction at the nonfiring burner also maintains a negative pressure inside the radiant tube. Preheated-air temperatures are within 55 °C (100 °F) of waste-gas temperatures.

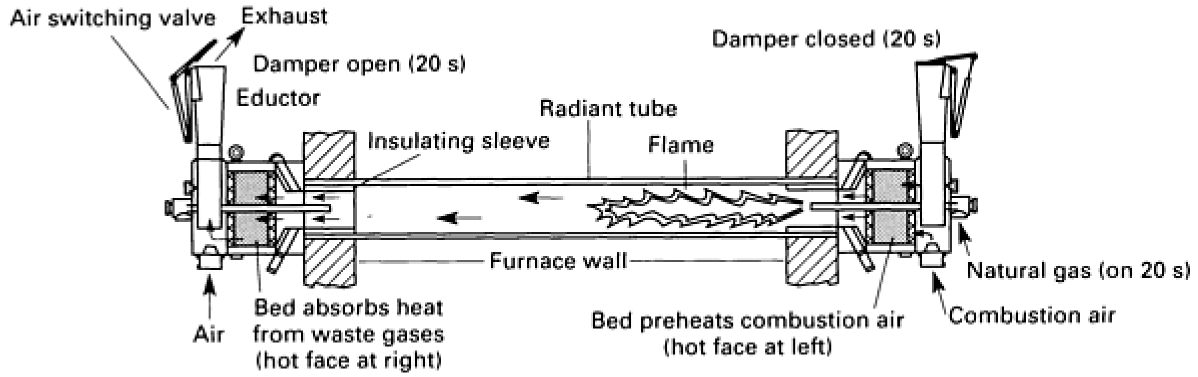

Fig. 7 Schematic of a regenerative radiant-tube burner system shows key components and principle of operation. Burner at right is firing using preheated combustion air, while burner at left reclaims heat from flue gases. Burners switch roles every 20 s. Burners are actually mounted side by side on the furnace wall, with the U-shaped radiant tube extending into the furnace.

The regenerative burner is probably the most significant advance in combustion technology in recent years. Successful heat-reclamation applications for regenerative burners are found in melting of nonferrous metals (aluminum reverberatory furnaces, for example), heat treating and forge heating (box, slot, car-bottom, and tunnel furnaces), continuous glass melters, and steel-mill pusher reheat furnaces, ladle preheaters, and continuous annealing furnaces. A specific application is described below.

Example 1: Fuel Savings with Regenerative Burners on an Annealing Furnace.

One of the first applications for regenerative radiant-tube burners, sponsored by the Gas Research Institute, was in 1984 on the annealing furnace for a continuous galvanizing line at the Inland Steel Company works in Gary, IN. The 15-zone galvanneal furnace uses 64 radiant tubes (128 regenerative burners) to heat steel strip prior to zinc coating. Annealing is performed under a protective hydrogen-nitrogen atmosphere to ensure good steel surface quality. Zone temperatures range from 815 to 980 °C (1500 to 1800 °F). The furnace originally was heated by conventional radiant-tube burners with U-shaped metallic tubes. Energy balances developed for the furnace both before and after conversion revealed that the use of regenerative burners reduced the requirement for purchased energy by more than 48%.

A microprocessor-based sequencer controls burner cycling. It serves primarily as a timer, switching fuel and air between each of the two burners of the tube at 20-s intervals (Fig. 7). Instead of modulating heat input, burners are turned on and off. Flame length is constant, which produces a uniform tube temperature from end to end.

Success of the regenerative system hinges on reliable combustion-air and gas switching valves. Under normal operating conditions, valves cycle approximately 432×10^3 times/y. In tests, these valves have survived more than 5×10^6 cycles.

Conventional radiant-tube burners create a hot spot a few feet from the burner, which is usually the point of tube burnout. Pulse firing of each regenerative burner equalizes temperatures in both tube legs. There were initial concerns that the short switching time associated with compact regenerators would induce temperature oscillations, which could cause thermal fatigue. However, because the mass of the radiant tube is large, and switching times are short, temperature fluctuations are negligible.

Furnace Design and Operation

Although flue losses often constitute the major source of energy loss in a typical fuel-fired furnace (Fig. 1), energy efficiency is also affected by wall losses, opening losses, and conveyor system losses (that is, heating and cooling of trays, fixtures, and/or skids). The energy needed to heat a furnace to temperature can also be classified as a source of energy loss. Therefore, if intermittent operation of a batch furnace is necessary, the relative costs of idling a furnace versus furnace reheating after shutdown should be considered.

Once a furnace reaches a steady-state operating condition, the furnace losses from the furnace walls, openings, and conveyor system will remain constant provided that the operating conditions are unchanged, regardless of whether the furnace is being operated empty or with a capacity load. This constant loss reduces the relative efficiency of a furnace when it is operated at less than rated capacity. Therefore, operating below the heating rate capacity of a given furnace results in a decrease of efficiency. This effect is shown in Fig. 8 for a pusher-type furnace operating at 950 °C (1750 °F). Bringing the workpiece to temperature as quickly as possible thus can provide energy savings. Energy can also be saved by:

- Reducing the extent of opening losses
- Selecting effective materials that reduce wall and conveyor losses
- Improving heat transfer to the workpiece
- Reducing treatment temperatures and hold times, if possible

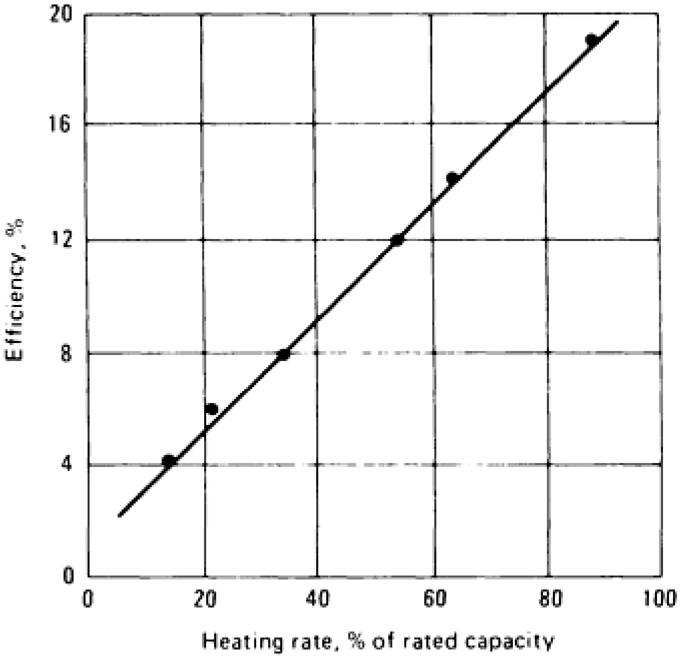

Fig. 8 Relationship between furnace efficiency and heating rate. Data are based from the metering of gas use in a pusher-type furnace operating at 950 °C (1750 °F).

Opening losses occur primarily from radiation losses, which are proportional to the area of the opening and the fourth power of temperature (T) in degrees kelvin (T^4).

Convective heat losses are also proportional to the effective area of the door opening. However, this loss can be accentuated when both doors are opened at the same time on a continuous furnace, because a tunnel effect is created. Convective losses also result around closed doors and through other openings in fuel-fired furnaces. To conserve energy, all unintentional openings should be sealed. The number of intentional openings should be reduced to the absolute minimum, and these openings should be sealed when not in use. Even when not permitting convective losses, openings in furnaces can permit infiltration of cold air, which must be heated to exit-gas temperature. Proper control of furnace pressure will help prevent these convective losses through necessary openings.

Ceramic fiber lining has replaced conventional brickwork in many batch and continuous heat treatment furnaces. Ceramic linings reduce heat loss by conduction through the walls and decrease furnace heat-up time because of their low thermal conductivity and low heat storage mass. Their low mass, reduced heat capacity, and good insulation properties are ideal for intermittent furnace operation. The low mass of ceramic linings also has structural advantages in the design of new furnaces. In some cases, the rapid thermal response of ceramic liners can be a problem.

Ceramic fiber linings are available in three basic product forms:

- Ceramic fiber blanketing
- Ceramic fiber veneer or tiles
- Sprayed-on ceramic fiber

Each of these product forms is based on the use of alumina and silica fibers containing a small amount of reducible metal oxides. Alumina contents are increased for higher operating temperatures. For temperatures above 1250 °C (2280 °F), it is necessary to use ceramic fibers with 95% alumina (such as Saffil). Saffil has a maximum recommended temperature of 1600 °C (2900 °F).

Ceramic fiber blanketing is limited to temperatures up to about 1000 °C (1830 °F) because the blanketing is susceptible to splitting from shrinkage at higher temperatures. To minimize shrinkage problems, the continuous operating

temperature of the furnace should be at least 200 °C (360 °F) below the maximum temperature rating of the fiber. Fiber blankets are also unsuitable in highly reducing atmospheres because of the disintegrating action of the atmosphere at typical temperatures.

Ceramic fiber veneer has a modular tile construction with some advantages over ceramic fiber blanketing. However, because reliable anchoring can be a concern, a safety lining of 25 to 40 mm (1 to $1\frac{1}{2}$ in.) blanket behind the veneer can be desirable. Veneer is useful in reducing atmospheres or when shrinkage from high temperatures (<1000 °C, or 1830 °F) is a concern.

Ceramic Fiber and High-Emissivity Coatings. Because veneer can have adherence or anchoring problems, sprayed-on ceramic fiber is used in veneer installation. High-emissivity coatings (for example, Pilbrico) are used to improve emissivity, which can be low (0.4 to 0.5) for some ceramic fiber products. In one application, a high emissivity coating allowed an initial 10 °C (5 °F) reduction in furnace temperature and a further 50 °C (25 °F) reduction after aging for a number of months (Ref 11).

Equipment Replacement or Modification. Proper application of refractories in reworked furnaces often can reduce or eliminate constant heat losses that may occur in water-cooled members. Water-cooled skid pipes can be replaced with alloy load supports if maximum temperature of operation permits, or with skid blocks made of high-strength, high-temperature refractories. Walking beam rails sometimes can be topped with refractory shoes rather than with noninsulating alloy shoes. Refractory materials in use include silicon nitride ceramics. Silicon nitride provides a good combination of excellent high-temperature strength along with resistance to oxidation and thermal shock.

Addition of alloy fans to existing furnaces sometimes can change a stagnant atmosphere into a high-velocity stream. This increase in ambient velocity breaks up boundary layers of furnace gases that surround the workpieces and shortens the heating time. This reduced heating time is a result of the change from heating only by radiation heat transfer to a combined radiation and convection transfer. The energy savings accrue through reduced furnace time required per cycle.

When the opportunity arises, much energy can be saved by altering the gases used in atmosphere heat treating. In some cases, an inert carrier gas can be added to the normal working gas.

Other energy-saving opportunities may be realized by improving the insulation systems in heat-treating furnaces. The energy lost through a furnace wall is a function of area, operating temperature, and composition of the insulation. The first two factors are fixed, but heat flow through and heat storage in the insulating system can be reduced by addition of insulation. Heat storage, which is the amount of heat contained in the wall, can be greatly reduced by using newly developed insulating materials, principally ceramic fibers and mineral wools. At the same time, the thickness of a wall for a given heat flow (loss) also can be changed significantly. One major heat-treating firm not only reduced energy requirements by using ceramic-fiber insulating materials, but also was able to heat treat larger rolls because of the decrease in required wall thickness, which in turn provided greater furnace work-zone width.

Energy Savings with Improved Quality Control. Energy savings can sometimes be achieved by improving heat-treating quality controls. For example, pyrometers can be used to measure surface temperature of workpieces in the furnace and thereby provide information for assessing required hold times in the furnace. This approach requires some relatively simple modeling of heat transfer within the workpiece. The potential savings accrue from knowledgeable reductions in soak times instead of relying on general specifications of soak times. Improved quality control also reduces scrap from improper treatment.

Furnace Design and Modeling. Another aspect of energy use is furnace design, which affects the transfer of heat from the burners to the workpiece. Direct-fired furnaces can provide efficient heat transfer depending on the design and disposition of the burners and flow patterns within the furnace. High-velocity burners, as mentioned earlier, are effective in improving heat transfer in direct-fired furnaces.

Improvements in furnace design depend on the particular application, and often improvements are based on experimental judgment and good furnace instrumentation. In some cases, however, modeling techniques such as those described in Ref 12 are also useful in avoiding costly furnace trials. Those techniques are summarized below.

Experimental modeling techniques utilize air, water, or perspex plastic models to study convective flow and establish the type and disposition of burners. Another method is the acid-alkali technique (Ref 13), which allows the

shape and size of diffusion flames to be observed directly in a perspex model. The use of this technique has led to burner designs that have achieved up to 30% fuel savings on glass melting furnaces (Ref 14).

Mathematical models provide a more quantitative assessment of the effects of firing conditions on furnace performance. Commonly used techniques are based on methods developed several decades ago by Hottel and coworkers (Ref 15). These methods are described by Tucker (Ref 16, 17) in more recent reviews. Modeling is also used to optimize or improve the analysis of energy use (Ref 18, 19, 20, 21, 22, 23, 24).

Energy Requirements of Different Furnace Types. As noted in the introduction of this article, energy efficiency and cost are related concerns. Some furnaces are very energy efficient, but the associated costs may not warrant their use. This is particularly true of electric furnaces, which are more efficient than gas-fired furnaces, but are often more expensive to operate because of the higher cost of electricity. An energy-cost comparison of various gas and electric furnaces is given in Fig. 9. Additional comparisons between electric and fuel-fired furnaces are discussed in the article"Types of Heat-Treating Furnaces" in this Volume.

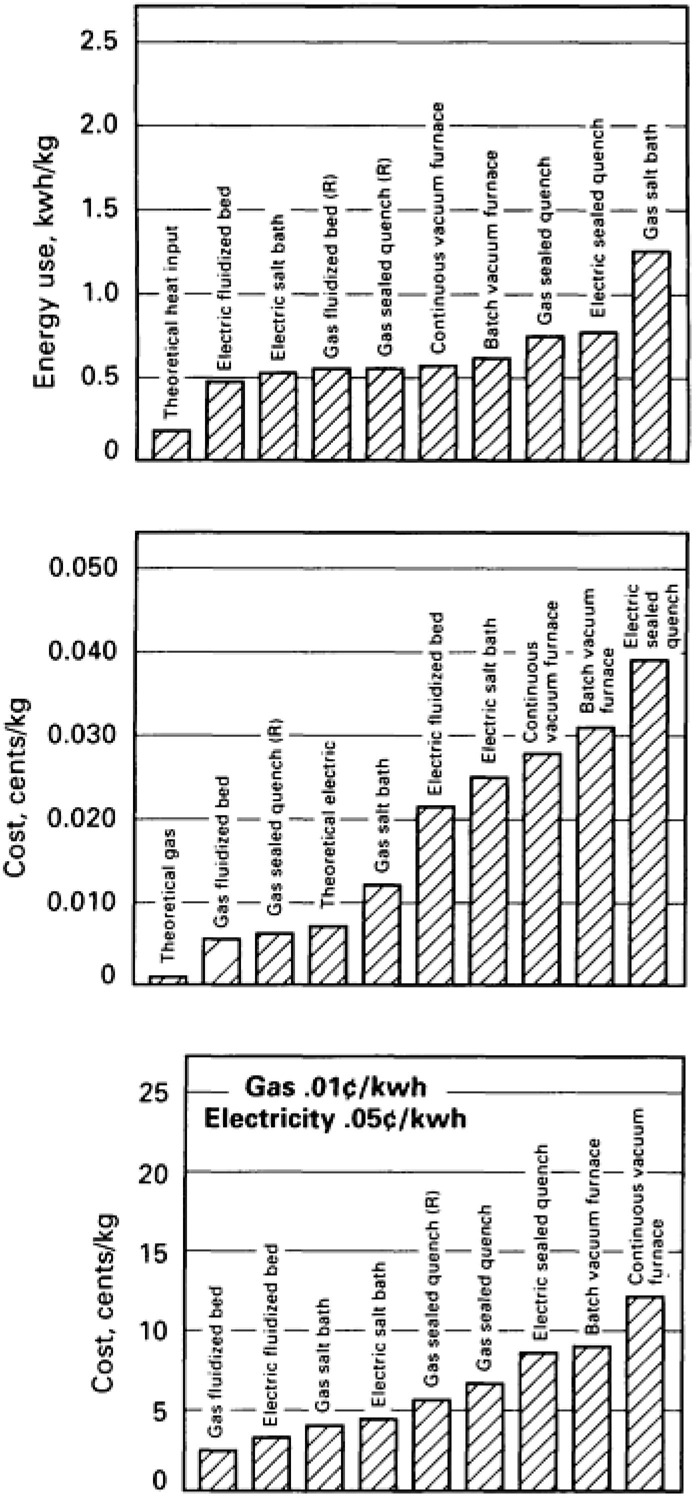

Fig. 9 Energy and cost comparisons of various furnace types with a soak temperature of about 850 °C (1560 °F). Data includes energy to heat furnace to temperature. R, recuperators fitted to burners. Source: Ref 25

Temperature Control in Heat Treating

Albert S. Tenney III, Leeds & Northrup, Unit of General Signal Corp.

Introduction

TEMPERATURE CONTROL is an integral part of heat-treating operations, which generally consist of three separate functions: material movement, the application of energy, and the supervision of process conditions. In a typical heat-treat operation, work is moved into a furnace, heated according to a time-temperature program, cooled or quenched, and finally moved out of the furnace or quench vessel. The temperature, and frequently the atmosphere, must be controlled precisely in order to achieve the desired metallurgical results.

Temperature Control Loops

Temperature instrumentation and control systems include temperature sensors, controllers, final control elements for controlling energy flow, measurement instruments, and set-point programmers. Temperature control also requires an understanding of the heat transfer mechanisms of conduction, convection, and radiation.

In recent years the separate functions of material movement, application of energy, and supervision of process conditions have been handled in the following way: programmable logic controllers (PLCs) have been used to handle material movement; analog variables (energy, temperature, pressure, flow, vacuum, percent carbon, and so on) have been controlled by single-loop controllers and set-point programmers; process supervision or data management has been done by strip chart recorders or data loggers. This separation of functions requires communication among the logic controllers, loop controllers, and data-acquisition equipment. Finally, when a supervisory computer is required to handle such functions as scheduling, parts purchasing, and statistical process control, a further layer of interfaces is required to tie the whole set of instrumentation together.

A basic control loop (Fig. 1) includes a temperature sensor, controller, and final control element. The heat process temperature is detected by a temperature sensor that generates a signal proportional to the process temperature. This actual temperature is compared to the desired temperature determined by the controller set point. Based on this comparison, the controller develops an output signal that adjusts the final control element regulating heat flow to the heat-treating process.

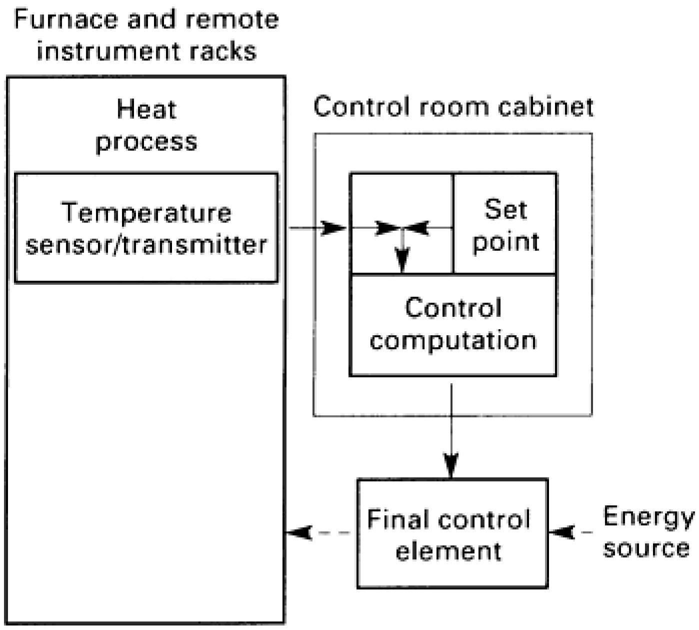

Fig. 1 Basic control loop

Sensor Signal Transmitter. The basic control loop may incorporate a temperature transmitter to amplify the temperature sensor signals. This amplification is desirable when the control instrument is remotely located from the temperature sensor. The amplification also helps to avoid interaction between two or more instruments using a common sensor. For example, the temperature signal may be transmitted to a remote central control room where it is connected to several controllers, a recorder, a data-acquisition system, or a digital computer.

Auxiliary devices used with the basic control loop include measurement instruments with set-point programming (Fig. 2). The measurement instrument monitors the same temperature sensor as that used by the controller. The set-point programmer automatically varies the controller set point to provide a temperature cycle or temperature program in accordance with an established plan.

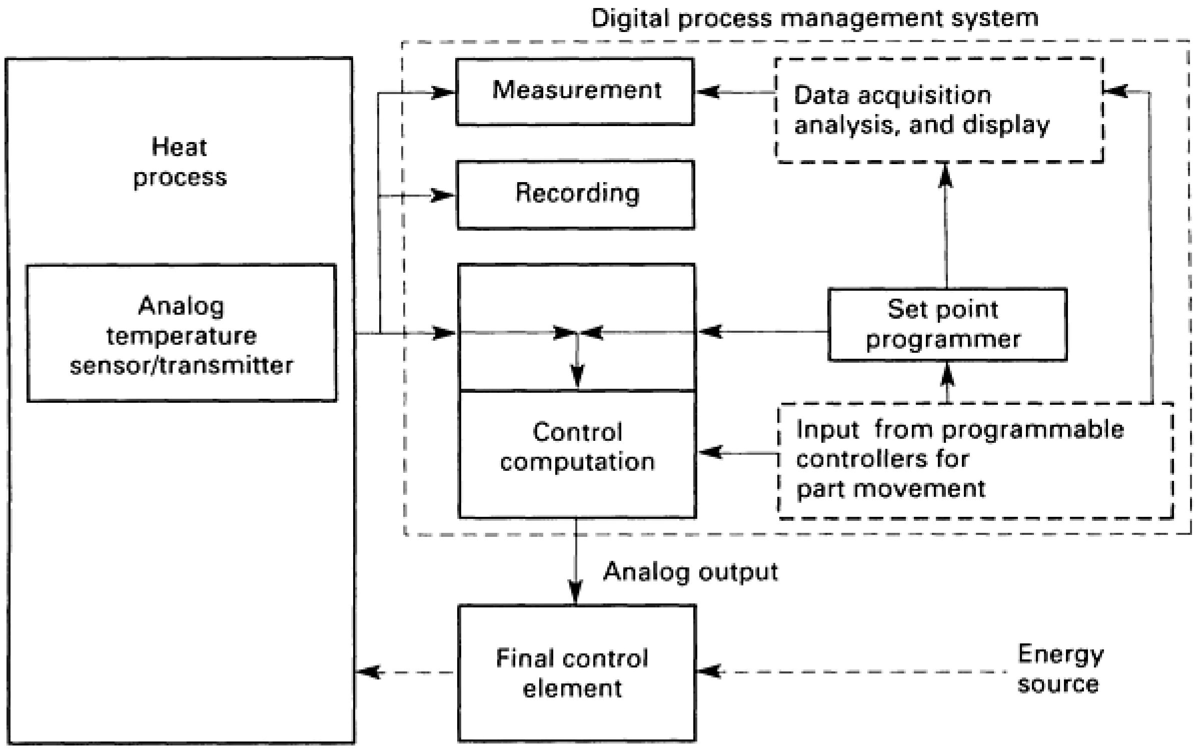

Fig. 2 Basic control loop with auxiliary devices. Functions in an integrated digital process management system are shown in the dashed blocks.

The reduced cost and more compact packaging of digital support hardware has spawned the integration of temperature control with auxiliary functions such as process documentation and workpiece flow. These process management systems can (Fig. 2) integrate the functions of temperature measurement, loop control, variable set-point control, logic (parts movement) control, data acquisition, data management, results display, and report writing, all in a package no more costly than a multipoint recorder and a few single-loop controllers.

Temperature Scales. Effective 1 January 1990, the standards groups of the world have agreed upon a new temperature scale called the International Temperature Scale of 1990 (ITS-90) (Ref 1). It differs in many respects from the last temperature scale, the International Practical Temperature Scale of 1968 (IPTS-68). Most notably, the new scale is extended down to 0.65 K; the platinum resistance thermometer is used to realize the scale up to 1234.93 K (replacing the type-S thermocouple over the upper portion of this range), and deviations between ITS-90 and IPTS-68 are less than 1 °C (2 °F) below 2400 °C (4350 °F). Additional information on the use of these temperature scales is provided in the article "Thermocouple Materials" in *Properties and Selection: Nonferrous and Special-Purpose Materials,* Volume 2 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.*

Temperature Control in Heat Treating

Albert S. Tenney III, Leeds & Northrup, Unit of General Signal Corp.

Temperature Sensors

Temperature sensors are classified as either contact or noncontact, and as either electrical or nonelectrical. For example, the mercury thermometer is a contact, nonelectrical type. Because of high-temperature requirements and the trend toward electrical instrumentation, most heat-treating applications require electrical sensors. When selecting a contact sensor, certain variables should be considered, such as cost, temperature range, useful life, accuracy, size, and response speed. The selection of noncontact sensors involves similar considerations plus those related to radiation factors such as target size, surface emissivity, focal length, and sighting path interference.

Thermocouples and resistance temperature detectors (also known as resistance thermometers) are the most important contact-type electrical temperature sensors used in the metals industry. Well over 90% of the sensors used in this industry are estimated to be thermocouples. A thermocouple is rugged, inexpensive, accurate, fast in response, and covers wide temperature ranges. A resistance thermometer is more accurate and stable than a thermocouple. However, the resistance thermometer is limited to lower temperatures.

Thermocouples

Thermocouples consist of two dissimilar wires joined at one end, forming a measuring, or hot, junction. The other end, which is connected to the copper wire of the measuring instrument circuitry, is called the reference, or cold, junction. The electrical signal output in millivolts is proportional to the difference in temperature between the measuring junction (hot) and the reference junction (cold). The different types of thermocouples, classified by their metallurgical compositions, have differing output signal calibrations (see the article "Thermocouple Materials" in *Properties and Selection: Nonferrous and Special-Purpose Materials,* Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*).

The thermocouple wire combination, with or without insulators, is called a thermocouple element. A complete thermocouple assembly includes the element and a protection tube or well to protect the element from contamination and provide mechanical strength (see Fig. 3). In addition, the assembly provides mounting fittings and a terminal junction in a head assembly. Extension lead wires, which match the thermoelectric characteristics of the thermocouple elements, are used to connect these terminal junctions to the instrumentation. Figure 4 shows a simple thermocouple with lead wires and reference junction. The lower sketch of this figure shows details of a complete thermocouple assembly in a protection tube. The operating life and accuracy of a thermocouple depend on its operating temperature, time at the operating temperature, ambient atmosphere, and number of high-to-low temperature cycles.

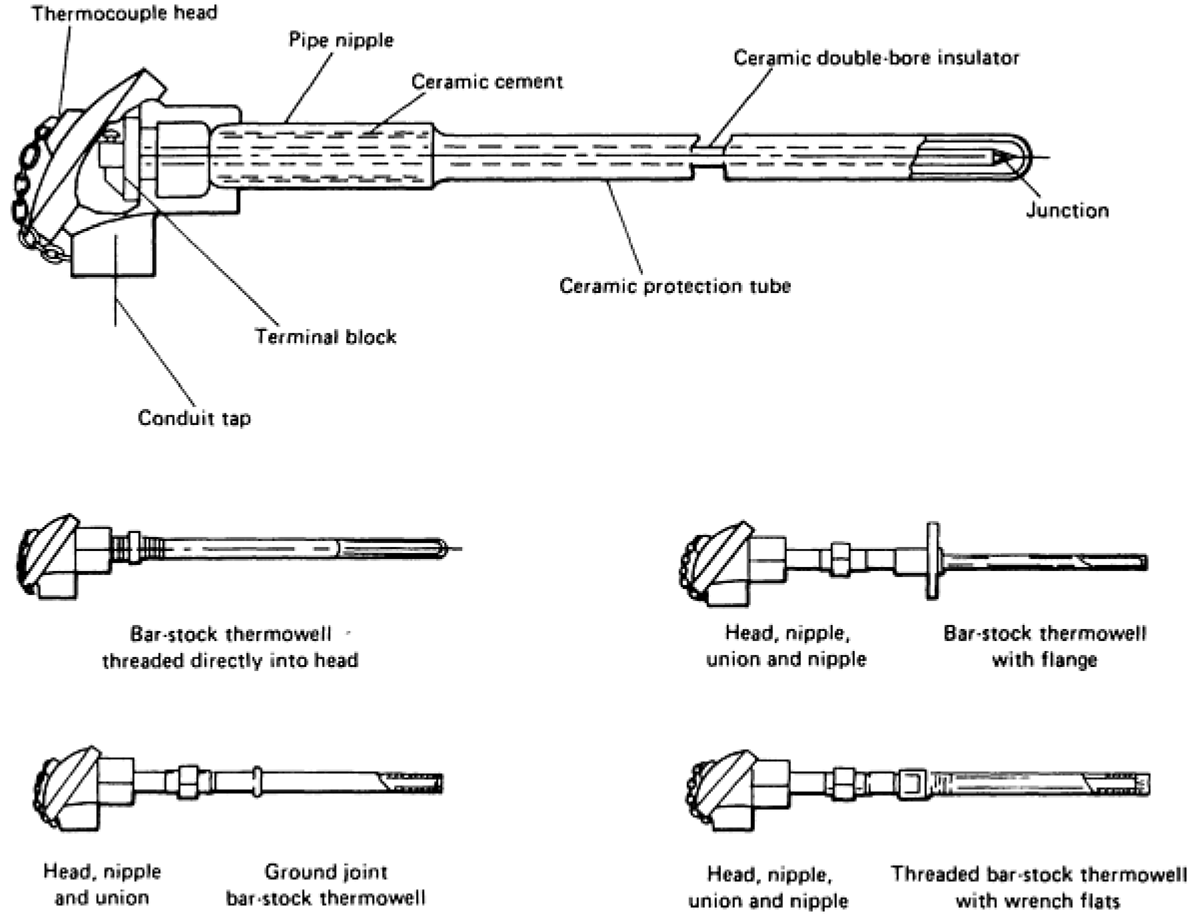

Fig. 3 Typical industrial thermocouples insulated with hard-fired ceramics

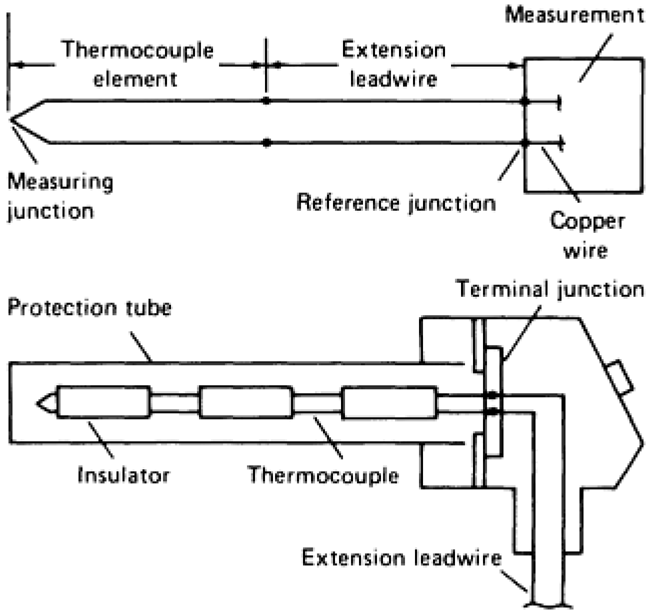

Fig. 4 Simple thermocouple (upper view); and cutaway of a thermocouple assembly (lower view)

Precautions. Heat-treating operations that rely on thermocouples require numerous precautionary measures. For example, thermocouple error due to contamination normally is characterized by a low output signal. Contamination comes from touching the wires with bare hands during assembly, dirty insulators, oils and dirt inside the protection tube, or the atmosphere used in the process. Consequently, cleanliness is important in assembling thermocouples. Insulators that become contaminated in normal service should not be reused. Even the cutting oils used to cut threads on protection tubes contain sulfur, which can cause contamination. These tubes should be thoroughly degreased before use. In high-temperature applications, the furnace atmospheres penetrate protection tubes and sheath materials. Consequently, routine replacement of the contaminated thermocouple elements is required. Frequency of replacement depends largely on operating temperature, environment, and freedom from mechanical stress.

Thermocouple Location. Location of thermocouple measuring junctions must allow exposure to the correct heat process temperature. Normally, the tip of the thermocouple (measuring junction) is placed near the work in the furnace. Thus, it is exposed to the same heating environment as the workpieces.

A common error occurs when the thermocouple assembly is not inserted far enough into the furnace. Under this condition, heat is conducted by the thermocouple assembly away from the measuring junction, toward the colder furnace wall. Consequently, the thermocouple indicates a temperature lower than the actual work temperature. One way to determine correct location is to place an adjustable flange on the thermocouple protection tube. The correct insertion depth then can be determined by adjusting the flange to achieve the maximum temperature and the minimum insertion depth, while the furnace is in operation. However, thermocouples never should be located near burners or heating elements because radiant heat may cause erroneous readings.

The speed of response of the thermocouple to process temperature changes should be as fast or faster than that of the work in the furnace. If the workpieces are small and the thermocouple is contained in a heavy protection tube, the thermocouple temperature will lag behind the actual work temperature. Consequently, workpieces will be overheated when they are initially brought up to control temperature.

Furnace temperature uniformity is important and should be checked before installing the permanent control thermocouple. If an air recirculating system is used, an average temperature in the duct work can be measured by installing three or more thermocouples across the duct width connected in parallel. (A single thermocouple in the center of the duct typically will indicate a higher temperature because this location is normally the hottest.)

However, in order for the average to be valid, the electrical resistances of the several thermocouples must be equal. A superior solution to averaging thermocouple signals is to measure each individually and average digitally. Furthermore, a true temperature profile can be detected this way. Finally, if one thermocouple signal deviates significantly from the others, failure of that element may be found. Microprocessor-based recorders and data management systems make these types of calculations easy.

Types of Thermocouples. Thermocouples most commonly used in heat processing applications are listed in Table 1. Table 2 gives temperature limits for thermocouples in oxidizing atmospheres, and Table 3 contains limits of error as a percentage of the temperature readings for these thermocouple types. (For more information on thermocouples, see the article "Thermocouple Materials" in *Properties and Selection: Nonferrous and Special-Purpose Materials,* Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*).

Table 1 Comparison of thermocouple types

Type	Usable temperature range		Advantages	Restrictions
	°C	°F		
J (iron-constantan)	-185-870	-300-1600	Comparatively inexpensive; suitable for continuous service to 870 °C (1600	Maximum upper limit in oxidizing atmosphere is 760 °C (1400 °F), due to the oxidation of

			°F) in neutral or reducing atmospheres	the iron; protection tubes should be used above 480 °C (900 °F); protection tubes should always be used in a contaminating medium
K (nickel, chromium-nickel, aluminum)	-20-1370	0-2500	Suitable for oxidizing atmospheres; in higher temperature ranges, provides a more mechanically and thermally rugged unit than platinum, rhodium-platinum, and longer life than iron-constantan	Especially vulnerable to reducing atmospheres, requiring substantial protection when used
N (nickel, chromium, silicon-nickel, silicon, magnesium)	-245-1300	-410-2370	Significantly greater stability and longer life than type K in oxidizing atmospheres and somewhat superior in reducing atmosphere	
T (copper-constantan)	-185-370	-300-700	Resists atmosphere corrosion; applicable in reducing or oxidizing atmospheres below 315 °C (600 °F); its stability makes it useful at subzero temperatures; has high conformity to published calibration data	Copper oxidizes above 315 °C (600 °F)
E (nickel,chromium-constantan)	-185-870	-300-1600	Has high thermoelectric power; both elements are highly corrosion-resistant, permitting use in oxidizing atmospheres; does not corrode at subzero temperatures	Stability is unsatisfactory in reducing atmospheres
S (platinum, 10%	-20-	0-	Usable in	Easily

rhodium-platinum) R (platinum, 13% rhodium-platinum)	1480	2700	oxidizing atmospheres; provides a higher usable range than type K; frequently more practical than noncontact pyrometers; has high conformity to published calibration data	contaminated in other than oxidizing atmospheres
B (platinum, 30% rhodium-platinum, 6% rhodium)	870-1650	1600-3000	Better stability than types S or R; increased mechanical strength; usable to higher temperatures than types S or R; reference-junction compensation is not required if junction temperature does not exceed 65 °C (150 °F)	Available in standard grade only; high temperature limit requires the use of alumina insulators and protection tubes; easily contaminated in other than oxidizing atmospheres

Table 2 Temperature limits for thermocouples in oxidizing atmospheres

Upper temperature limits are a function of wire diameter; because temperature tends to have deleterious effects on thermocouples, the larger the amount of material in thermocouple cross section, the longer it can be expected to last.

(a) When expressed as a percentage, the limit of error is a percentage of the temperature reading, not of the range.

Selection of a specific kind of thermocouple is based primarily on the required temperature range and cost. However, the choice also is affected by its metallurgical properties. For example, type J is superior to type K in a reducing atmosphere, and type K is superior to type J in an oxidizing atmosphere. Type K is very susceptible to sulfur contamination, such as sulfur dioxide in combustion gases. Type K should be used in a large protection tube or one with a ventilated design. If the ambient atmosphere has a low oxygen concentration, the resulting green-rot corrosion results in a low output signal. Green rot is caused by preferential oxidation of chromium at low oxygen concentrations. The type-N thermocouple was designed to overcome some of the limitations of type K (Ref 2), and repeated results suggest superior performance for bare wire (Ref 3).

The two major thermocouple design classifications are the compacted ceramic, and the protection tube or well-type, with integral element insulators.

Compacted ceramic thermocouples use a ceramic powder to insulate the thermocouple wires. These wires are compacted inside a metal sheath, providing protection from the environment. This compacted ceramic thermocouple is small in outside diameter, provides fast response and can be bent easily to suit installation requirements. It can be used at high pressures and high temperatures. Two types of compacted ceramic thermocouples, grounded and ungrounded, are shown in Fig. 5. The metal sheath has a plug of the same metal welded in place as the tip. In the grounded type, the end of the thermocouple is permitted to touch this plug, providing more rapid response. The ungrounded type is used when required by the measurement and/or control circuit electronics. Recent results suggest that the superiority of type N over type K observed in bare wire thermocouples may not be so great for compacted ceramic thermocouples (Ref 4).

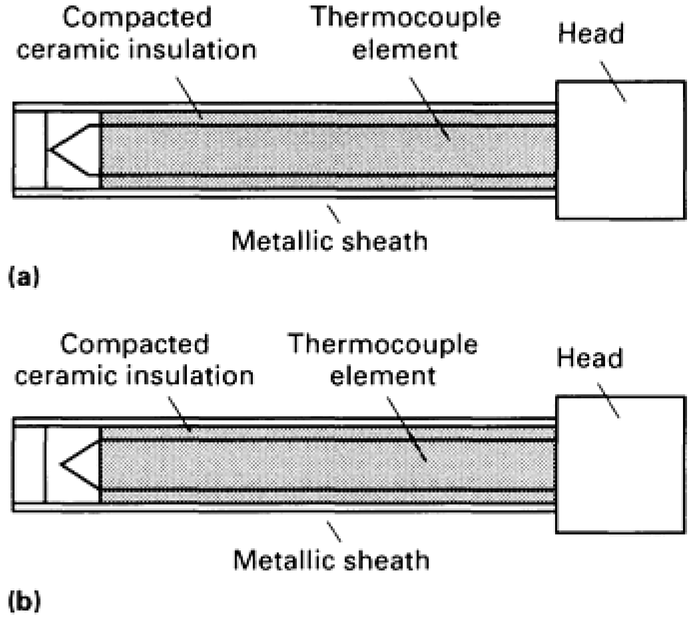

Fig. 5 Grounded and ungrounded types of compacted ceramic thermocouples. (a) Grounded. (b) Ungrounded

Protection Tubes and Wells. Thermocouple elements with insulators and compact ceramic elements are used inside protection tubes and wells (Fig. 3). The thermocouple elements with insulators are less expensive than the compacted ceramic elements and can be manufactured by users. Protective tubes and wells are used to provide mechanical support and protect the thermocouple from the process environment. Protection tubes are made from metallic or ceramic materials and are used in air or other gaseous atmospheres (Table 4). These atmospheres are near atmospheric pressure such as those used in heat-treating furnaces.

Table 4 Protection tube and thermowell materials

Material[a]	Recommended maximum temperature		Description
	°C	°F	
Metal and metal-ceramic materials			
Carbon steel	540	1000	Satisfactory in any except corrosive atmospheres
Yoloy (Ni-Cu alloy steel)	700	1300	Resistant to corrosion in both oxidizing and reducing environments; ideally suited for use in condensate return lines, salt-water and brine solutions, condenser water lines, vent and waste piping, or corrosive water lines
Cast iron	700	1300	Generally more useful than Yoloy in the chemical industry; resistant to concentrated sulfuric acid and caustic solutions; can be used to 870 °C (1600 °F) in reducing atmospheres
304 stainless steel (18Cr-8Ni)	870	1600	Resistant to oxidation and corrosion; generally used in wet-process applications such as steam lines, oil refineries, and chemical solutions; resists nitric acids well, halogen acids poorly, and the sulfuric acids moderately
316 stainless steel (18Cr-8Ni-2Mo)	870	1600	Superior to 304 stainless steel in corrosion resistance; resists pitting in phosphoric and acetic acids
446 stainless steel (28Cr, Fe)	1095	2000	Excellent corrosion resistance at high temperatures; used extensively in general-purpose alloy tubes; highly resistant to sulfur attack
Nickel	1095	2000	Resistant to attack by many chemicals at high temperatures; principally used for hot caustic and molten-salt baths; should not be used where sulfur is present
Inconel 600 (80Ni-15Cr)	1150	2100	For general high-temperature use; has greater mechanical strength than 446 stainless steel; should not be used in sulfur atmospheres
R-Monel (67Ni-30Cu)	480	900	Used where high strength and resistance to corrosion are required, such as sea water, dilute sulfuric acid, and strong caustic solutions

F-11 ($1\frac{1}{4}$ Cr-$\frac{1}{2}$ Mo)	595	1100	Generally used in power plants, on water and steam line applications; available in thermowells only
F-22 ($2\frac{1}{4}$ Cr-1Mo)	595	1100	Same as F-11, except has better oxidation resistance
LT-1 (77Cr-23Al_3O_4)	1370	2500	For high-temperature applications; intermediate between metal and ceramic tubes, has good thermal and mechanical shock resistance
Ceramic materials			
L&N Fyrestan	1540	2800	A highly refractory porcelain, normally used for primary protection and often for secondary protection. L&N Fyrestan tubes can be substituted in many applications for nickel or chromium-alloy tubes, and although not as strong as metal alloys, are fully as gas-tight. Having a softening point of 1650 °C (3000 °F), these tubes can be mounted vertically at a temperature of 1540 °C (2800 ° F). When mounted horizontally, the recommended maximum temperatures are 1510, 1455, 1370, and 1260 °C (2750, 2650, 2500, and 2300 ° F) for unsupported lengths of 75, 150, 300, and 450 mm (3, 6, 12, and 18 in.), respectively. The tubes are impervious to air to 1650 °C (3000 °F) and to dry hydrogen to 1400 °C (2550 °F). Their low rate of thermal expansion gives good thermal shock resistance
High-purity alumina	1870	3400	A highly refractory 99+% pure alumina, normally used for primary or secondary protection. Alumina tubes have excellent deformation resistance and superior resistance to reducing atmospheres and chemical reactions at temperatures as high as 1870 °C (3400 °F). (If the tube is mounted horizontally, it must be supported at temperatures above 1650 °C (3000 °F.) Its excellent resistance to oxidizing and reducing atmospheres, as well as its exceptional stability at elevated temperatures, make this material the ideal choice for protection of precious-metal thermocouples--especially type B. These tubes are highly resistant to corrosive alkaline vapors and aluminum chloride vapors, and are stable to acids, alkalis, molten metals, most glass fluxes; molten salts, and slags. The tubes are also impermeable to most gases under the conditions found in industrial furnaces
Silicon-carbide refractory	1650	3000	Highly resistant to the cutting action of flames and gases and the corrosive effects of SO_2, tubes of silicon carbide refractory can be used for primary as well as secondary protect for temperatures up to 1650 °C (3000 °F). Ceramic-bonded silicon carbide features high thermal conductivity, high thermal-shock resistance, high strength, and low permeability at differential pressures less than 50 to 75 mm (2 to 3 in.) H_2O

(a) Materials are, in general, arranged in the order of their increasing resistance to oxidation, increasing mechanical strength at elevated temperatures, and increasing limit of useful temperatures.

Wells are metallic and made of either drilled metal bar stock (one-piece construction) or from welded pipes. Most often, wells are used to protect the thermocouple in liquid or gaseous environments with pressures greater than 345 kPa (50 psi) for the drilled design. Typically, they are used in quench tanks, hydraulic systems, or steam lines.

If the insulation between the thermocouple wires in the element or extension leadwire breaks down from heat, contamination, or mechanical damage, a low output signal results. This signal indicates an erroneously low temperature. This type of error results in process operation at an excessive temperature. Valuable energy is lost, and the work can be damaged or destroyed.

Thermocouple Applications. A typical thermocouple construction includes the thermocouple wire element with insulators mounted in a protection tube. The thermocouple head provides terminals for a junction between the thermocouple element and leadwire used for connection to instrumentation.

A typical application is a car-bottom annealing furnace used up to 1100 °C (2000 °F) with an air atmosphere. An 8 gage type K or N thermocouple in a ceramic protection tube is selected because it is useful up to 1260 °C (2300 °F) in an oxidizing atmosphere and is less expensive than the noble metal types R, S, and B. A 16 gage type K or N leadwire with synthetic fiber insulation is selected because it matches the type K element up to 200 °C (400 °F), suitable for a heat-treating area, and is strong enough for pulling through a conduit. Type K or N should be used for all the furnace measurements to maintain uniformity; that is, recording and control of furnace temperatures, plus the high limit safety control and work temperatures.

The furnace temperature thermocouple element should be 8 gage for maximum life and long enough so that its tip or measuring junction can be inserted well into the furnace cavity while the head is far enough back from the furnace wall to prevent its rising above 200 °C (400 °F). A ceramic protection tube will meet the process temperature requirements and is strong enough not to sag if mounted horizontally. An adjustable flange permits changing the depth of insertion in the furnace to the optimum depth. For example, when the furnace is at operating temperature, the thermocouple may be slowly withdrawn until its temperature indicator starts to drop, showing that it is too close to the cold furnace wall. The adjustable flange may then be locked in place on the protection tube. Location of thermocouples depends on furnace design, but, in any event, the thermocoupler must be inserted to locations where representative temperatures exist.

Resistance Temperature Detectors

Resistance temperature detectors (RTDs) are contact-type sensors. Their electrical resistance is proportional to temperature. Typical detector materials are platinum, copper, and nickel. They are more stable, accurate, and interchangeable than thermocouples, but even the platinum detectors have an upper temperature limit of approximately 750 °C (1380 °F), which reduces their usage in the metals industry.

Resistance temperature detectors are normally larger in size and slower in response than thermocouples. However, the new thin-film deposited detectors minimize this advantage, which characterizes the conventional wire-wound detectors.

Resistance temperature detectors are used typically in quenching systems, low-temperature annealing furnaces, and tempering furnaces. Resistance is measured with a two-lead, three-lead, or four-lead configuration. With the two-lead configuration, the resistance measured includes that of the leads, so this effect must be small enough to be ignored or a correction must be made for it. The correction is complicated by the fact that the resistance of the leads (typically copper wires) depends on the temperature of the leads, and the leads will be going through a temperature gradient. A three-lead measurement compensates for lead resistance but not for any difference in resistance between two leads. This is the configuration used for most process control applications. The four-lead configuration eliminates all lead effects and is generally reserved for those applications requiring great accuracy. A four-lead measurement is used with the standard platinum resistance thermometers in realizing the International Temperature Scale.

Noncontact Temperature Sensors

Temperature is a measure of the ability to transfer heat. Heat may be transferred by conduction, convection (actually conduction to a fluid followed by translation), and by thermal radiation. Noncontact temperature sensors depend on the thermally generated electromagnetic radiation from a surface of a test object. Electromagnetic radiation is emitted from a heated body when electrons within the body change to a lower energy state. Both the intensity and the wavelength of the radiation depend on the temperature of the surface atoms or molecules. For a blackbody, the radiation wavelength and spectral emission power vary as a function of temperature, as shown in Fig. 6(a). Planck blackbody distributions of spectral radiance for temperatures typically encountered in the heat treating of metals are shown in Fig. 6(b).

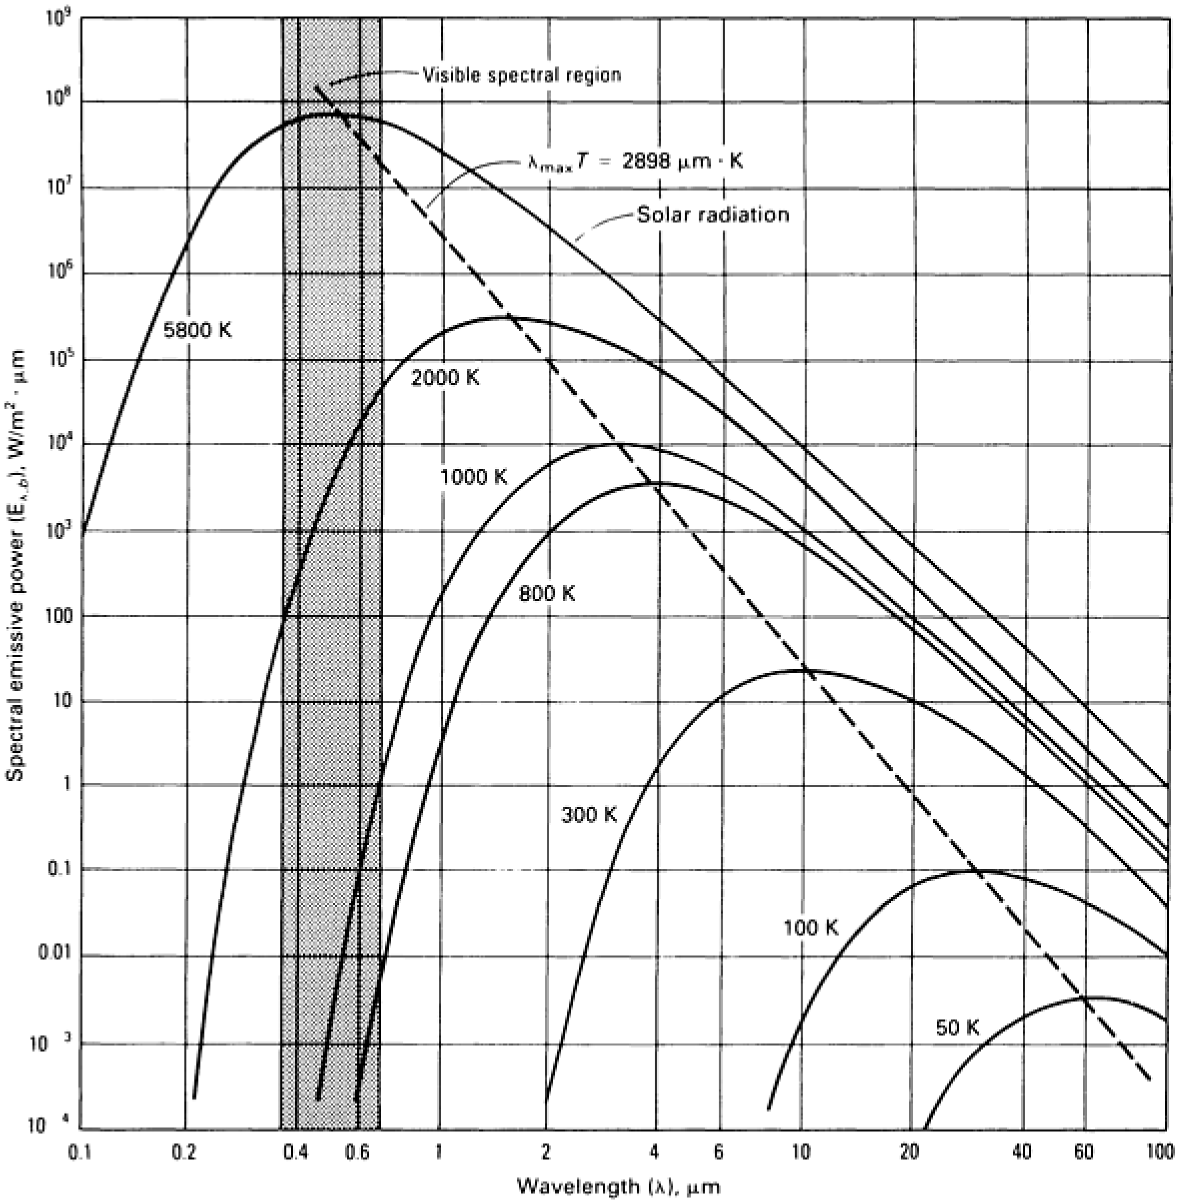

Fig. 6(a) Spectral blackbody emissive power for wavelengths in the thermal radiation spectrum (0.1 to 100 μm)

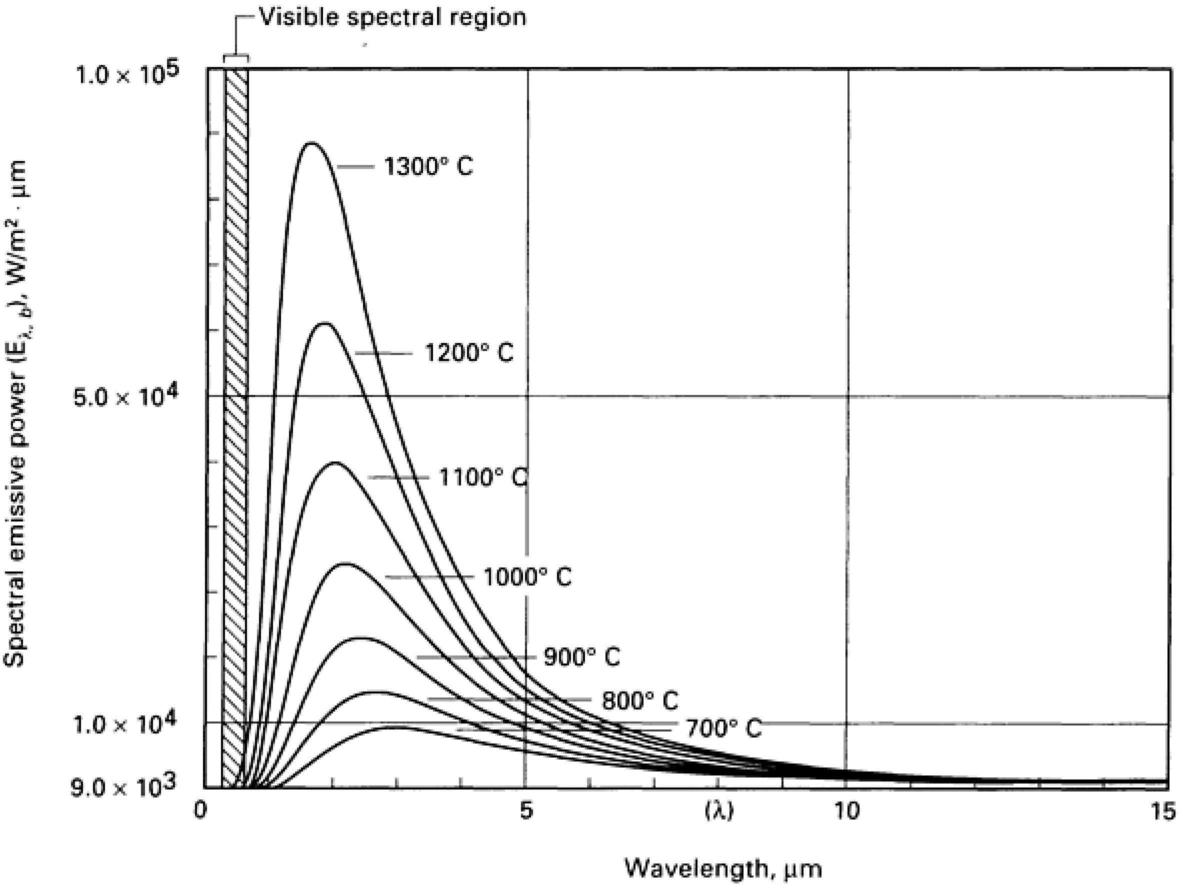

Fig. 6(b) Spectral blackbody emissive power for wavelengths in the near-infrared radiation spectrum (0.75 to 3.0 μm). Dominant wavelengths are shown for temperatures typically encountered in the heat treating of metals.

Blackbodies, the most efficient radiators and absorbers of electromagnetic radiation, have an emissivity of 1.0. All other bodies have an emissivity less than 1.0. Variations in emissivity change the power of radiation emitted at a given temperature and thus affect radiation temperature measurements.

Instruments that determine temperatures from measurements of thermal radiation are called radiation thermometers. The various types of noncontact temperature sensors include infrared imaging sensors, radiometers, and pyrometers. Radiometers and pyrometers are devices for measuring radiation, or spot or line temperatures, respectively, without the spatial resolution needed for an imaging system. Radiometers, because they usually have slow response times, are most useful for monitoring constant or slowly varying temperatures. Pyrometers are used as non-contacting thermometers for temperatures from 0 to 3000 °C (32 to 5400 °F). Newer instruments can superimpose a line trace of the temperature on the visible-light image of the surface or scene being viewed. Radiometers and pyrometers are usually rugged, low-cost devices that can be used in an industrial environment for the long-term monitoring of processes.

The tremendous advantage of radiation thermometers is that they yield accurate temperature measurements of the target without touching the test object (which is referred to here as a target because radiation thermometers must be sighted on the object of interest). Thus, radiation thermometers are preferred to contact thermometers (thermocouples, resistance thermometers, and so on) where the target is difficult to touch because it is moving, fragile, small, of small "thermal mass," hot, corrosive, or in a corrosive or protected environment. Radiation thermometers are thus a useful alternative to contact thermometers. The principal challenge is to be able to infer temperature from a signal that can depend not only upon target temperature but also upon target emittance, background emittance coupled with target reflectivity, intervening absorptance, or emittance and partial targets.

Optical Pyrometers. As the temperature of a heated target approaches 700 °C (1300 °F), it begins to emit thermal radiation in the visible portion of the spectrum (Fig. 6(a), 6(b)) as a deep red color. Further increases in temperature result

in changes in color from red, through orange, to white, with concurrent increases in brightness. Because of these variations in color and intensity, an experienced eye can make a fairly accurate prediction of temperature.

However, it would be far better to have the eye compare the temperature of the target of interest to that of a target of known temperature. This is exactly the principle of the disappearing filament optical pyrometer (Fig. 7). The hot target is viewed through a small terrestrial telescope that contains a lamp filament having brightness that can be adjusted by varying the amount of current through it. The current is adjusted until the brightness of the lamp filament equals that of the target and the filament seems to disappear into the glowing background of the target (Fig. 8). The temperature of the filament, and thus that of the target, is known from previously established calibration curves. Optical pyrometers generally are used to calibrate radiation sensors.

Fig. 7 Typical optical pyrometer

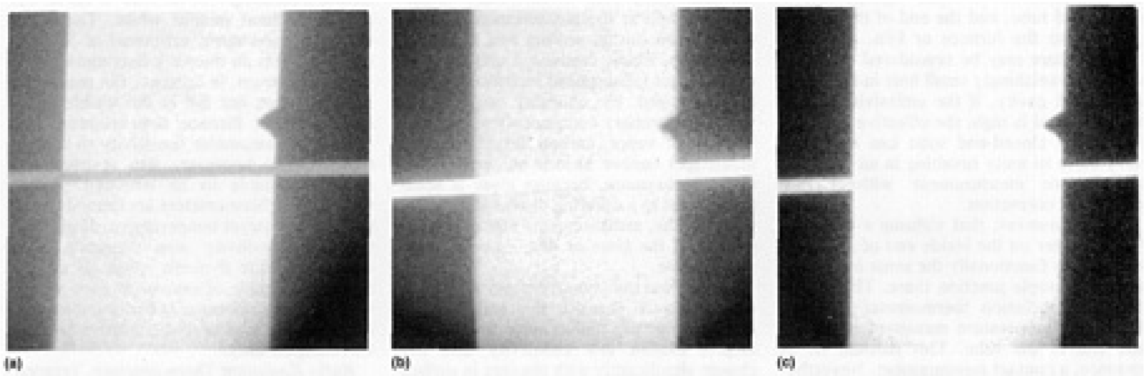

Fig. 8 Pyrometer filament (thin horizontal line) with various amounts of current paralleling radiation brightness of various temperatures. (a) Too low (cold). (b) Too high (hot). (c) Balanced (filament "disappears")

On-Line Radiation Thermometers. Radiation thermometers that do not depend on the eye consist of a detector sensitive to thermal radiation, an optical system to collect thermal radiation and concentrate it on the detector, a housing to support and protect the optics and the detector (Fig. 9), and electronics to measure the signal from the detector and compute and display the temperature. Even though selectivity can be controlled by the choice of a detector, it is often restricted further with optical filters (including windows and lenses).

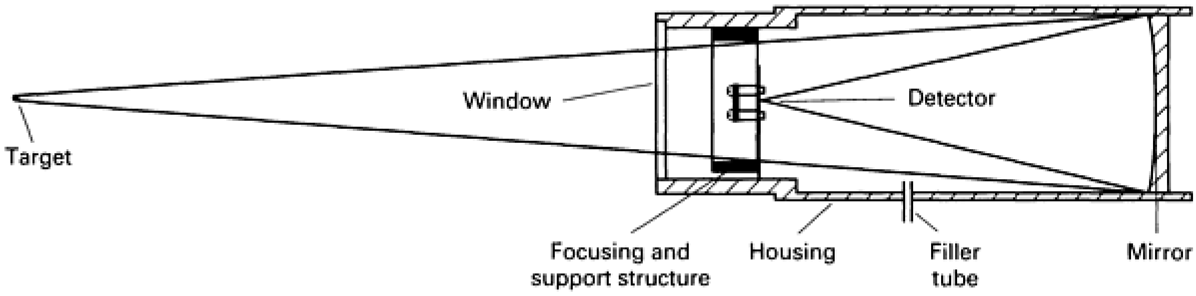

Fig. 9 Diagram of a radiation thermometer with a silicon thermopile

The detector is usually either a quantum (photon) detector, producing a quantity of electrons proportional to the number of photons impinging upon the detector, or a thermal detector, producing a signal proportional to an increase in the temperature of one part of the detector with respect to another part. An example of the former is the silicon photodiode, whereas thermopiles and pyroelectric detectors are frequently used thermal detectors. The silicon thermopile is a recent advance that provides a previously unobtainable combination of sensitivity, stability, speed, and broad spectral response (Fig. 10). Thin-film thermopiles include several layers: a radiation absorber, a metal, a second different metal, and an electrically insulating support. The signal is magnified by connecting multiple metal junctions in series. Replacing one of the metals with polycrystalline silicon can increase the signal further by almost an order of magnitude.

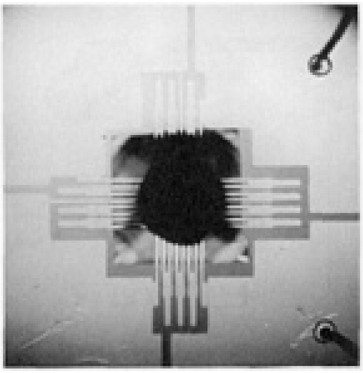

Fig. 10 Silicon thermopile with electrical connects. The circular radiation absorber at the center is 460 μm (18 mil) across.

Emissivity Errors and Calibration with Blackbody Cavities. In order for the target temperature to be inferred from the detector signal, the thermometer must be calibrated. At first glance, calibration might seem to consist of simply sighting the thermometer on a target of known temperature (as determined by a contact thermometer) and measuring the signal. However, different targets at the same temperature can emit significantly different amounts of energy because of variations in emissivity. Thus, the single measurement--detector signal--depends on two, usually independent, quantities: the temperature of the target and the emissivity of the target. Much of the following discussion is aimed at choosing thermometers and procedures that minimize uncertainties resulting from targets with uncertain or varying emissivity. These uncertainties are called emissivity errors. To eliminate emissivity errors during the calibration of radiation thermometers, so-called blackbody targets are used. Blackbody targets, which are perfect absorbers and emitters of radiation, can be approximated by a large uniformly heated cavity with a small hole for the emission of radiation (or the nearly perfect capture of incoming radiation).

Minimizing Interferences. An interference is defined as any condition that can cause a change in the amount of thermal radiation reaching the detector but that is unrelated to a change in target temperature. Unaccounted interferences lead to errors in temperature measurement. Potential interferences include variations in target emissivity, absorption or emission of radiation in the sight path between the thermometer and the target, radiation reflected by the target from hot surroundings to the thermometer, and variations in target size where the target does not always fill the field of view of the thermometer. The choice of the thermometer is often dictated by the need to reduce errors resulting from these interferences. The principal methods successful in reducing interference errors are to control the shape of the target, to purge the sight path between the target and the thermometer, and to choose the best wavelength. The use of ratio thermometers might also reduce the errors associated with interference effects.

Shaping. The most common use of target control is in the measurement of the internal temperatures of furnaces and kilns. Here the thermometer is often sighted into a closed-end tube, and the end of the tube is placed into the furnace or kiln. Although this structure may be considered fairly far from the vanishingly small hole in the large, isothermal cavity, if the emissivity of the tube material is high, the effective emissivity of the closed-end tube can approach very close to unity resulting in an accurate temperature measurement without any emissivity correction.

Note, however, that sighting a radiation thermometer on the inside end of a closed-end tube is functionally the same as placing a thermocouple junction there. That is, although a radiation thermometer is being used, the temperature measured is that of the end of the tube. This method is, in essence, a contact measurement. Nevertheless, this is often done in high-temperature metals applications where, for instance, the temperature is too high for thermocouples, or the sight tube is in an erosive or vibration environment where failure is frequent and resulting loss of a thermocouple is being prevented.

Purging can be important where the target is being obscured by absorbing or radiating gases, flames, or gas-born particles. Purging is usually accomplished with a so-called purged sight tube, where the thermometer sights at the target through an open-ended tube extending from the thermometer to a point close enough to the target that intervening interferences can be ignored. The tube is, typically, constantly purged with a nonabsorbing gas (frequently nitrogen or dry air) to keep the sight path free from the interfering material. Purging also helps to keep the lens or window of the thermometer clean. The distance through an absorbing medium may also be minimized by using fiber optics. Notice, however, that even where the sight path can be kept clean, emittance errors can destroy measurement accuracy.

Wavelength Selection. Because the temperature of the target may be determined from energy in any part of this distribution (total area, single band, band ratio, energy maximum, inflection points, and so on), one way to achieve accurate temperature measurements is to pick spectral regions where the effects of intervening interferences are minimized and target emittance is known. An illustrative (and commercially important) example is the measurement of glass temperature during sealing and annealing operations. Flame (emission) and combustion product (absorption) interferences can be minimized by choosing wavelengths where the primary components of combustion (water vapor, carbon dioxide, carbon monoxide) neither absorb nor emit radiation. Furthermore, because glass is semi-transparent to a differing degree at different wavelengths, measurements specific to the surface of the glass or deep into the glass are possible.

While glass radiation thermometry can be very accurate because the emittance of glass is generally reproducible, most metal targets exhibit low emissivity that can change significantly with changes in surface roughness or with oxidation. The effect of changing emissivity can be minimized by choosing a thermometer having a signal strongly dependent on target temperature, such as in the case of a radiation thermometer sensitive to short wavelengths (see Example 1 at the end of the section "Emissivity Values" in this article). The benefit of choosing a thermometer with short-wavelength sensitivity can be seen in the blackbody spectral distribution of Fig. 6(a) and 6(b). Notice that although the energy increases with increases in temperature at all wavelengths, it rises much faster at the shorter wavelengths. The curves become skewed to the left (shorter wavelengths) with increases in temperature. This means that the signal from a thermometer sensitive to short wavelengths only will rise much faster with increases in temperature than that for a thermometer sensitive to longer wavelengths. The short-wavelength-sensitive thermometer will be more sensitive to temperature changes. This is apparent to an observer. At 1000 °C (1830 °F), the color of a furnace enclosure viewed through a small hole is a pleasing red. At 1600 °C (2910 °F), it is a brilliant painful white. The sun's surface temperature, estimated at 5500 °C (9930 °F), has an intensity maximum in the visible spectrum. In contrast, the maximum intensity does not fall in the visible spectrum at most furnace temperatures. Restricting thermometer sensitivity to shorter wavelengths, however, also restricts the energy available to be detected. Short-wavelength thermometers are limited to relatively high target temperatures. High-temperature sensitivity also demands of a detector a wide dynamic range. If a thermometer capable of measuring over a very wide temperature range is desired, it may be necessary to choose one sensitive to long wavelengths only.

Ratio Radiation Thermometers. Temperature also can be inferred from the ratio of signals measured at two different wavelengths. Instruments making such a measurement are called two-color, dual wavelength, or ratio thermometers. Ratio thermometers are potentially useful in three areas:

- Partial targets where the target is too small to fill the field of view of the thermometer
- Occluded targets where the target is partially obscured by dust, smoke, and so on
- Targets for which emittance varies but does so equally in the two spectral regions to which the thermometer is sensitive

In all of these cases, variations (in target size, occlusion, emittance) that affect the signal equally for both wavelength regions do not affect the signal ratio or the temperature inferred. However, applying ratio thermometry should include the following considerations:

- The temperature is determined from the ratio of two signals, both of which are rising with increases in temperature. Therefore, the ratio can be less sensitive to temperature changes than either individual signal. Although the temperature sensitivity of the signal ratio can be increased by making the wavelengths farther apart, this diminishes the likelihood that the emittance will behave identically at each wavelength
- A decrease in signal will result in a lower apparent temperature for any signal wavelength thermometer. A lower apparent temperature will result from a decrease in signal at the shorter wavelength for a ratio thermometer, but a higher apparent temperature will be inferred from a relative decrease in signal at the longer wavelength. Therefore, an increase in absorptance (or decrease in emittance) can result in either negative or positive errors from a ratio thermometer
- Compared to single-wavelength thermometers, ratio thermometers are generally more complicated to construct, more fragile, and more expensive. For a more detailed analysis of ratio thermometers, see Ref 5

Emissivity Values. Emissivity is a function of several variables such as surface roughness and wavelength. The emissivity value in a given situation can be determined experimentally by measuring the signal from the target, measuring the target temperature independently, and calculating the correction to the calibration curve required to make the thermometer agree with the independent method. The independent method is usually to use a contact device (thermocouple) but may involve knowing that the target is at a fixed point such as a melting point.

Where such independent determination of target emissivity is not practical, published data may be used. However, great caution should be exercised here because the apparent emissivity of the target depends not only on the emissivity of the target material but also on the shape, roughness, and degree of oxidation of the target. Furthermore, emissivity values frequently depend on target temperature and the wavelength of the thermometer. With all of these cautions in mind, Table 5 shows values of emissivities for materials at 0.65 μm (the wavelength used by the disappearing filament optical pyrometer) (Ref 6). More detailed values are given in Ref 7. Besides emissivity values, this reference includes descriptions of how different preparation techniques and temperatures affect emissivity. Values at different wavelengths are also shown.

The relatively low emissivity values of most metals can be significantly affected by changes in surface roughness or oxidation. These variations in emissivity also affect temperature measurements by changing the power of radiation emitted at a given temperature. The errors from these uncertainties in emissivity values can be reduced by making temperature measurements at shorter wavelengths. The example below illustrates the potential effects of uncertainties in emissivity (or absorptance) in four thermometers with different spectral responses.

Example 1: Temperature Measurements from Four Radiation Thermometers with Different Spectral Sensitivities.

Figure 11 shows calibration curves--plots of signal versus temperature--for four thermometers: a thermometer sensitive to a narrow spectral region centered at 0.65 μm, a thermometer sensitive to a narrow spectral region centered at 0.9 μm, a ratio thermometer sensitive to 0.65 and 0.9 μm, and a "total radiation" thermometer sensitive to radiation at all wavelengths. The curves are normalized to be equal at 1500 °C (2730 °F). The effect of a 20% decrease in signal at 1500 °C (2730 °F) is also shown.

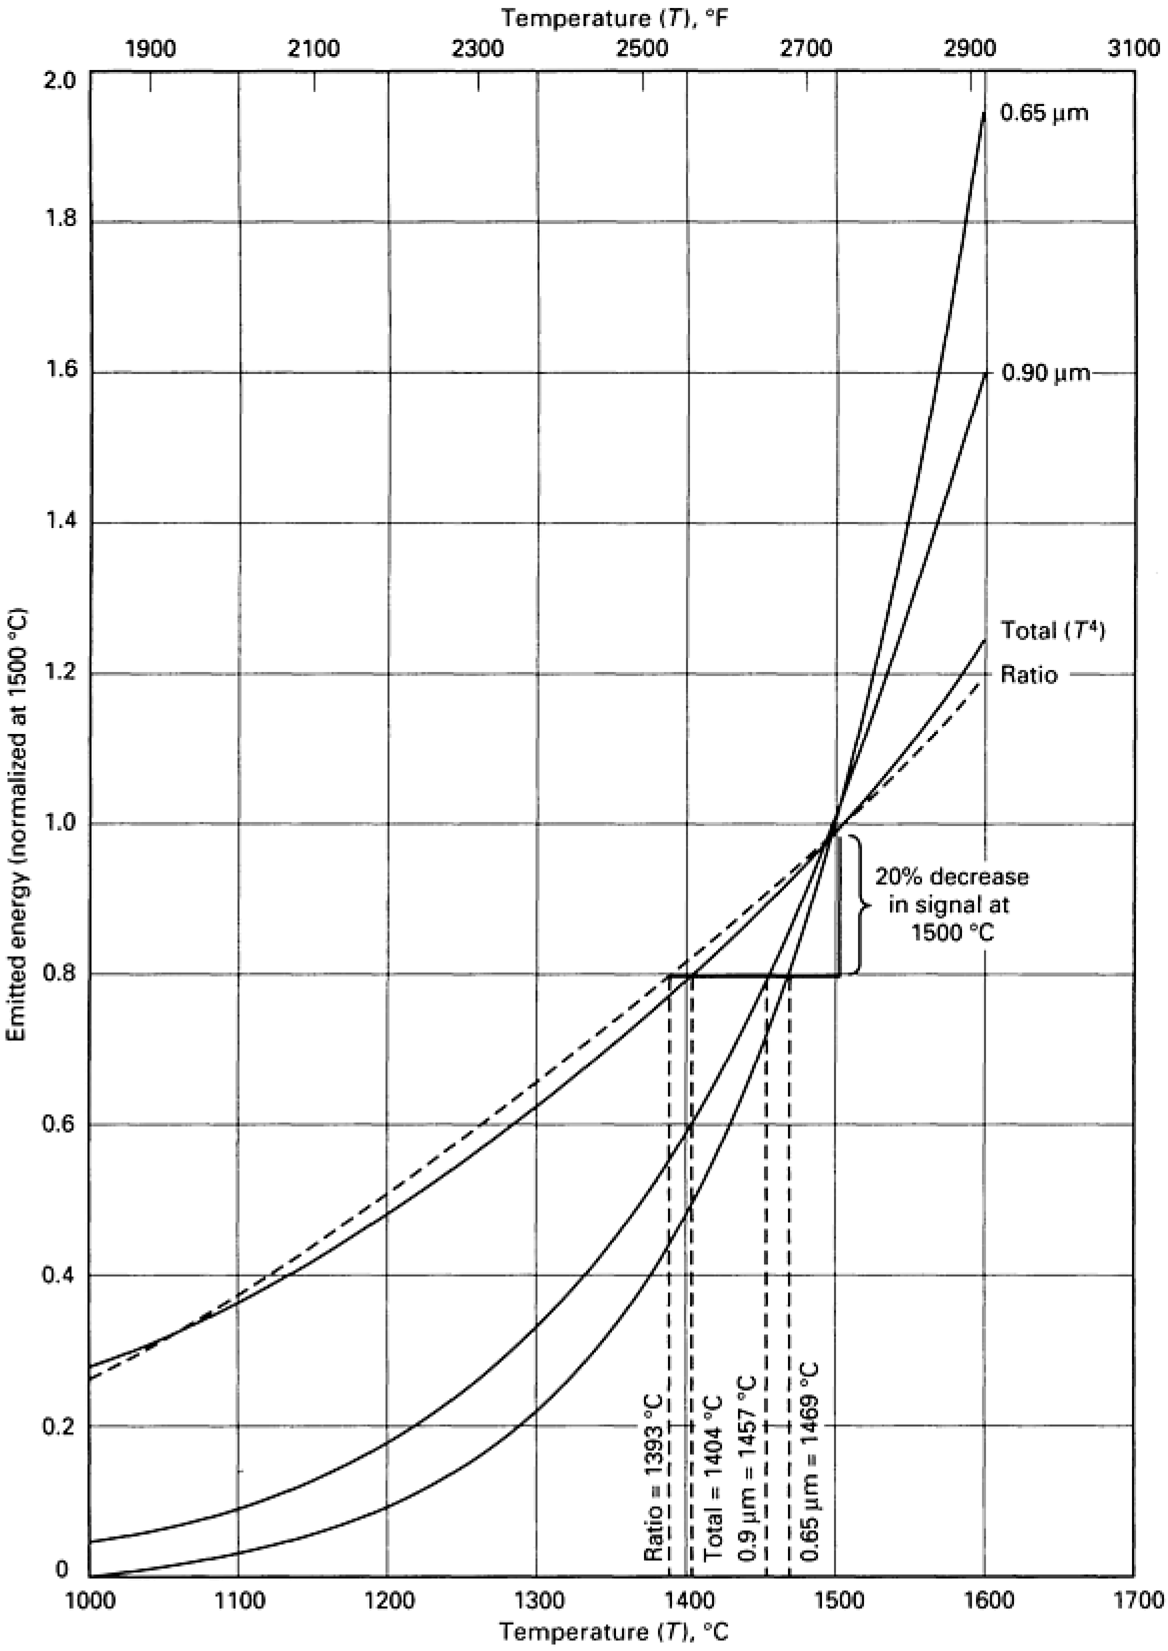

Fig. 11 Calibration curves of four thermometers with various spectral sensitivities

First, looking at the general shape of the four curves, it can be seen that the 0.65 μm curve rises most rapidly, which can also be inferred from the blackbody curves (Fig. 11), where it is seen that energy at short wavelengths increases most rapidly with increases in temperature; the 0.9 μm curve rises less rapidly than the 0.65 μm curve for the same reason; the

total radiation curve shows a weaker temperature dependence than the short-wavelength curves because most of the energy contributing to this curve comes from wavelengths longer than 0.65 or 0.9 μm, where temperature dependence is weaker; the ratio curve shows weak temperature dependence simply because it is the result of the two other curves (0.65 and 0.9 μm), which have very similar temperature dependences. (The apparent similarity between the ratio curve and the total radiation curve is coincidental and results from the specific choices of wavelengths and temperatures for this example.)

The effect of a 20% decrease in signal (or signal ratio for the ratio thermometer) from a 1500 °C (2730 °F) target should now be considered. Very simply, the results from thermometers with steeper calibration curves are affected less. The 0.65 μm and 0.9 μm thermometers show errors of 31 and 43 °C (56 and 77 °F), respectively, and the less-temperature-sensitive total and ratio thermometers exhibit errors of 96 and 107 °C (173 and 193 °F), respectively, for identical changes in signal. Such a signal change could result from an uncompensated 20% decrease in target emittance (at the shorter wavelength for the ratio thermometer), a 20% increase in absorptance (again at the shorter wavelength for the ratio thermometer), or some combination of the two. (In general, the performance of a properly chosen ratio thermometer is better than that indicated here because many interferences have a nearly equal effect in both wavelength regions.)

To summarize, using shorter wavelengths results in smaller errors from uncertainties in emissivity or absorptance. Selecting short wavelengths to minimize emissivity error is even more useful for bare metals in the open because the emissivities of most metals decrease with increases in wavelength. Exceptions to this rule are when choosing a shorter wavelength results in signals that are too small to be measured accurately, and when the target is surrounded by a hotter environment. In this latter case, energy reflected by the target from the hot environment to the thermometer will be richer in short-wavelength energy and may cause a larger positive error for a short-wavelength thermometer. This situation, an example of which is a soaking pit, cannot generally be solved with a single thermometer.

Measurement and Control Instruments

The various measurement and control loop configurations must function properly to achieve optimum operation of the system. Although the necessity of this coordination is obvious, one or more elements of the system are commonly neglected. For example, if the temperature sensor, which may be only 1% of the instrumentation cost, is out of calibration or not properly located, the performance of the complete system is degraded. Poor input into even the most sophisticated temperature measurement and control systems will produce poor output.

Measurement Instruments and Accuracy. The accuracy of the measurement depends greatly on the accuracy of the temperature sensor and the connecting circuitry. The accuracy of the measurement instrument is defined in its specifications under referenced conditions for its power supply, ambient conditions (temperature and humidity), electrical noise rejection, and maximum source impedance. Transmitters, which are used in some sensors to amplify and condition the temperature signal, have similar qualifications on their accuracy specifications.

Temperature measurement instruments incorporate reference junction compensation in their circuitry for thermocouple measurements and emissivity compensation for noncontact radiation sensors. Reference junction compensation automatically adjusts the measurement depending on the temperature at the junction between the thermocouple wire and the copper wire of the measuring circuit of the instrument. Radiation-type temperature measurements require an emissivity compensator. This compensator makes a calibration adjustment by comparing measurement of the same target with an optical pyrometer or calibrated thermocouple. The emissivity compensator is adjusted to make the radiation pyrometer measurement indication agree with the reference calibration instrument.

In the measurement area, the problem is always to make the sensor as sensitive as possible to the variable being measured and as insensitive as possible to changes in all other variables. Consequently, there will be more use of multiple sensors to compensate for systematic errors given by single sensors. For example, in a reheat furnace, the thermal radiation signal received from a target can be a combination of radiation emitted by the target plus radiation emitted by the furnace walls and reflected by the target. Using a second radiation thermometer to measure this wall contribution can yield superior results in such applications (Ref 8).

Single-Loop Control. A temperature controller should provide just enough energy to satisfy process requirements, even though operating conditions vary. Variations include changes in process load, fuel characteristics, and ambient temperature. Thus, controller requirements are more stringent when process requirements are demanding and especially when operating conditions vary significantly.

In operation, the controller set point that represents the desired temperature is compared with the process or actual temperature. The stability of the controller and its sensitivity to the difference between desired and actual temperatures are critical. Based on this comparison, the controller regulates the energy flow to the process.

The two basic types of control are the two-position, or on-off, type and the proportioning, or modulating, type. These two basic types exist in many variations.

On-off types of controllers are inexpensive, simple to operate, and easy to maintain. On-off types, however, use energy inefficiently and increase the cost of heater and brickwork maintenance, particularly when controlling high-temperature processes in which heat transfer lags are long. The process temperature cycles above and below the controller set point as the controller turns the heat input on and off. During start-up, the heat remains on until the temperature reaches the controller set point and then turns off. Consequently, the thermal inertia of the process, equipment, and work load, causes an overshoot beyond the set point, and energy is wasted.

After the temperature has stabilized in a characteristic on-off cycle, energy is still wasted because of the effects of heat transfer. Assuming that the temperature cycles are equally distributed above and below the controller set point, the average actual temperature will equal the set-point temperature. However, heat transfer losses or wasted energy, which result from losses above the set point, exceed the savings that result from temperatures below the set point. Thus, a net loss is produced, even though the average actual temperature is equal to the set point. These losses increase as operating temperature increases.

The magnitude of the temperature cycle, that is, the magnitude of the deviation from the set point, is directly related to the heat transfer characteristics and measuring lags of a particular process. Therefore, if the temperature measurement responds rapidly to changes in heat input, departure from the set point will be small. Conversely, when response is slow, substantial temperature deviations will result.

The effect of process demand on two-position (on-off) control is illustrated in Fig. 12. The curve in Fig. 12(a) shows that temperature cycles evenly above and below the set point. In other words, the heater on and off times are equal. Shown in Fig. 12(b) is the response for a higher process demand, such as more heat required to maintain a given temperature. In this case, the on time is greater. In the curve in Fig. 12(c) the temperature cycles are at a lower average value. The average value is higher than the set point. The curve in Fig. 12(d) shows the effects reversed for a lower process demand, which again brings the average to very near the set point. The relationship between heat supply, the controlled variable, and the set point at about one-half load conditions also is shown in Fig. 12(e).

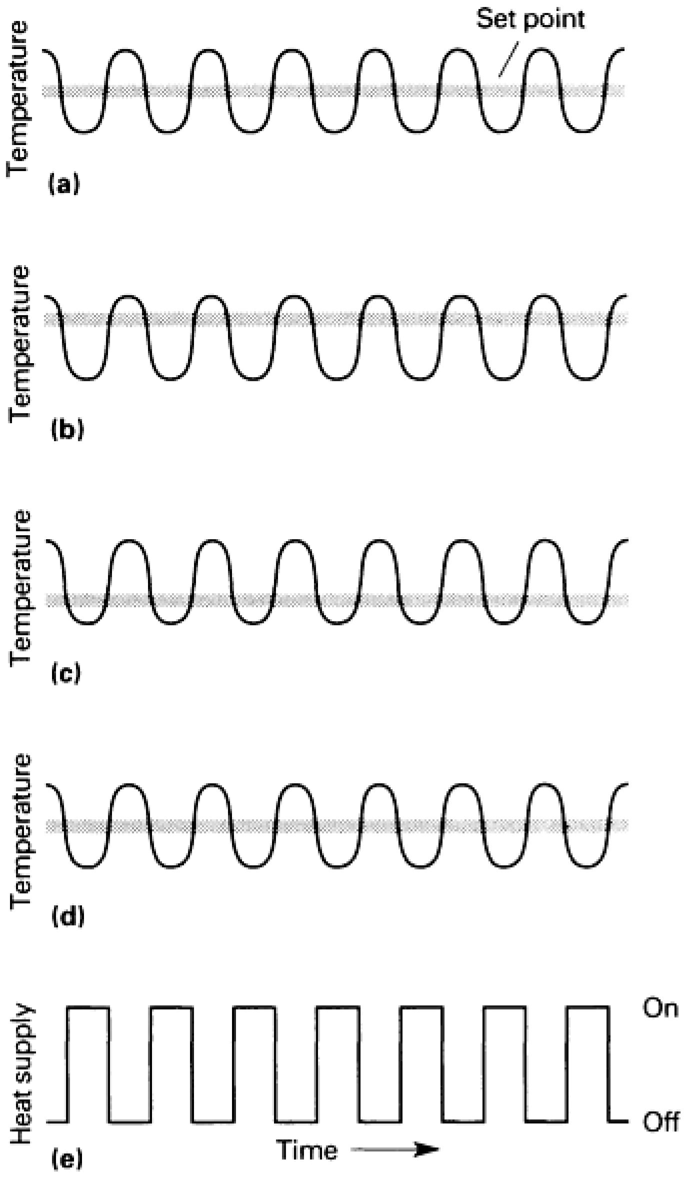

Fig. 12 Effect of process demand on two-position (on-off) control

Cyclic process temperatures cause cyclic process pressures in enclosed gas atmosphere furnaces and ovens. This condition can cause breathing, or inspiration of ambient air, resulting in additional energy losses.

In summary, on-off controllers have the advantage of low cost and simple installation. However, they should be considered only for relatively noncritical processes.

Proportioning or Modulating Controllers. When process temperatures are critical, or when large quantities of energy are consumed, proportioning control should be considered. Compared to on-off controllers, proportioning or modulating controllers are more expensive and sophisticated. They are less expensive to operate, however, because they use energy more efficiently. The process temperature is consistently maintained at the controller set-point temperature because the controller adjusts the heat input to match the heat demand of the process. Any changes in the process demand temperature will be matched by corresponding changes of the heat input to offset the temperature changes and maintain the desired temperature. Proportioning controllers can be designed to minimize or eliminate set-point overshoot, which is caused by the thermal inertia of the furnace and work load when the process is initially brought from ambient to operating temperature. Normally the process heat head, if not controlled, causes the temperature to overshoot.

The process-control response characteristics vary significantly for various processes. They even can vary for the same process when different operating conditions exist. For example, a furnace might be idled at 120 °C (250 °F) and operated at 1095 °C (2000 °F). The proportioning controller, in response to the error signal comparison (set-point temperature versus actual temperature), performs a computation to solve the control equation. This computation includes proportional, integral, and derivative terms; thus, the controller is referred to as a PID, or three-mode, controller. The proportional term is proportional band or gain, and its units are percent proportional band or gain. The integral term is reset, and its units are repeats per minute. The derivative term is rate, and its units are minutes. These tuning adjustments (proportional band, reset, and rate) match the controller response to the process dynamics. Proportional band relates to the size of the error signal. Reset relates to the error signal size plus the length of time it has existed. Rate relates to the error signal speed of change. Consequently, the controller, when properly tuned in response to these error-signal characteristics, continuously adjusts the energy input to the process to maintain the desired controller set-point temperature. A properly tuned proportional controller will reduce energy losses significantly by closely maintaining the desired temperature.

Proportional controllers, which are classified according to their outputs, include current-adjusting type (CAT), position-adjusting type (PAT), and duration-adjusting type (DAT). The CAT may be used with an electric power regulator, such as a silicon-controlled rectifier (SCR), to control electrically heated processes. It also can be used with an electropneumatic converter to regulate an air-operated valve. The PAT may be used with an electric motor drive unit to regulate a lever-operated valve. The DAT may be used with an electrical contactor, electric motor drive unit-valve combination, or solenoid-operated valve.

Typical applications include the use of a CAT controller to regulate an SCR. The SCR, in turn, regulates electrical power to heater elements in a furnace. A PAT controller typically is used with electric-motor drive to operate a valve on a gas-fired furnace. The DAT controller is used with an electric contactor to regulate electric power to heater elements. Electric contactors are less expensive than SCRs and are adequate for slow-response, high-temperature furnaces. DAT control also is used to operate gas valves on radiant tube-fired furnaces to achieve uniform heating throughout the tube.

The process temperature, even with PID control, tends to overshoot the control set point during start-up. This action is because of the system's thermal inertia. If the temperature sensor is of heavy construction, its slow response speed will compound this condition. A feature called Approach Action may be specified in the controller to minimize this problem, if the controller is properly tuned. This function also can be achieved with a feature called reset limiting.

Energy Flow Regulators. The final element of the control loop responds to the controller output by regulating the energy flow. It may consist of one or more components such as valves, dampers, power regulators, heater elements, converters, or actuators. Some desirable characteristics include fast response speed, linear response, high sensitivity, adequate power, and reliability. The final element should have a linear response over its full range; that is, a change in the final element should produce a corresponding change in temperature. The sizing of the valves, power regulators, and heaters should match the process requirements to optimize control performance. The final element may provide feedback devices, such as slidewires and limit switches, for use in the control system. The final element also may be designed to drive to a limit or to lock in its last position, in the event of a power failure.

Some final elements used with electric controllers are:

- An electric motor-valve combination used to regulate flow of steam or hot water
- An electric motor-valve-burner combination used to regulate fuel combustion
- Pneumatic valves used to regulate fuel; an electropneumatic converter used to convert the output signal from the controller
- Electrical resistance-type heating elements used with contactors, saturable core reactors, silicon-controlled rectifiers, and triacs

Design of the final element in any energy-efficient control system is extremely critical because it regulates the energy flow. For example, butterfly valves are frequently selected instead of proportioning valves because the butterfly valves cost less. However, their flow characteristics are nonlinear, which makes control over the entire range more difficult. In butterfly valves, a large flow change occurs near the closed valve position, and a small change occurs near the open position.

Data Acquisition. Traditionally, the day-to-day control of thermal processes has been enhanced by comparing present results with previous results and watching trends within a current run (batch or continuous) using traces printed by strip chart recorders. Besides this control aid, increasing emphasis is being placed by customers and quality control managers on statistical results and even on proof that a specific run, or even a specific piece, has experienced the right time-temperature treatment. To help manage this increasing data and results requirement, a class of powerful, microprocessor-based recorders has been developed. These instruments (Fig. 13) provide not only usual strip chart multipoint display of temperature as a function of time, they also calculate results (for example, averages of several thermocouple readings), print in a data logging format, indicate the occurrence of discrete events, and provide a variety of alarm functions.

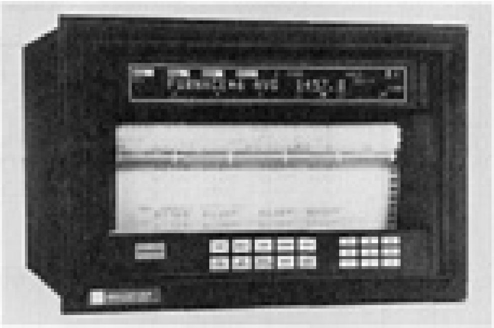

Fig. 13 A microprocessor-based recorder with control, analysis, and alarm function capabilities

Process Management Systems. As described earlier in the section "Auxiliary Devices," computer technology has allowed the development of small process management systems that integrate all the functions required to manage a heat-treat system. Process management systems provide a common database for all functions and allow the integration of analog loop control, discrete logic control, data acquisition, data management, statistical calculations, and reporting. Communications and interconnection are also by means of soft wiring, that is, by configuration and programming instead of physical hard wiring.

A further advantage is that while all system information is available at a central management station (consisting of a computer, keyboard and CRT screen, control, and data acquisition), other functions can be located in local processing units close to the process. This minimizes wiring costs on installation (or future upgrades in the installation) and maximizes reliability; even if communication to the central management station is severed, the local processing unit will continue to function following whatever predetermined course of action it has been configured to do in that situation. The capabilities of a process management system are described in more detail in Ref 9.

Distributed Control Systems (DCSs). When a process control requirement reaches a certain size, the capabilities of a DCS are needed. The main capabilities that a DCS might hold over a minicomputer process management system are size (the number and types of analog and discrete inputs and outputs the system can handle), speed, redundancy (reliability), ease of configuration, graphics available, or complexity of calculations or control algorithms. In general, if there are only a few control loops with little action required between loop (analog) and logic (discrete) control, and if recorders will suffice for the data acquisition, a hardwired interconnection system should be considered. When the number of control loops has grown from 10 to 100, when integral control of loop and logic functions or calculations are required, and when downloading of many different process recipes is required, a minicomputer process management system, at least, will probably be chosen. A DCS is appropriate for even larger processes, the integration of many processes, or where special reliability capabilities are required. One special capability of some present DCSs is full redundancy with doubly redundant fiber-optic communication networks among the components of the system. These fiber-optic links allow the system to be distributed over several miles of a large plant.

Characteristics of Process, Product, and Production

A control system regulates the energy input to the process to achieve desired heating and cooling rates and maintains soak temperatures by matching heat input to heat losses. If these heat losses were always constant, a preset heat supply could keep temperature in balance indefinitely.

In practice, this never happens. Furnaces must be started up, idled, and operated at varying production rates and temperatures.

To handle such changes efficiently, control systems must constantly readjust heat input so that the work temperature is maintained despite changing operating conditions.

Two principal characteristics of the instrumentation and the process equipment influence the selection of a control system, lag and thermal inertia.

In a heat-treating furnace, refractory, muffles, or retorts through which the heat must flow represent heat barriers. The greater their number, the greater the heat transfer resistance or lag, with the result that there is a longer delay between the heat input change and a change in product temperature. After this mass is heated--refractory, muffles, retorts--thermal inertia is a consideration.

The thermal inertia of a process is its capacity to continue a temperature change in the same direction after the heat supply is altered, before it begins to move in the opposite direction. The time it takes to turn a process around determines the extent of its thermal inertia. A furnace with a large, heavy muffle has a high heat storage capacity. Heat heads build up rapidly during heat input periods, and the momentum from the latent heat continues to push product temperature up after the heat is turned off. The converse is also true: Product temperature continues to drop after the heat is turned on. In short, the furnace is sluggish, and the temperature swings are wide and slow.

In addition to the resistance to heat transfer and the thermal inertia of the product and process equipment, there are five characteristics of the product to be considered in the selection of a temperature control system. The first characteristic of the product is its state. This is important in deciding the degree of acceptable temperature tolerances. For example, a solid product such as steel or a ceramic may have a temperature tolerance of ±3, 6, 8 °C (±5, 10, 15 °F), or even more.

The second characteristic concerns the material of the product, that is, whether it is ferrous or nonferrous. Most nonferrous and high-alloy steel products have temperature tolerances of ±3 or 6 °C (±5 or 10 °F). On the other hand, low-carbon steel and other ferrous metals may have a temperature tolerance of ±8 to 14 °C (± 15 to 25 °F).

The third characteristic--assuming the furnace is properly designed for the job--is the mass and shape of the product. This determines the responsibility the control system must assume for uniform heat penetration. The mass and shape of a large roll of steel influences the selection of not only the furnace design but also the control system required to maintain uniform heat from top to bottom and side to side.

The fourth characteristic of the product is its critical temperature. As the temperature of the product approaches its critical temperature, the more accurate and responsive must be the control system.

The fifth and last characteristic of the product is the quality of the product after heating. In heat treating, for example, the effect of furnace atmosphere varies with temperature. Oxidation and carburizing occur faster at higher temperatures. For parts of uniform quality, temperature must be held uniformly throughout the furnace load.

Furnace Atmospheres for Heat Treating

Revised by Paul Johnson, National-Standard Company

Introduction

CONTROL OF FURNACE ATMOSPHERES has become increasingly critical to successful heat treating with more precise metallurgical specifications. The prevention of surface oxidation or scaling when metals are exposed to elevated temperatures remains an important task of the furnace atmosphere. In a more sophisticated view, the atmosphere within the furnace chamber is a full-fledged partner in achieving the chemical reactions that occur during heat treating.

Properly applied and controlled, furnace atmospheres provide the source of elements in some heat-treating processes, surface cleansing of parts being treated in other processes, and a protective environment to guard against adverse effects of air when metals are exposed to elevated temperatures in still other processes.

Practical Flow Formula

Control of the flow of gases through a furnace chamber is important to ensure that sufficient atmosphere gas is being admitted to the furnace to seal the mechanical leaks against air infiltration or that a vestibule is being purged rapidly enough. In common practice, a chamber is considered essentially purged after five volume changes.

The simple way to adjust atmosphere flow to a furnace is through a meter that can be read directly. In some instances, however, atmosphere distribution among various inlets is required even though total atmosphere flow is metered. Flow rate is a function of the volume of a furnace chamber and time. A practical flow formula that is sufficiently accurate to deal with furnace atmosphere flows is as follows:

$$Q = 1651.25 \times A \times C \times \sqrt{h/d} \qquad \textbf{(Eq 1)}$$

where Q is flow rate, in ft^3/h; A is area of orifice, in $in.^2$; C is coefficient of discharge; h is differential pressure, and d is specific gravity of the gas.

For a thin-plate orifice in this equation, $C = 0.61$; for spuds with a tapered entrance, $C = 0.95$; and for spuds used in reverse (tapered outlet), $C = 0.9$.

Fundamentals of Gases

Gas molecules are somewhat widely separated, and they move about unceasingly in the space in which they are contained. Gases differ from liquids in two respects; gases are highly compressible and they fill any closed vessel in which they are placed. Gases resemble liquids in that both are capable of:

- Flowing
- Exerting pressure upon surfaces they contact
- Exhibiting flow velocity that can be measured through an orifice

Although there is no clear distinction between gases and vapors, the term vapor usually is applied to a gas that is near its liquefying temperature. Steam and carbon dioxide usually are called vapors because they are easy to liquefy. Air, hydrogen, and nitrogen ordinarily are called gases.

Gas Pressure. The characteristic of compressibility of gases leads to a very simple relationship between the pressure of a gas and its volume. The relationship is known as Boyle's law: The volume of a confined body of gas varies inversely as the absolute pressure, provided the temperature remains unchanged.

The pressure of confined gases can be measured by U-shaped manometer tubes containing mercury or other liquids. The gas whose pressure is to be measured is connected to one side of the manometer, and the other leg of the tube remains open. Pressure exerted by the gas will force the liquid up the leg open to the atmosphere. The difference in height of the liquid in the two columns multiplied by the density of the liquid indicates how much the gas pressure exceeds atmospheric pressure. This pressure is known as gage pressure, to distinguish it from absolute pressure, which includes the pressure of the atmosphere.

Diffusion. When two or more closed vessels, originally containing different gases, are joined so that each gas has access to all containers, and assuming no chemical reaction takes place, molecular motion causes each gas to penetrate the entire volume of all containers. By this diffusion, the mixture eventually becomes homogeneous. Each gas expands into the total available volume as though the other gas were not present. According to Boyle's law, the absolute pressure of each gas is reduced to a lower value called its partial pressure. The pressure of the resulting mixture of gases will be equal to the sum of the partial pressures of the constituent gases. This phenomena is expressed as Dalton's law: A mixture of several gases that do not react chemically exerts a pressure equal to the sum of the pressures that the several gases would exert separately if each were allowed to occupy the entire space alone at the given temperature.

Avogadro's law states: At the same temperature and pressure, equal volumes of different gases contain equal numbers of molecules. When this law is applied to a particular quantity of a gas, the quantity is known as a mole (abbreviated mol), or gram-molecule, or gram-molecular weight. The mole of a substance is a mass in grams numerically equal to the sum of the atomic weights of the atoms in a molecule of that substance. The number of molecules in a mole of gas is known as Avogadro's number. A mole of any gas contains 6.02×10^{23} molecules, and at 0 °C (32 °F) and standard atmospheric pressure of 760 mm (100 kPa) mercury, or sea level pressure, occupies 22.4 L (0.79 ft^3) of space.

Density. The density of a gas is the amount of mass contained in a unit volume, and the density is influenced by pressure and temperature. The density and pressure increase in the same proportion, and gases expand when heated and contract when cooled. The density of air has been determined with great care. One liter (0.038 ft^3) of air at standard temperature and pressure weighs 1.293 g (0.04561 oz), or an air density of 1.3 kg/m^3 (0.081 lb/ft^3). The specific gravity of a gas is normally expressed with reference to air as standard (Table 1).

Table 1 Properties of common gases and vapors

Gas	Chemical symbol	Approximate molecular weight	Density[(a)]		Specific gravity[(b)]
			kg/m^3	lb/ft^3	
Air	. . .	28.97[(c)]	1.293	0.0807	1.000
Ammonia	NH_3	17.03	0.760	0.0474	0.588
Argon	Ar	39.95	0.178	0.0111	1.380
Carbon dioxide	CO_2	44.02	1.965	0.1228	1.520
Carbon monoxide	CO	28.01	1.250	0.0780	0.967
Helium	He	4.00	0.179	0.0112	0.138
Hydrogen	H_2	2.02	0.090	0.0056	0.070
Methane	CH_4	16.04	0.716	0.0447	0.552
Nitrogen	N_2	28.01	1.250	0.0780	0.968
Oxygen	O_2	32.00	1.429	0.0892	1.105

Propane	C_3H_8	44.09	1.968	0.1229	1.522
Sulfur dioxide	SO_2	64.06	2.860	0.1785	2.212

(a) Standard temperature and pressure: 0 °C (32 °F) and 760 mm Hg.

(b) Relative density compared to air.

(c) Because air is a mixture, it does not have a true molecular weight. This is the average molecular weight of its constituents.

Viscosity. Molecular friction, or viscosity, is present in gases as well as in liquids, although the wide spacing of the molecules results in appreciably lower viscosity in gases. This friction retards the motion of gases through such channels as tubes and ducts. The coefficients of viscosity for gases and liquids are expressed in poise or centipoise. A rise in temperature causes a rise in the viscosity of gases and a lowering of liquid viscosity.

Temperature Effect. Charles's law states: The volume of a fixed mass of gas and its pressure vary directly with the absolute temperature.

Using the effect of temperature, a general gas law can be written in the form of a mathematical equation, as follows:

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2} \qquad \textbf{(Eq 2)}$$

where P is absolute pressure, V is volume of a fixed mass, T is absolute temperature, and subscripts 1 and 2 are two different sets of conditions of pressure, volume, and temperature.

When a furnace atmosphere is required to contribute an element or elements during heat treating, these fundamental gas laws become important. Many forms of control are used to develop carbon potential, or the potential of an element, within an atmosphere. Differing amounts of an element can be utilized in the heat-treating chemical reaction, with a constant potential reflected. A quantitative measure of an element is developed by an understanding of the chemical formula involved in the reaction and the partial pressures of the formula gases used to produce the element.

Principal Gases and Vapors

Air is an important gas in furnace atmospheres because it comprises the atmosphere in a furnace in which no protective atmosphere is used, and because it is a major constituent in many prepared atmospheres. The chemical makeup of air is approximately 79% nitrogen and 21% oxygen, with trace amounts of carbon dioxide. As an atmosphere, air behaves like an oxygen atmosphere because oxygen is the most reactive constituent in air.

Oxygen reacts with most metals to form oxides. In addition, oxygen reacts with carbon that is dissolved in steel to lower the carbon content of its surface.

Nitrogen. Molecular nitrogen is passive to ferrite and is entirely satisfactory for use as an atmosphere in the annealing of low-carbon steels; however, it must be completely dry to be used as a protective atmosphere for high-carbon steels because small amounts of water vapor in the nitrogen will cause decarburization. Molecular nitrogen is reactive with many stainless steels and cannot be used in their heat treatment. Atomic nitrogen (created by the temperatures of normal heat treating) is not a protective atmosphere because it combines with iron to form finely divided nitrides that impart hardness to the surface.

Carbon Dioxide and Carbon Monoxide. These two gases are important in atmospheres used in processing steel. At austenitizing temperatures, carbon dioxide reacts with surface carbon in a steel surface to produce carbon monoxide:

$$(C) + CO_2 \text{ € } 2CO \qquad \textbf{(Eq 3)}$$

in which (C) represents carbon dissolved in austenite. This reaction continues until there is no carbon dioxide available or until the steel surface is completely free of carbon--at which point, if there is a continuing supply of carbon dioxide, iron and ferrous oxide will be oxidized by the following reactions:

$$Fe + CO_2 \text{ € } FeO + CO \qquad \textbf{(Eq 4)}$$

$$3FeO + CO_2 \text{ € } Fe_3O_4 + CO \qquad \textbf{(Eq 5)}$$

Ferrous oxide (FeO) is the stable oxide formed above 555 °C (1030 °F), whereas the magnetic oxide (Fe_3O_4) is formed below 555 °C (1030 °F) as shown in Fig. 1.

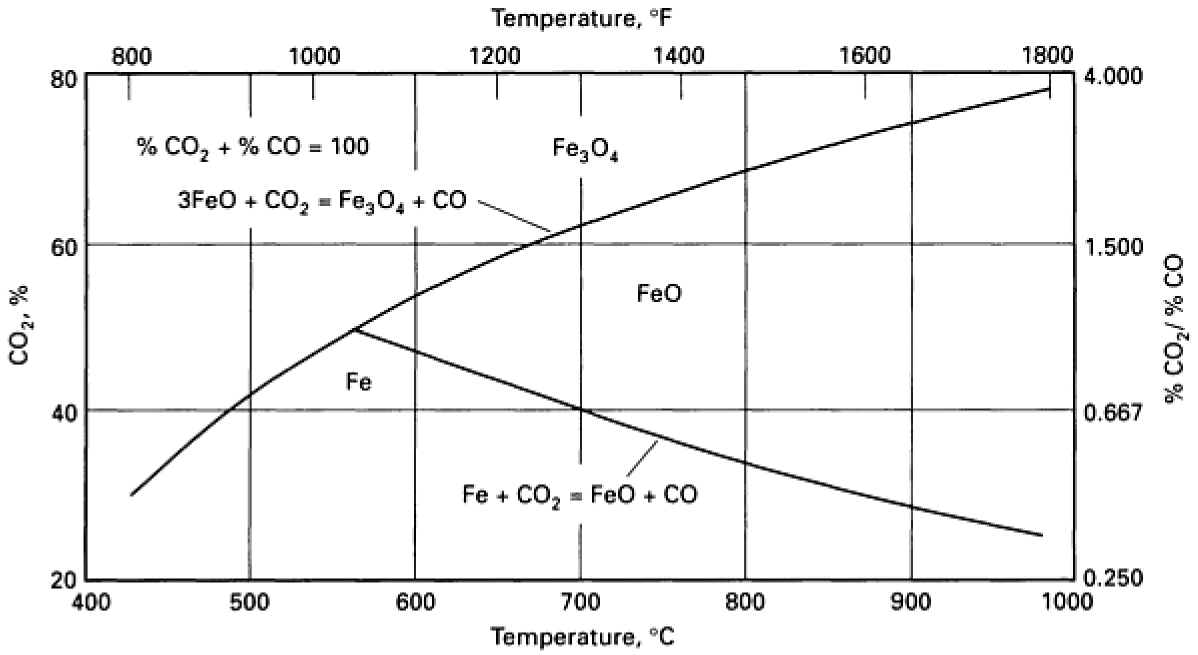

Fig. 1 Equilibrium curves for the formation of scale (FeO and Fe_3O_4) when heating iron in a CO-CO_2 atmosphere at different temperatures

The above reactions will proceed until equilibrium is established. These reactions progress at a rate depending on time, temperature, and pressure of the system. The equilibrium conditions for carbon steels of various carbon concentrations heated in a CO-CO_2 atmosphere are shown in Fig. 2.

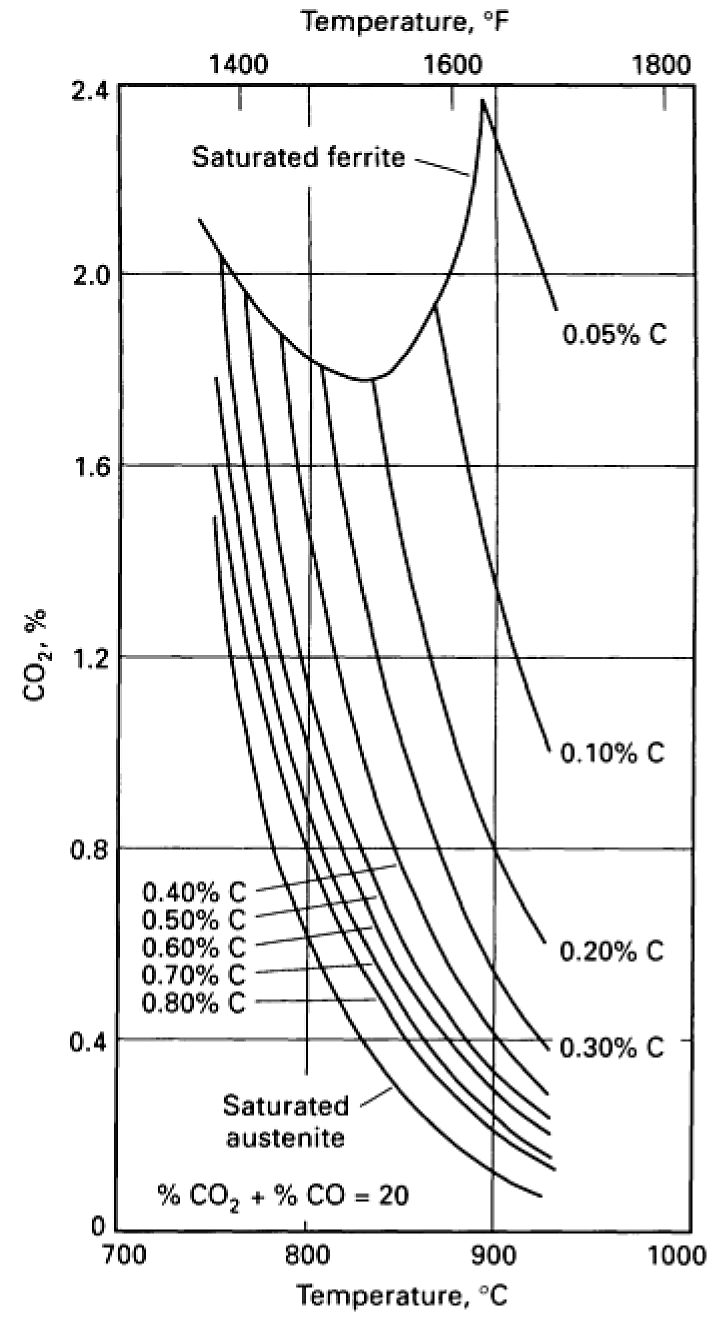

Fig. 2 Temperature and percentage of carbon dioxide for equilibrium conditions with carbon steels of various carbon contents

Hydrogen reduces iron oxide to iron. Under certain conditions, hydrogen can act to decarburize steel. The decarburizing effect of hydrogen on steel depends on furnace temperature, moisture content (of the gas and furnace), time at temperature, and carbon content of the steel. The decarburizing effect of hydrogen at 705 °C (1300 °F) or below is negligible, but it increases markedly above this temperature. Water vapor increases the decarburizing effect because it dissociates, thus providing a supply of nascent hydrogen and oxygen. Hydrogen reacts with carbon in steel to form methane:

$$(C) + 4H \rightleftharpoons CH_4 \quad \textbf{(Eq 6)}$$

Oxygen reacts with carbon in steel to form carbon monoxide as follows:

$$(C) + O \text{ € } CO \qquad \textbf{(Eq 7)}$$

Even a low-dew-point hydrogen atmosphere has some decarburizing effect, particularly on high-carbon steels because of the ability of the gas, even when it is not in the nascent condition, to react with carbon:

$$(C) + 2H_2 \text{ € } CH_4 \qquad \textbf{(Eq 8)}$$

Obviously, the decarburizing potential of hydrogen in either form is markedly influenced by the carbon content of the steel and may be expected to increase directly with the increase of carbon content.

Water vapor is oxidizing to iron:

$$Fe + H_2O \text{ € } FeO + H_2 \qquad \textbf{(Eq 9)}$$

and combines with carbon in steel to form carbon monoxide and hydrogen:

$$(C) + H_2O \text{ € } CO + H_2 \qquad \textbf{(Eq 10)}$$

It is reactive to steel surfaces at very low temperatures and low partial pressures. It is a principal cause of blueing during cooling cycles.

The effect of water vapor on the oxidation of iron at various temperatures is indicated by the equilibrium curves shown in Fig. 3.

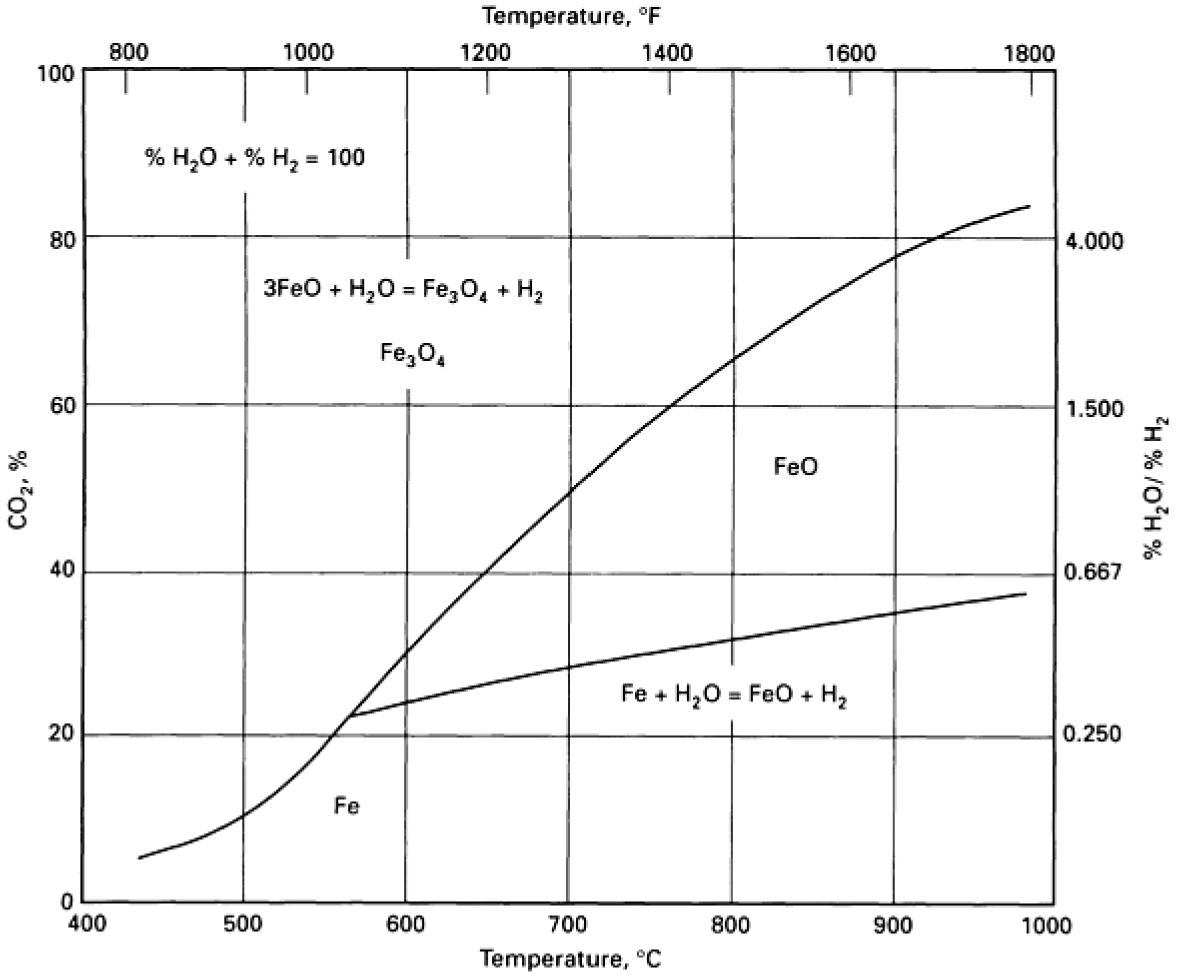

Fig. 3 Equilibrium curves for the formation of scale (FeO and Fe_3O_4) when heating iron in a H_2-H_2O atmosphere at different temperatures

Hydrocarbons. The most common hydrocarbon gases added to or found in furnace atmospheres are methane (CH_4), ethane (C_2H_6), propane (C_3H_8), and butane (C_4H_{10}). These gases impart a carburizing tendency to a furnace atmosphere. The chemical activity in reacting with the surface of hot steel depends on their thermal decomposition and their tendency to form nascent carbon at the steel surface, and on the temperature of the furnace chamber and work load. Thermal decomposition results in formation of soot in amounts proportional to the number of carbon atoms in the hydrocarbons; therefore, butane and propane are more likely to cause soot in the furnace chamber than are ethane and methane.

Inert Gases. The inert gases of argon and helium are frequently used during the thermal processing of reactive metals and alloys of these metals. Argon, approximately half the cost of helium, is generally favored. Because helium sources are limited, the price of helium is more dependent on end-use location than is argon.

Air contains approximately 0.93% argon by volume. Argon is recovered by liquefying air followed by the fractionation of liquid air. Helium is recovered by similar cryogenic methods from natural gas deposits found in the western United States. A limited number of deposits in the United States and Mexico contain 1 to 8% helium. Because of the low density of helium (0.179×10^{-3} g/cm^3, or 6.47×10^{-6} lb/in.^{3}, at 20 °C, or 70 °F), much of the helium released into the atmosphere is permanently lost beyond the atmosphere of the earth. As a result of this loss, the future supply of helium is threatened.

Protective atmospheres of inert gases are particularly useful during thermal processing of metals and alloys that cannot tolerate the usual constituents of other protective atmospheres. Two applications of inert gases are as protective atmospheres during the bright hardening of stainless steels, and the heat treatment of titanium alloys. Oxygen and water vapor must be avoided during the bright hardening of stainless steels. Oxygen content of less than 0.01% and dew points

below -50 °C (-60 °F) are essential. Titanium alloy heat treatments require atmospheres free of hydrogen, oxygen, and carbon-bearing gases.

Caution: Careful consideration should be given to the residual entrapment of inert gases and nitrogen. When human entry into vessels and chambers is a function of operation or maintenance, special precautions are recommended. Although these gases are not toxic, asphyxiation can occur in entrapped areas. Being odorless and colorless, inert gases and nitrogen are not readily recognized as dangerous.

Helium and nitrogen can be trapped in overhead chambers of bottom-loaded furnaces, and argon and nitrogen can be trapped in vertical top-loaded furnaces. Agitation and flushing with air is recommended before entry. Other appropriate safety procedures may also be beneficial.

Furnace Atmosphere Gas Reactions

Flue gases in a direct-fired furnace are the effluent products created by combustion of hydrocarbon fuel. The composition of these gases inside a furnace contains a mixture of some, or all, of the following principal components: carbon dioxide, carbon monoxide, hydrogen, oxygen, nitrogen, and water vapor.

When burners are adjusted to operate with an excess of combustion air, the products of incompletely burned fuel, carbon monoxide, and hydrogen, are minimized, but measurable amounts of residual oxygen remain. Conversely, burners operating with a combustion-air deficiency consume all of the available oxygen before complete burning of the fuel. In this case, resultant oxygen is minimized, and measurable quantities of unburned carbon monoxide and hydrogen remain. Under all conditions, substantial quantities of water vapor are produced by the combustion.

Other major factors that may materially affect the overall flue-gas furnace atmosphere are burner efficiency, tightness of the furnace and size of the door openings. The openings contribute to the rate of possible air infiltration and the amount of oxygen present. Moreover, furnaces that are equipped with multiple burners may be operating with various air-fuel ratios that can produce a mixed atmosphere of unpredictable composition.

When flue gases contain excess oxygen along with water vapor and carbon dioxide, the oxidizing potential promotes rapid formation of loose scale on steel. Air-deficient burner operation produces much less oxygen and greater amounts of carbon monoxide and hydrogen, which are reducing constituents that can cause steel surface decarburization. Carbon dioxide and water vapor, in this instance, promote formation of a tight oxide that is not easily removed. In both instances, the amount of scale formation is a function of furnace temperature and the amount of time material is held at temperature.

Although a direct-fired furnace cannot be expected to provide a completely neutral atmosphere, specially designed direct-fired furnaces with closely controlled burner systems and specific time/temperature process cycles are capable of cost-efficient heat treating and heat processing for a variety of applications with fully acceptable results.

Carbon Dioxide Plus Hydrogen. Hydrogen will react with either carbon dioxide or oxygen to form water vapor. Water vapor has a high oxidizing potential or decarburizing potential for steel and must be controlled in a furnace atmosphere.

Water Gas Reaction. The reactions listed below by which steel or iron is oxidized at elevated temperatures are irreversible and cannot be controlled:

$$2Fe + O_2 \rightarrow 2FeO \qquad \textbf{(Eq 11)}$$

$$4Fe + 3O_2 \rightarrow 2Fe_2O_3 \qquad \textbf{(Eq 12)}$$

$$3Fe + 2O_2 \rightarrow Fe_3O_4 \qquad \textbf{(Eq 13)}$$

Other oxidizing gas-metal reactions, however, are reversible and can be controlled, and hence may be employed to advantage. In the reactions:

$$Fe + H_2O \rightleftharpoons FeO + H_2 \qquad \textbf{(Eq 14)}$$

$$Fe + CO_2 \text{ € } FeO + CO \quad \textbf{(Eq 15)}$$

water vapor and carbon dioxide are oxidizing gases, and hydrogen and carbon monoxide are reducing gases. Ultimately, the quantity of reducing gas or oxidizing gas formed may become great enough for one to cancel the effects of the other. By proper control of these reactions, a neutral, reducing, or oxidizing effect may be produced.

The opposing reactions may be controlled according to the water gas reaction, which is as follows:

$$CO + H_2O \text{ € } CO_2 + H_2 \quad \textbf{(Eq 16)}$$

The gases that enter into the water gas reaction react with the surface of steel to cause oxidation or reduction, depending on the equilibrium condition corresponding to the temperature and composition of the system.

At 830 °C (1525 °F), the oxidizing potentials of carbon dioxide and water vapor are equal, and the reducing potentials of carbon monoxide and hydrogen are equal. At this temperature, therefore, the equilibrium constant of the water gas reaction has a value of unity. Above 830 °C (1525 °F), carbon dioxide is a stronger oxidizing agent than water vapor, and hydrogen is a stronger reducing agent than carbon monoxide. Below 830 °C (1525 °F), the reverse is true. Consider the reactions:

$$C + CO_2 \rightarrow 2CO \quad \textbf{(Eq 17)}$$

$$CO + H_2O \text{ € } CO_2 + H_2 \quad \textbf{(Eq 18)}$$

$$C + H_2O \text{ € } CO + H_2 \quad \textbf{(Eq 19)}$$

and their equilibrium constants, which are, respectively:

$$K_1 = \frac{[CO_2]}{[CO]^2} \quad \textbf{(Eq 20)}$$

$$K_2 = \frac{[CO][H_2O]}{[CO_2][H_2]} \quad \textbf{(Eq 21)}$$

$$K_3 = \frac{[H_2O]}{[CO][H_2]} \quad \textbf{(Eq 22)}$$

Calculations for the data in Table 2 were developed, assuming that the hydrogen content of the system remains constant at 40% and the CO + CO_2 content remains constant at 20%. Figure 4 shows the equilibrium conditions for steels with carbon concentrations from 0.10 to 1.20%.

Table 2 Variation of equilibrium constants, composition, and dew point of an H_2-H_2O-CO-CO_2 system

The hydrogen content is assumed to remain constant at 40% and the CO + CO_2 content is assumed to remain constant at 20%.

Temperature		Equilibrium constants			Composition, %		Dew point	
°C	°F	K_1	K_2	K_3	CO_2	H_2O	°C	°F
650	1200	3.770	0.51	1.922	4.5	4.5	+32	+90
705	1300	0.942	0.66	0.695	2.6	3.4	+24	+75

760	1400	0.348	0.83	0.363	1.2	2.0	+18	+65
815	1500	0.125	1.02	0.127	0.5	1.02	+7	+45
870	1600	0.050	1.22	0.061	0.2	0.49	-3	+27

$$\% H_2 = 40$$

$$\% CO_2 + \% CO = 20$$

$$\% H_2O = K \times \% H_2 \times \frac{\% CO_2}{\% CO}$$

$$\text{Dew point} = T - 459.6$$

$$\% H_2O = 10^{8.0615 - \frac{407}{T}}$$

Fig. 4 Dew point for equilibrium conditions with carbon steel of various carbon concentrations

Ammonia Vapor. Ammonia dissociates in the endothermic reaction:

$$2NH_3 \rightarrow N_2 + 3H_2 \qquad \textbf{(Eq 23)}$$

with the dissociated ammonia containing 75% hydrogen and 25% nitrogen. Dissociation occurs when ammonia vapor is heated and passed over the proper catalyst. Dissociated ammonia then is cooled and often passed through a purifying molecular-sieve absorption system to remove undissociated ammonia and water vapor.

Ammonia vapor also may be used as an additive to suitable carbon-bearing carrier atmospheres for carbonitriding, or it may be used directly for nitriding processes. In these instances, partial ammonia dissociation occurs inside the furnace, allowing nitrogen to react with heated steel surfaces to form hard nitrides.

Lithium Vapor. Lithium vapor reacts with water vapor in the furnace atmosphere to form lithium oxide and hydrogen:

$$2Li + H_2O \rightarrow Li_2O + H_2 \qquad \textbf{(Eq 24)}$$

Lithium vapor also combines with any free oxygen present in the furnace atmosphere to form lithium oxide:

$$4Li + O_2 \rightarrow 2Li_2O \qquad \textbf{(Eq 25)}$$

The lithium oxide formed by these reactions oxidizes some of the carbon monoxide present in the atmosphere, causing the release of a certain amount of lithium:

$$2Li_2O + CO \rightarrow Li_2CO_3 + 2Li \qquad \textbf{(Eq 26)}$$

The lithium liberated can then pick up more oxygen.

The practical application of this vapor as a furnace atmosphere has been in forging furnaces as a protection against scaling of the surface of steel heated to forging temperature.

Sulfurous Gases. Sulfurous gases in a furnace atmosphere are basically deleterious and are to be avoided. These gases result from the presence of sulfur compounds in industrial fuels, furnace refractories, and cutting oils on work being processed.

Sulfur compounds occur as hydrogen sulfide (H_2S); sulfur dioxide (SO_2), or sulfur trioxide (SO_3); mercaptans; thiophene (C_4H_4S); and metallic sulfates. When sulfur is present in reducing atmospheres, it is generally found as hydrogen sulfide from the following reaction:

$$SO_2 + 3H_2 \rightleftharpoons H_2S + 2H_2O \qquad \textbf{(Eq 27)}$$

$$C_4H_4S + 6O_2 \rightarrow 4CO_2 + 2H_2O + SO_2 \qquad \textbf{(Eq 28)}$$

$$2SO_2 + 3Fe + 2Ni \rightarrow Fe_2O_3 + NiS + NiO + FeS \qquad \textbf{(Eq 29)}$$

When sulfur is present in atmospheres in which high-nickel steels are heated, both nickel sulfide and nickel oxide are formed, and an alligator surface results. In addition to damaging parts being treated, this effect accelerates the failure of high-nickel, high-chromium, heat-resistant alloy furnace parts, trays, and fixtures. In general, the presence of sulfur in a furnace atmosphere accelerates the rate of scaling, and this rate increases as temperature increases.

Classifications of Prepared Atmospheres

Most prepared atmospheres are commonly referred to in the field by their generic names, or, in some instances, by trade names. The American Gas Association has classified the commercially important prepared atmospheres into six groups on the basis of method of preparation or on the original constituents employed. These groups are designated and defined as follows:

- *Class 100, exothermic base:* Formed by partial or complete combustion of a gas-air mixture; water vapor may be removed to produce a desired dew point
- *Class 200, prepared nitrogen base:* An exothermic base with carbon dioxide and water vapor removed
- *Class 300, endothermic base:* Formed by partial reaction of a mixture of fuel gas and air in an externally heated catalyst-filled chamber
- *Class 400, charcoal base:* Formed by passing air through a bed of incandescent charcoal
- *Class 500, exothermic-endothermic base:* Formed by complete combustion of a mixture of fuel gas and air, removing water vapor, and re-forming the carbon dioxide to carbon monoxide by means of reaction with fuel gas in an externally heated catalyst-filled chamber
- *Class 600, ammonia base:* This can consist of raw ammonia, dissociated ammonia, or partially or completely combusted dissociated ammonia with dew point regulated

These broad areas of classification are subclassified and numerically designated to indicate variations in the method by which they are prepared. This subclassification is differentiated by replacing the two zeros of the six basic designators by one of the following two-digit numbers that indicate some special preparation of the furnace atmosphere:

- *01:* Use of a lean air-gas mixture
- *02:* Use of a rich air-gas mixture
- *03 and 04:* Preparation of the gas was completed within the furnace itself without the use of a separate machine or generator
- *05 and 06:* Original base gas was subsequently passed through incandescent charcoal before admission to the work chamber
- *07 and 08:* Addition of a raw hydrocarbon fuel gas to the base gas before admission to the work chamber
- *09 and 10:* Addition of a raw hydrocarbon fuel gas and raw dry anhydrous ammonia to the base gas before admission to the work chamber
- *11 and 12:* Addition of a combusted mixture of chlorine, hydrocarbon fuel gas, and air to the base gas before admission to the work chamber
- *13 and 14:* Base gas has had all sulfur or all sulfur and odors removed before admission to the work chamber
- *15, 16, 17, and 18:* Addition of lithium vapor to the base gas before admission to the work chamber
- *19 and 20:* Preparation of the gas was completed within the furnace itself with the addition of lithium vapor
- *21 and 22:* Some additional special treatment was given to the base gas before admission to the work chamber
- *23 and 24:* Addition of steam and air in conjunction with a catalyst within the generator to convert CO to CO_2, which is then removed
- *25 and 26:* Addition of steam in conjunction with a catalyst within the generator to convert CH_4 to H_2 and CO_2, which is then removed

This classification system provides for a large number of possibilities. In practice, only a few of the possible atmosphere classifications are industrially important. Table 3 lists significant furnace atmospheres and typical applications.

Table 3 Classification and application of principal furnace atmospheres

Class	Description	Common application	Nominal composition, vol%				
			N_2	CO	CO_2	H_2	CH_4
101	Lean exothermic	Oxide coating of steel	86.8	1.5	10.5	1.2	. . .
102	Rich exothermic	Bright annealing; copper brazing; sintering	71.5	10.5	5.0	12.5	0.5
201	Lean prepared nitrogen	Neutral heating	97.1	1.7	. . .	1.2	. . .
202	Rich prepared nitrogen	Annealing, brazing stainless steel	75.3	11.0	. . .	13.2	0.5
301	Lean endothermic	Clean hardening	45.1	19.6	0.4	34.6	0.3
302	Rich endothermic	Gas carburizing	39.8	20.7	. . .	38.7	0.8
402	Charcoal	Carburizing	64.1	34.7	. . .	1.2	. . .
501	Lean exothermic-endothermic	Clean hardening	63.0	17.0	. . .	20.0	. . .
502	Rich exothermic-endothermic	Gas carburizing	60.0	19.0	. . .	21.0	. . .
601	Dissociated ammonia	Brazing, sintering	25.0	. . .	. . .	75.0	. . .
621	Lean combusted ammonia	Neutral heating	99.0	. . .	. . .	1.0	. . .
622	Rich combusted ammonia	Sintering stainless powders	80.0	. . .	. . .	20.0	. . .

Furnace Atmosphere Hazards

Furnace atmospheres constitute one of the major safety hazards involved in heat treating. Generally, these hazards fall into three groups: fire, explosion, and toxicity.

Fire. When an atmosphere contains more than 4% of combustible gases, it is classified as flammable. Included in this percentage is a practical safety margin that should never be ignored. *Caution: The combustible gases H_2, CO, CH_4, and other hydrocarbon fuel gases should never be admitted to a furnace chamber at temperatures below 760 °C (1400 °F) without proper inert gas purging (per NFPA standard 86C).*

Explosion. At some point, mixtures of air and combustible gas will explode when ignited. When a furnace chamber is properly gassed with the chamber temperature at or above 760 °C (1400 °F), it is likely that combustible gases will burn before creating an explosion hazard. An adjacent cold chamber or vestibule can then be flared as the atmosphere flows from the furnace to the vestibule until it is free of oxygen from the air. The vestibule can then be closed. The positive flow of atmosphere through the furnace and adjoining cold chamber or vestibule can then be burned. An ignited effluent from an atmosphere furnace is an immediate visual sign that a safe condition prevails.

Toxicity. *Caution: Many of the gases making up furnace atmospheres are toxic.* Burning them at the furnace exits reduces their chemistry to the products of combustion. These products should then be vented outside the building to avoid

dilution of the available oxygen supply within the building. *Caution: Ventilation of the building containing atmosphere generators and atmosphere heat-treating furnaces is a major safety consideration*.

Furnace Atmosphere Hazards (Ref 1, 2, 3, 4, 5, 6, 7). Furnace atmospheres (endo, exo, dissociated ammonia, dissociated alcohols, and nitrogen based) normally consist of a mixture of gases, which may be flammable, toxic, asphyxiant, or a combination of these. Explosion, fire, and poisoning are potential hazards. National Fire Protection Association standard 86C covers various safety considerations pertaining to continuous conveyor belt furnaces used in the thermal processing industry.

Four intrinsic dangers are associated with producing and using the common atmosphere gases. A mixture of atmosphere gas and air can accumulate in a confined area and explode. Relatively small quantities of atmosphere gas can unexpectedly burn or flash out of control. Personnel may be poisoned by carbon monoxide, ammonia, or methanol. Simple asphyxiation is possible when asphyxiants are present in high concentrations.

Table 4 describes the characteristics of the common sintering atmosphere constituent gases. Most of the major constituents are flammable; four are toxic; and four are simple asphyxiants. Carbon monoxide, ammonia, and methanol are both flammable and toxic. The percentage by volume of the flammable ingredients ranges from 75% hydrogen in dissociated ammonia atmosphere to only a few percent in purified exothermic and nitrogen-based atmospheres.

Table 4 Potential hazards and functions of heat treating atmosphere-constituent gases

Gas	Potential hazard			Atmosphere function
	Flammable	Toxic	Simple asphyxiant	
Nitrogen	. . .	. . .	Yes	Inert
Hydrogen	Yes	. . .	Yes	Strongly reducing
Carbon monoxide	Yes	Yes	. . .	Carburizing and mildly reducing
Carbon dioxide	. . .	Yes	Yes	Oxidizing and decarburizing
Natural gas	Yes	. . .	Yes	Strongly carburizing and deoxidizing
Ammonia	Yes	Yes	. . .	Strongly nitriding
Methanol	Yes	Yes	. . .	Carbon monoxide and hydrogen generating

Dangers are present even when heat treating with atmospheres that contain relatively small percentages of hazardous ingredients because the gases may accumulate or concentrate. Under typical operating conditions, however, the active ingredients in nitrogen systems are diluted below the level that is flammable, even if all the nitrogen is replaced by air. Explosion, burning, poisoning, and asphyxiation hazards are thus reduced, but not eliminated.

The explosive ranges of typical atmosphere constituents are:

Atmosphere constituents	Concentration in air, %
Hydrogen	4.0-74
Carbon monoxide	12.5-74
Methane	5.3-14
Ammonia	15.0-28
Methanol	6.7-36

Any mixtures between the high and low limits of flammability will burn when ignited, and, under certain conditions, detonate or explode. The destructive power of the pressure wave from an ignited flammable mixture depends on the amount of gas and the heat of combustion of the fuel gas, the combustion mode (deflagration or detonation), and the configuration of the confinement space. The energy released is either absorbed by the surroundings or destroys them.

The explosive potential of the large volumes of flammable gases used in sintering furnaces poses an important safety consideration. To ensure the safety of sintering and heat treating, the equipment and systems that handle gases must be designed, operated, and maintained to prevent accumulation of explosive mixtures. Dangerous accumulations that cannot be readily detected by personnel can occur. Properly designed safety systems, maintained and operated by well-trained and competent personnel, substantially reduce explosion hazards.

Generally, sufficient volumes of atmosphere gas flowing through the furnace leave the charge and discharge doors, mix with air, and burn uniformly and completely. However, several conditions may exist that prevent the atmosphere gas from burning off properly. Sometimes, a combustible mixture of air and gas may form in the furnace throats or vestibules. It may burn rapidly and forcefully exhaust, or flash, flames and hot gases through the furnace door. Unprotected personnel in the vicinity may be burned. Eyes are particularly sensitive to damage.

Although flashes of this type are more common than explosions, they are potentially less destructive. Nonetheless, personnel who approach these areas without safety glasses, protective face shields, gloves, and flameproof clothing risk serious flash burns. If safe methods are established and used for cleaning jam-ups, inspecting the furnace interior, and removing products from the furnace, this hazard is substantially reduced.

Protective guards and shields used for routine operation are no substitute for the required protection of personnel working in the vicinity of the furnace doors. However, the possibility of flashback under nonflammable, nitrogen-rich atmospheres is remote.

Ammonia, carbon monoxide, and methanol, which are highly toxic, are used routinely in the sintering and heat-treating industries. Liquid ammonia produces dissociated ammonia or ammonia vapor for nitriding, and carbon monoxide is a constituent of exothermic, endothermic, and dissociated methanol gases. Methanol is used to produce dissociated methanol, which consists of hydrogen and carbon monoxide. Concentrations of less than $\frac{1}{2}$% ammonia or carbon monoxide in air are considered fatal in less than $\frac{1}{2}$h of exposure. The physiological effects of various concentrations of these gases are given in Tables 5 and 6.

Table 5 Physiological effects of ammonia

Concentration,	Physiological effects

ppm	
20	First perceptible odor
40	Slight eye irritation in a few individuals
100	Noticeable irritation of eyes and nasal passages after a few minutes of exposure
400	Severe irritation of the throat, nasal passages, and upper respiratory tract
700	Severe eye irritation; no permanent effect if the exposure is limited to less than $\frac{1}{2}$ h
1700	Serious coughing, bronchial spasms; less than $\frac{1}{2}$ hr of exposure may be fatal
5000	Serious edema, strangulation, asphyxia; almost immediately fatal

Table 6 Physiological effects of carbon monoxide

Concentration, ppm	**Physiological effects**
100	Allowable for an exposure of several hours
400	Can be inhaled for 1 h without appreciable effect
600	Causes a barely appreciable effect after 1 h of exposure
1000	Causes unpleasant symptoms, but not dangerous after 1 h
1500	Dangerous for exposure of 1 h
4000	Fatal for exposure of less than 1 h

Threshold limit values, published by the American Conference of Governmental and Industrial Hygienists, lists carbon monoxide, carbon dioxide, ammonia, and methanol as commonly used toxic chemicals. Concentrations as small as 35 ppm of ammonia, 400 ppm of carbon monoxide, and 250 ppm of methanol are harmful; therefore, only short exposures are allowed.

Protection from poisoning by raw ammonia or methanol vapor or from contact with liquid ammonia or methanol is provided partly by the design of the storage and delivery system. Suppliers are excellent sources of detailed safety information on ammonia and methanol systems and ammonia dissociators.

Carbon monoxide is not quite as toxic as ammonia; however, because is is odorless, it poses a greater safety hazard. Lethal concentrations can collect in isolated areas and remain undiscovered until personnel are overcome by the fumes.

According to Ref 2, ". . . in concentrations far short of the asphyxiation level, carbon monoxide is still dangerous, especially if exposure is prolonged. Carbon monoxide (poisoning) can be a contributing factor to death that ultimately results from other causes, such as fatal accidents, and is a health as well as safety problem." Carbon monoxide interferes with the ability to breathe, and, as a result, the ability of the body to utilize oxygen. It is over 200 times more attractive than oxygen to the blood hemoglobin that delivers oxygen throughout the body. A relatively small amount of carbon monoxide, therefore, depletes the body of a large amount of oxygen.

To ensure personnel safety, piping between the generator and the furnace must be leaktight, and all gas that enters the furnace must be either burned off or properly vented. The highly toxic nature of carbon monoxide requires use under carefully controlled conditions. The safest and most convenient disposition of carbon monoxide is to ensure complete mixing of the furnace atmosphere effluent with air to combustible proportions and subsequent ignition of the mixture. Products of combustion are far less toxic but should still be properly vented.

In some applications, carbon monoxide cannot be burned directly because it has been diluted in inert gas to a level that is nonflammable when mixed with air. Special precautions must be taken to vent and dilute it to below toxic limits. To ensure the continued effectiveness of the venting, carbon monoxide levels near the furnace setup must be monitored continuously. Consequently, apparatus using or emitting gas containing carbon monoxide that will not burn when mixed with air should not be operated unless the user is willing to accept the added liability. Additionally, special gas-monitoring and disbursing equipment should be installed.

Personnel should also be familiar with the early symptoms of carbon monoxide poisoning and trained in appropriate first aid. Early symptoms include slight dizziness, weakness, or headache. In the later stages of poisoning, the victim's lips and skin turn a characteristic cherry red.

Finally, the danger of asphyxiation is not intrinsic to the gases used in the heat treating industry, but is a concern. Asphyxiation can be caused by a harmless gas (for example, one that has no significant physiological effect) if it is present in high concentrations in the air. Normal oxygen content in air is about 21 vol%. Minimum oxygen content should be 18 vol% under normal atmospheric pressure.

Exothermic-Based Atmospheres

Exothermic gases (class 100) have been used extensively for many years as lower-cost prepared furnace atmospheres. Exothermic atmospheres are divided into two basic classes: rich and lean. Rich exothermic atmospheres (class 102) have moderate reducing capabilities of 10 to 21% combined carbon monoxide and hydrogen, and lean exothermic atmospheres (class 101), usually with 1 to 4% combined carbon monoxide and hydrogen, have minimal reducing qualities.

Rich Exothermic Atmospheres

The principal uses of rich exothermic furnace atmospheres include clean heat treating of certain ferrous and nonferrous applications. Among these are annealing and tempering of steel, brazing of copper and silver, and sintering of powdered metals.

Reducing properties of rich exothermic atmospheres may be varied to make them suitable for specific processes. Figure 5 indicates the usual operating range of the gas generator and reflects changes (by dry volumetric measurement) in the following constituents of the product gas at any particular setting: carbon dioxide, carbon monoxide, hydrogen, and unburned methane. The remainder of the mixture is nitrogen. Because these atmospheres have a carbon potential below 0.10%, steel heat treating is generally limited to processes for low-carbon steels to minimize decarburizing, or processes where decarburization is unimportant. Water vapor is present in substantial quantities and may be removed partially by initial cooling and refrigerant drying to an equivalent 5 °C (40 °F) dew point. This procedure may be followed by further dehydration with an adsorbent desiccant dryer for final few points of -40 to -50 °C (-40 to -60 °F), as applications require.

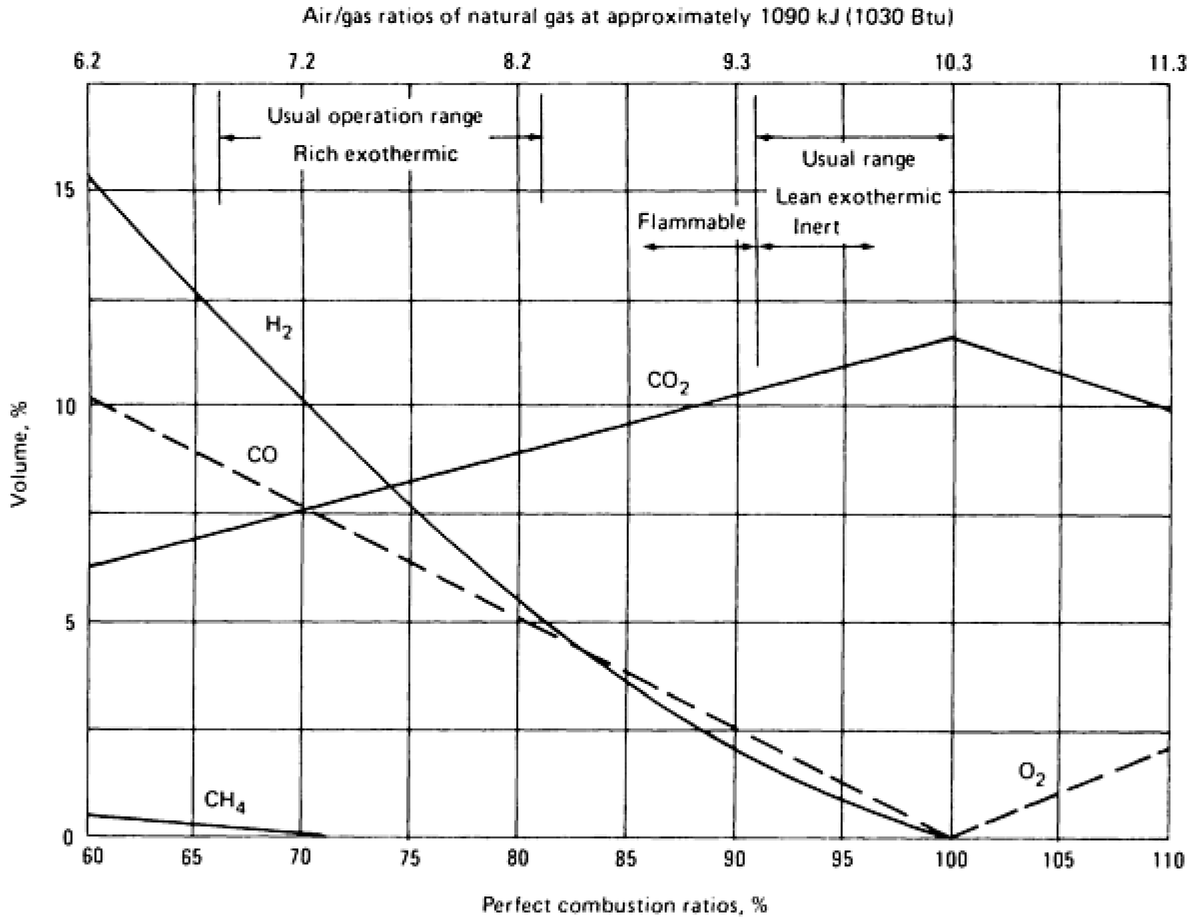

Fig. 5 Exothermic atmosphere composition versus air-to-fuel ratio (natural gas)

Gas Production. Rich exothermic gas is produced by combustion of a hydrocarbon fuel such as natural gas or propane with the air-to-fuel ratio closely controlled. This air-gas mixture is burned in a confined combustion space to maintain a reaction temperature of at least 980 °C (1800 °F) for sufficient time to permit the combustion reaction to reach equilibrium. Heat is obtained directly from combustion. The resultant gas is then cooled to remove part of the water vapor formed by burning and to permit convenient transportation and metering. In this process, the simplified theoretical reaction of methane with air is:

$$\begin{aligned} CH_4 + 1.25O_2 + 4.75N_2 &\rightarrow 0.375CO_2 \\ &+ 0.625CO + 0.88H_2 + 4.75N_2 \\ &+ 1.12H_2O + \text{heat} \end{aligned} \qquad \textbf{(Eq 30)}$$

where 1 volume of fuel and 6 volumes of air yield 6.63 volumes of product gas mixture, with water vapor removed. In practice, exothermic gas generators are seldom operated with an air-to-gas ratio lower than about 6.6 to 1, to prevent formation of soot as a result of incomplete reaction. Trace percentages of unreacted methane also exist in the product gas.

The basic rich exothermic gas generator (Fig. 6) has a refractory-lined combustion chamber, which in some designs may be partially filled with a catalyst. The chamber incorporates a burner with a combustion-control system especially designed to provide a constant supply of air and fuel gas with a closely maintained preselected ratio. The combustion chamber is followed by a water-cooled heat exchanger for primary gas cooling and partial water vapor condensation. At this point, product atmosphere is saturated with moisture at approximately 8 °C (15 °F) above the temperature of the cooling water.

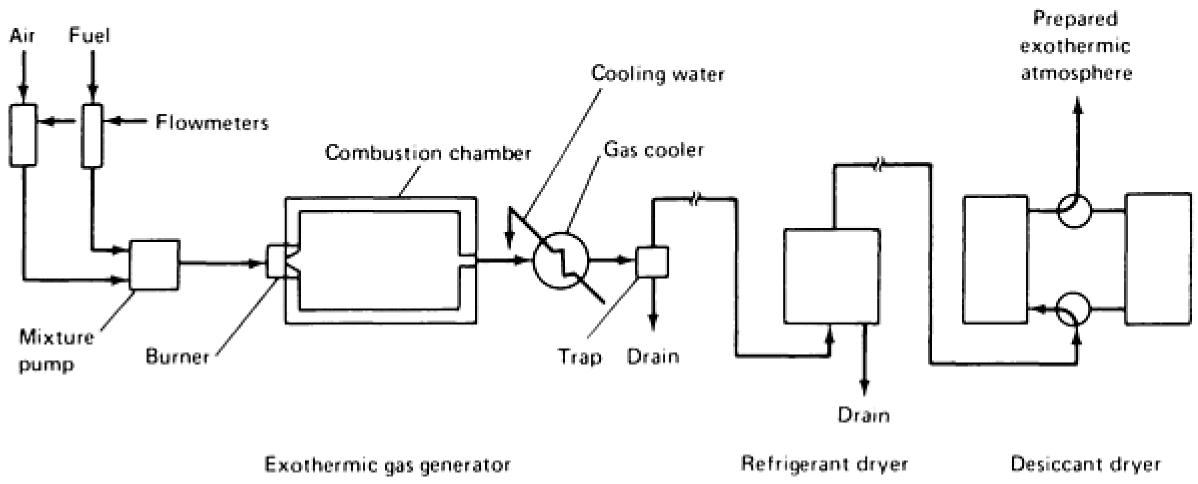

Fig. 6 Flow diagram of an exothermic gas generator system

Operation is uncomplicated and continuous, incorporating input air and fuel-gas flow meters with manual or automatic control of process flow and ratio. Safety devices include sequenced burner ignition, automatic flame monitoring, pressure switches, and manual-reset fuel-safety valves. Periodic operational monitoring consists of observing pressures and flow rates and taking occasional product gas samples for analysis of desired composition. Available continuous gas analyzers, either indicator-reading or recording, usually are calibrated to indicate the content of combustibles. Some analyzers may be adapted for automatic radio control.

Operating Economics. The following are requirements needed to produce 28 m^3 (1000 ft^3) of rich exothermic atmosphere:

Requirement	Value
Natural gas, m^3 (ft^3)	4.4 (155)
Electric energy consumption, MJ (kW · h)	1.4 (0.4)
Cooling water, L (gal)	1135 (300)
Electric energy consumption for refrigerant dryer, MJ (kW · h)	1.8 (0.5)
Electric energy consumption for desiccant dryer, MJ (kW · h)	5.4 (1.5)

Safety Considerations. *Caution: Rich exothermic atmospheres contain sufficient carbon monoxide and hydrogen to be considered flammable gases when mixed in proper proportions with air. In handling or use as a furnace atmosphere, they should be treated with the same precautions exercised with any combustible gas.* Established furnace-operating practices should be observed carefully, particularly with respect to proper purging procedures and prevention of air infiltration. Most generators are equipped with electrically programmed ignition sequencing and are monitored with additional safety devices. These devices should be periodically tested to ensure fail-safe operation. Because these atmospheres contain measurable amounts of carbon monoxide, extreme care should be taken to prevent leaking into the surrounding atmosphere. Proper venting, burnoff, and ventilation facilities should be employed. Furnace safety is discussed in this article in the section "Classifications of Prepared Atmospheres."

Lean Exothermic Atmospheres

Lean exothermic atmospheres generally have limited use in most heat-treating applications, particularly for ferrous materials, except when these atmospheres are used as intentional surface oxidizing agents or for specialized low-temperature operations. Lean atmospheres are used to some extent for processes such as copper annealing and are employed more widely when the primary processing aim is to exclude oxygen or to provide purging and blanket gas.

Figure 5 indicates the usual operating range of the gas generator and reflects changes (by dry volumetric measurements) in the product gas at any particular setting with respect to carbon dioxide, carbon monoxide, and hydrogen. The balance of the mixture is nitrogen. Reducing capabilities are limited. Water vapor that is present in substantial quantities may be removed partially by initial cooling and refrigerant drying to an equivalent 5 °C (40 °F) dew point. This process may be followed by further dehydration with an adsorbent desiccant dryer for final dew points in the range of -40 to -50 °C (-40 to -60 °F), as applications require.

Gas Production. Lean exothermic gas is produced by combustion of a hydrocarbon fuel such as natural gas, propane, or light fuel oil with the air-to-fuel ratio closely controlled. This air-fuel mixture is burned in a confined combustion space for sufficient time to permit the reaction to reach equilibrium. The resultant gas is then cooled to partially condense water vapor formed by burning and to permit convenient transport and metering. In this process, the simplified theoretical reaction of methane fuel with air is:

$$CH_4 + 1.9O_2 + 7.6N_2 \rightarrow 0.9CO_2 + 0.1CO + 0.1H_2 + 7.6N_2 + 1.9H_2O + \text{heat} \quad \textbf{(Eq 31)}$$

where 1 volume of fuel and 9.5 volumes of air yield 8.7 volumes of product gas mixture, with water vapor removed. In practice, exothermic gas generators are seldom operated with an air-to-gas ratio higher than that required to produce a minimum of 1% total carbon monoxide and hydrogen, to avoid unwanted quantities of residual oxygen. One exception involves certain purge and blanket applications where small amounts of oxygen can be tolerated and the presence of combustible materials is not desired. In this case, the air-to-gas ratio is further increased to operate with a slight amount of excess air, thus maintaining 1 to 2% oxygen in the product gas. The basic lean exothermic gas generator is shown in Fig. 6.

Operating Economics. The following are requirements needed to produce 28 m^3 (1000 ft^3) of lean exothermic atmosphere:

Requirement	**Value**
Natural gas, m^3 (ft^3)	3.3 (120)
Electric energy consumption, MJ (kW · h)	1.4 (0.4)

Cooling water, L (gal)	1590 (420)
Electric energy consumption for refrigerant dryer, MJ (kW · h)	1.8 (0.5)
Electric energy consumption for desiccant dryer, MJ (kW · h)	5.4 (1.5)

Safety Considerations. Lean exothermic gas generators that are operated at less than 4% total combustibles are considered non-flammable and may be handled and used in the same manner as other types of inert gases. *Caution: These atmospheres, however, usually contain measurable amounts of carbon monoxide, and extreme care should be taken to avoid leakage. Proper venting and ventilation facilities should be employed. Moreover, when lean exothermic gas is used for purging and blanket applications, the chamber or vessel will lack oxygen. If it becomes necessary to enter these spaces for any reason, the chamber should be purged thoroughly with air or an air mask and a lifeline should be employed, with someone outside holding the lifeline.*

Most generators are equipped with electrically programmed ignition sequencing and are monitored with additional safety devices that should be tested periodically to ensure fail-safe operation. Furnace safety is discussed in another article in this Volume.

Endothermic-Based Atmospheres

Endothermic-based atmospheres are produced in generators that use air and a hydrocarbon gas as fuel. These two gases are mixed in a controlled ratio, slightly compressed, and then passed into a chamber that is filled with a nickel-bearing catalyst. This chamber has been heated externally to approximately 1040 °C (1900 °F). The gases react in this chamber to form endothermic gas. Endothermic atmospheres thus produced must be cooled rapidly to ensure the integrity of their chemical compositions. Figure 7 is a schematic diagram of an endothermic gas generator.

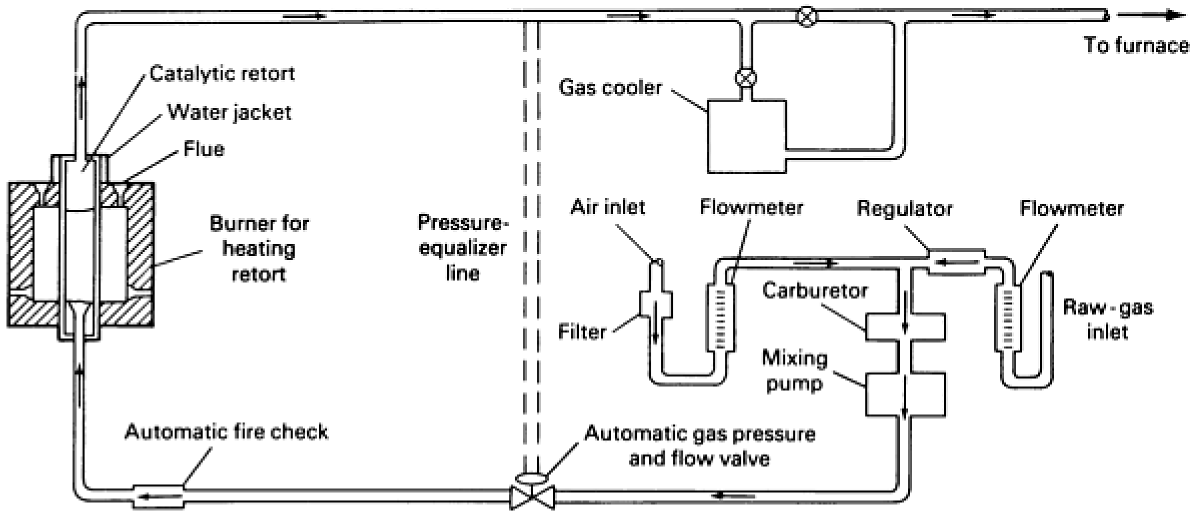

Fig. 7 Flow diagram of an endothermic gas generator system

Endothermic gas produced from natural gas, which is primarily methane, has a typical analysis as follows: 40.4% hydrogen, 39.0% nitrogen, 19.8% carbon monoxide, 0.5% methane, 0.2% water vapor, and 0.1% carbon dioxide. Although natural gas is commonly employed, endothermic generators satisfactorily crack propane, butane, or other hydrocarbon gases. The product endothermic gas chemical composition will vary when alternate hydrocarbon gases are used. When propane is used as the hydrocarbon gas, a typical analysis shows 45.3% nitrogen, 31.1% hydrogen, 23.4% carbon monoxide, 0.2% methane, <1% water vapor, and virtually no carbon dioxide.

Common Applications. Endothermic atmospheres can be used in virtually all furnace processes that require strong reducing conditions. The most common use is as carrier gases in gas carburizing and carbonitriding applications. Because of the wide range of carbon equivalencies possible, however, endothermic atmospheres also are used for bright hardening of steel, for carbon restoration in forgings and bar stock, and for sintering of powder compacts that require reducing atmospheres. It is generally necessary to couple the generator with the process to ensure that the carbon equivalent being produced in the generator is appropriate for the process. However, in gas-carburizing applications, the addition of a hydrocarbon gas to the furnace will raise the carbon equivalency of the furnace gas, thus allowing a more neutral carrier gas to be produced at the generator.

Generation of Endothermic Atmospheres. In generating endothermic-based atmospheres, hydrocarbon gas and air are metered in proportions that ensure that only sufficient oxygen is admitted to form carbon monoxide and hydrogen, without any excess for the formation of carbon dioxide or water vapor. After being compressed to about 7 to 14 kPa (1 or 2 psig), the air-gas mixture is passed through a fire-check valve to the heated catalyst, which is contained in a pressure-tight retort. The retort is externally heated, usually by natural gas.

For a completely reacted gas of consistent analysis, the temperature inside the catalyst bed should be approximately 980 to 1040 °C (1800 to 1900 °F). Furthermore, the ratio of the diameter of the retort to its length must be correct for any given capacity.

After passage over the catalyst, the reaction is frozen by quickly chilling the gases to below 315 °C (600 °F) in a water jacket surrounding the top of the retort, thus preventing the reaction from reversing and forming carbon and carbon dioxide from carbon monoxide:

$$2CO \rightarrow C + CO_2 \qquad \textbf{(Eq 32)}$$

The reaction in the direction indicated predominates at temperatures of 705 to 480 °C (1300 to 900 °F). The soot-free reacted gas can be further cooled in the gas cooler for metering and distribution.

Because natural gas is composed chiefly of methane (CH_4), the overall chemical reaction taking place in the endothermic generator using natural gas as its fuel can be expressed as follows:

$$2CH_4 + O_2 \rightarrow 2CO + 4H_2 \qquad \textbf{(Eq 33)}$$

neglecting 3.8 volumes of nitrogen (before and after) for each 2 volumes of methane.

The reaction takes place in two stages. In the first stage, some of the methane burns with air and generates heat. In the second stage, the surplus methane reacts with the carbon dioxide and water vapor produced in the first stage, and this later reaction is definitely endothermic. Therefore, a high temperature and a clean and sufficient catalyst bed are required to obtain a completely reacted gas and to minimize carbon dioxide, excess methane, or excess water vapor.

A completely reacted gas is, in practical operations, one in which the methane content does not exceed about 0.4 to 0.8%. If the temperature is not high enough and the gas is not completely reacted, the reaction will produce soot. Once the catalyst accumulates soot, it becomes ineffective, and the gas composition will drift, resulting in more methane and higher percentages of carbon dioxide and water vapor in the products. When this occurs, the generating process cannot be controlled to maintain a definite carbon potential. Furthermore, unreacted methane will break down in the heat-treating furnace to produce soot.

Clean, active catalyst is extremely important for accurate control of carbon potential. The catalyst most commonly used is of the porous refractory-base type, impregnated with nickel oxide.

The presence of hydrogen sulfide (H_2S) in natural gas will seriously affect an endothermic generator. Hydrogen sulfide will cause the generator to produce high concentrations of CO_2, CH_4, and water vapor, and become unresponsive to control adjustments of the air-to-gas ratio. This causes the endothermic atmosphere being produced to have a low carbon equivalent. Specifically, any H_2S concentration over 30 ppm in natural gas of 0.6 specific gravity will have a noticeable effect on the resultant product gas.

Most endothermic generators are controlled by monitoring the dew point of the product gas. The dew point is controlled by either manual or automatic adjustment of the ratio of air and gas going into the generator. The relationship between carbon dioxide and dew point in endothermic gas is presented in Fig. 8. In broad terms, a dew point of 16 to -12 °C (60 to 10 °F) will create a product gas in equilibrium with steel containing 0.20 to 1.5% C at normal hardening or carburizing temperatures. Figure 9 shows the relationship between dew point and carbon content in plain carbon steels at temperatures from 815 to 925 °C (1500 to 1700 °F). Producing endothermic gas of -7 °C (20 °F) dew point or higher will ensure gas that is clean enough for continuous operation without weekend shutdowns for burnout. In some instances, the percentage of carbon dioxide or the ratio of carbon monoxide to carbon dioxide or the oxygen probe is used as the controlling method of the generator.

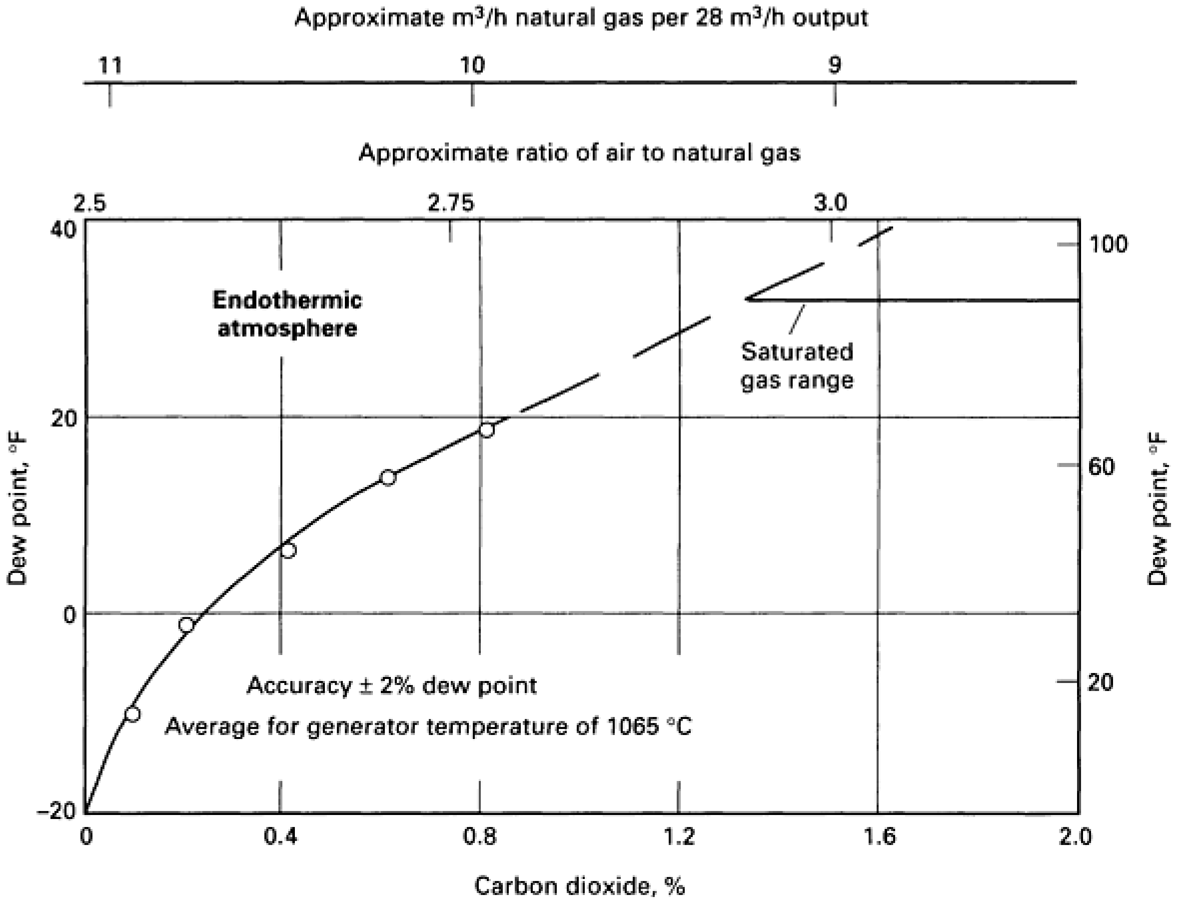

Fig. 8 Relation between dew point and carbon dioxide content in the generation of an endothermic-based atmosphere

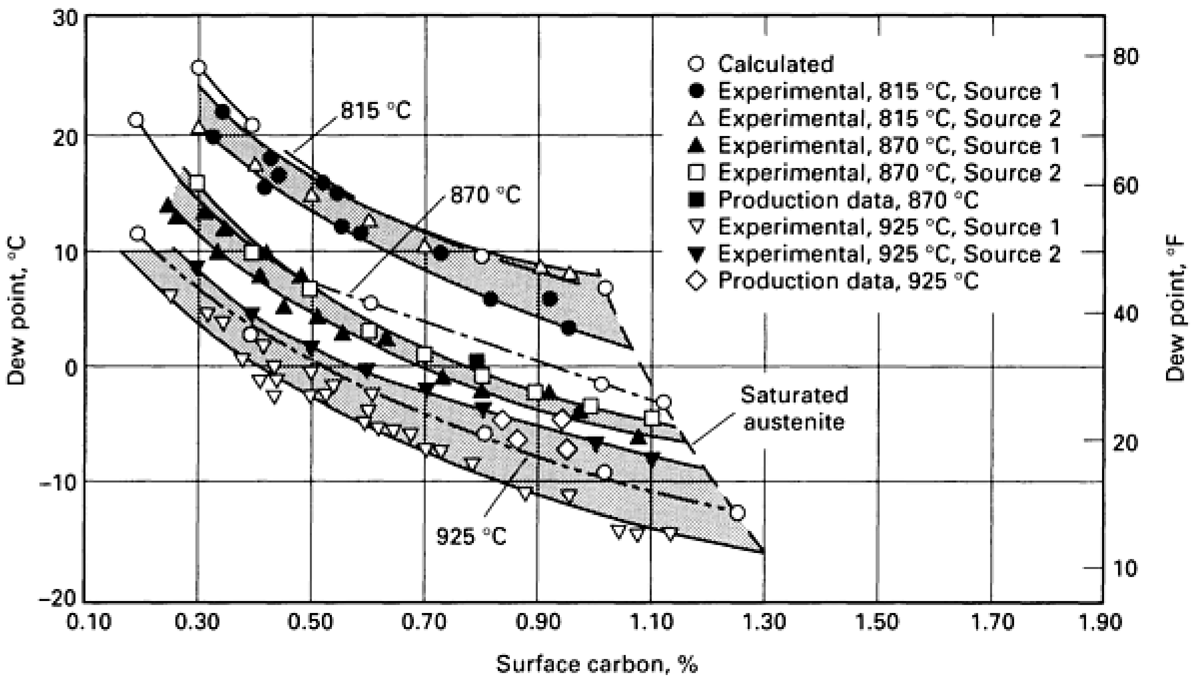

Fig. 9 Equilibrium between carbon steels and endothermic-based atmospheres

Endothermic Generator Maintenance. The maintenance requirement schedules for gas-fired endothermic-based atmosphere generators are:

Weekly and/or monthly

- Burn out carbon in generator
- Clean air filter
- Check calibration of control instruments
- Inspect thermocouples
- Service controller sample system

Annually, or as prescribed in operating instructions

- Test all safety controls
- Inspect catalyst in retort and fill to proper level or replace
- Inspect and clean burners
- Check compressor blades and bearings in mixer pump and lubricate if necessary
- Check motor bearings on mixer pump
- Clean gas lines to furnaces if necessary

Safety Precautions. *Caution: Because endothermic gas is highly toxic and highly flammable and because it forms explosive mixtures rapidly, a safety program is imperative.* The exact program will depend on the equipment being used, local ordinances, normal operating procedures, types of emergency equipment available, plant layout, and capabilities of personnel. The best safety equipment available cannot substitute for properly trained personnel.

Several areas of concern must be addressed in safety procedures and training. First, because an endothermic generator is in itself a furnace, often a gas-fired furnace, all the safety precautions normally applied to any furnace must be applied to

the generator. No attempt should be made to produce endothermic gas if the generator is not at temperature. The fire-check valve, which is installed in all generators, must be in operating condition or the danger exists of the explosive gas in the mixer being ignited. Care must be taken to prevent the volume of air in the mixture from increasing to a point at which the mixture becomes exothermic and hence explosive. Further, the cooling process must be maintained to prevent overheating of the supply system. *Caution: Overheating would allow a reversible reaction in the gas and create an explosive mixture*.

Prepared Nitrogen-Based Atmospheres

Prepared nitrogen-based atmospheres are exothermic atmospheres (produced by combustion of a mixture of air and fuel gas) from which almost all of the carbon dioxide and water vapor has been removed. The combination of very low dew point, approximately -40 °C (-40 °F), and the virtual absence of carbon dioxide accounts for the marked difference between the properties and applications of prepared nitrogen-based atmospheres as compared with those designated exothermic base.

The above definition conforms with the classification system used by the American Gas Association (AGA). Accordingly, the term prepared nitrogen-based atmospheres is not appropriate for furnace atmospheres consisting of a mixture of commercial nitrogen and other gases, nor for ammonia-based atmospheres, although both have a nitrogen base.

The high concentrations of carbon dioxide and water vapor in the products of combustion can be reduced to desirable low levels by either of two distinctly different systems. One system involves coadsorption of both gases on a molecular-sieve desiccant. The other system is a somewhat complicated miniature chemical plant that employs pumps and several heat exchangers. The carbon dioxide is absorbed by a water solution of monoethanolamine (MEA), and the water vapor is reduced by a refrigerator condenser, followed by desiccant drying.

Classification. Regardless of the method of generation, prepared nitrogen-based atmospheres are of two major types, either lean or rich. The relative richness of carbon monoxide and hydrogen in a typical rich atmosphere (class 202) is compared with a typical lean atmosphere (class 201) in Table 3.

Significantly important subtypes, which are carried in the AGA classification system as classes 223 and 224, involve the removal of almost all the carbon monoxide so that the generated atmospheres consist almost exclusively of nitrogen and hydrogen.

The methods of generator control to attain each of these two major types are described in the "Advantages and Disadvantages" and the "Typical Applications" sections of the "Prepared Nitrogen-Based Atmospheres" portion of this article.

Advantages and Disadvantages. The principal advantage of prepared nitrogen-based atmospheres is their applicability to a variety of heat-treating operations for low-carbon, medium-carbon, and high-carbon steels and for some other metals. Because of their low dew point and the virtual absence of carbon dioxide, these atmospheres (in the absence of oxygen-bearing contaminants introduced as a result of furnace operations) are neither oxidizing nor decarburizing, in contrast to the exothermic-based atmospheres. In addition, the nominal cost per unit volume of atmosphere produced are lower than for several other protective atmospheres except for the exothermic-based atmospheres.

Modified nitrogen-based atmospheres, classes 223 and 224, have the additional advantage of being nonsooting even at low furnace temperatures.

The main disadvantages of these atmospheres lie in the high initial cost of equipment, the large space requirements, and the need for more exacting maintenance and control of the generators. Further, as with any generator-based atmosphere system, extra inspection and testing of the material in process are required when generator conditions develop that force a shutdown.

Typical Applications. These atmospheres can be used in virtually all furnace applications that do not require highly reducing conditions. Because they are not decarburizing, they can be used in annealing, normalizing, and hardening of medium- and high-carbon steels. The low carbon monoxide contents of lean gases render them equally suitable for the thermal treatment of low-carbon steels. However, their usefulness in the heat treating of steels is predicated on their very low dew point, which can be maintained only if furnace design and operation prevent furnace atmosphere contamination

with air or any other oxygen-bearing chemical compound. Consequently, in actual practice, one of the more common uses is for the annealing of steel coils in airtight bell-type furnaces. For this application, ratios of about nine parts of air to one part of natural gas are employed to produce a dry, nondecarburizing, nonexplosive atmosphere containing about 4.0% combustibles. When these atmospheres are modified to eliminate the carbon monoxide (class 223), an additional advantage in annealing is that they do not produce soot during the period of slow cooling to relatively low temperatures.

Nitrogen-based atmospheres enriched with methane or other hydrocarbons are occasionally used as carrier gases in annealing, gas carburizing, and carbon restoration, but endothermic and other protective atmospheres generally are preferred because of their higher carbon potentials and better control capability.

Lean atmospheres (with a maximum of 4.0% combustibles) are also used for purging explosive gases from furnaces and for blanketing the in-process material during furnace idle periods. Although lean exothermic atmospheres are sometimes used for these purposes, the nonoxidizing, nondecarburizing nature of the nitrogen-based atmosphere is often advantageous. The rich atmospheres are not approved for use as purge gases because of the high contents of combustibles. The lean atmosphere is also used for these purposes in numerous applications within the chemical-processing industry.

Another common use of the lean atmosphere is with large semicontinuous and continuous annealing furnaces. In many instances, a lean nitrogen-based atmosphere is blended with an endothermic atmosphere to maintain adequate furnace pressure at lower overall cost. With this blend and appropriate adjustments, the higher carbon potential of the endothermic atmosphere can be maintained. With large semicontinuous furnaces, class 201 gas is often used to purge the furnace vestibules economically. The lean gas is almost always used with either type of furnace, and a part of the gas is stored under high pressure for purging the furnace when an unexpected shutdown occurs, for example, during an electrical power failure. Rich gas is avoided because it is not approved for purging for the reasons described above.

Rich nitrogen-based atmospheres may be used for the annealing or brazing of steel or copper alloys and for sintering of iron powder compacts.

Generation. In both common systems of generating prepared nitrogen-based atmospheres, molecular-sieve or MEA scrubbing, the starting gas is produced by burning an appropriate mixture of air and a hydrocarbon fuel gas, which most frequently is natural gas. Combustion is accomplished within one or more refractory lined chambers. Sufficient air is provided under pressure to partially burn the fuel, and in no situation is enough air supplied to carry the burning to so-called complete combustion. Because the ratio of air to fuel for complete combustion varies widely depending on the analysis of the fuel, the ratios cited are only approximate, and for ease in communication, are related to the analysis of natural gas that is commonly distributed in the midwestern areas of the United States.

The products of combustion consist of nitrogen, water vapor, carbon dioxide, carbon monoxide, and hydrogen, with almost undetectable amounts of free oxygen. Figure 10 indicates the approximate pattern in which percentages of carbon monoxide and hydrogen vary in the final atmosphere versus the air-to-gas ratio of the feed mixture.

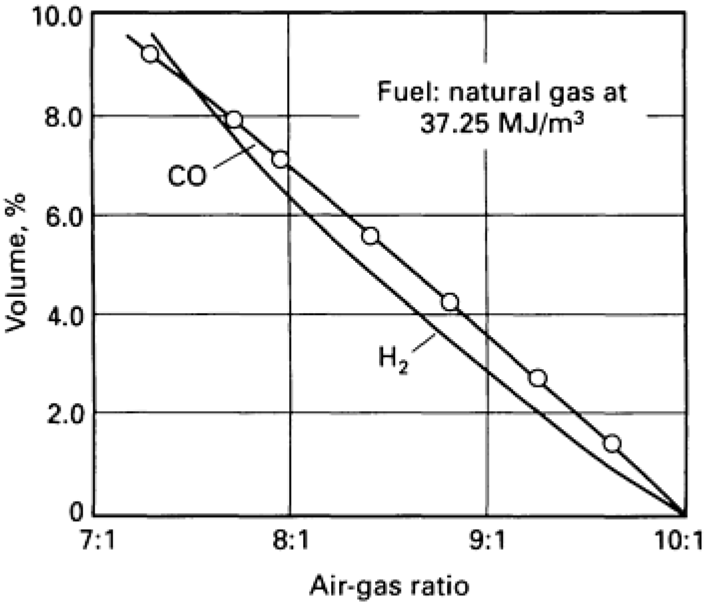

Fig. 10 CO and H_2 versus air-to-gas ratio. Approximate carbon monoxide and hydrogen contents of the generated atmosphere versus the air-to-gas ratio of the feed mixture

To maintain precise control of the air-to-gas ratio for the combustion process, it is common practice to use automatic analyzer/recorder/controller equipment. For simplicity, the various designs for control of air-to-gas ratios are not displayed in the flow diagrams of Fig. 11 and 12.

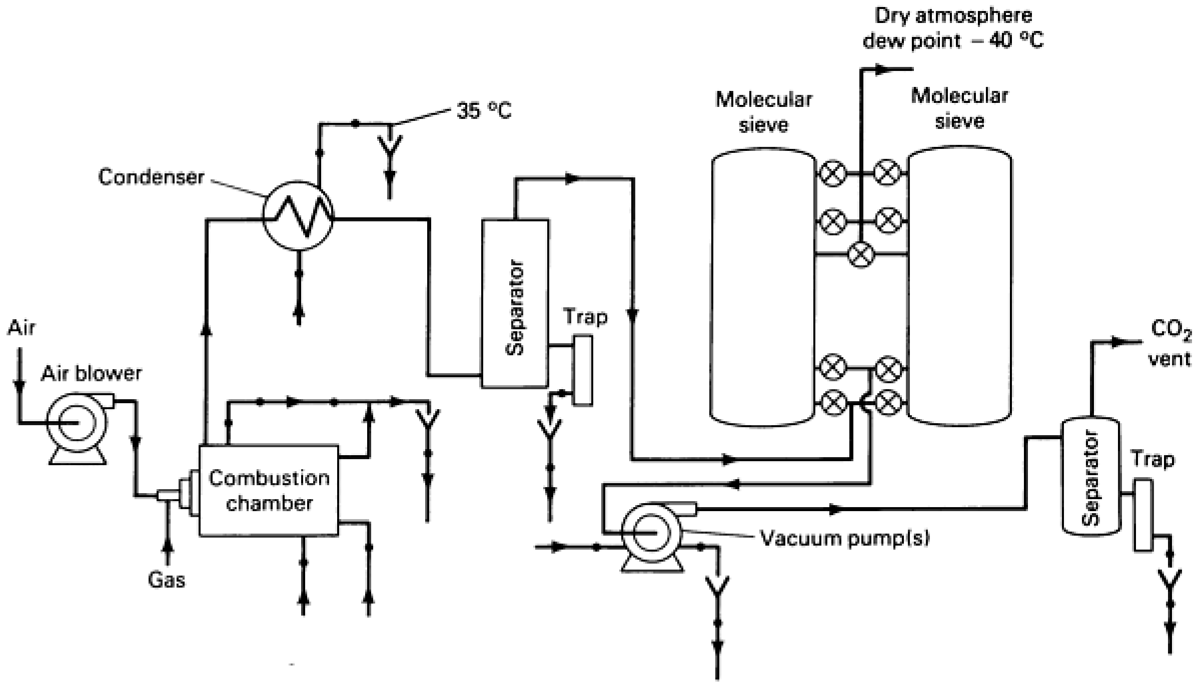

Fig. 11 Flow diagram of nitrogen-based atmosphere generator incorporating molecular-sieve removal of carbon dioxide and water vapor (and using negative-pressure regeneration of the sieves). Gas lines are indicated by solid straight lines; water lines are shown as solid lines with closed circles. Autocontrolled valves are shown as the larger circles located between the molecular sieves.

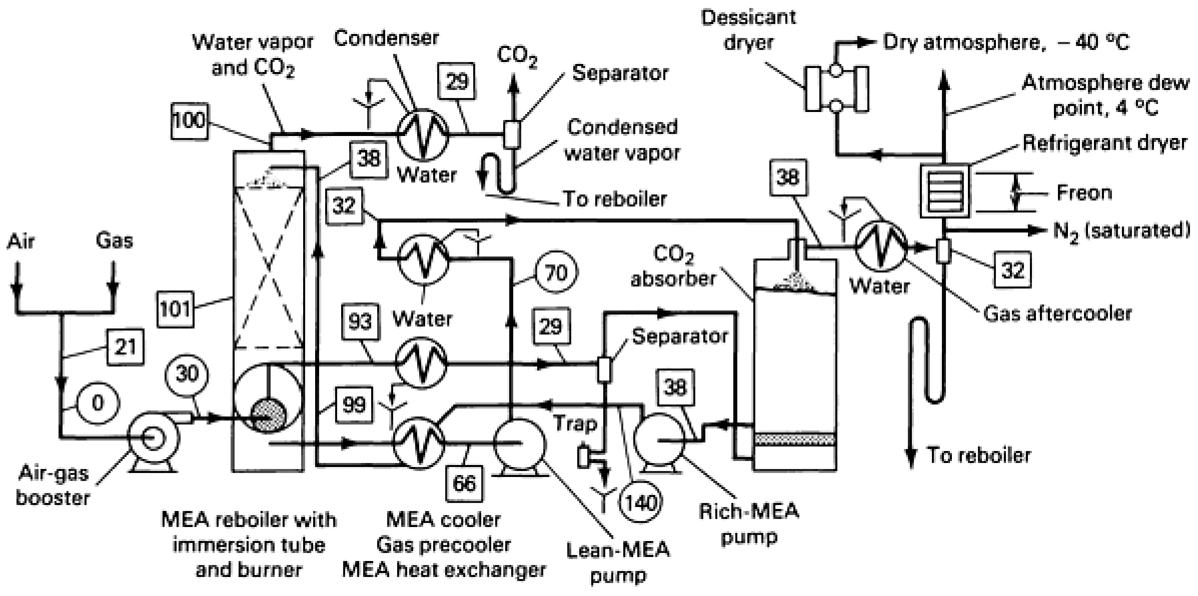

Fig. 12 Flow diagram of nitrogen-based atmosphere generator incorporating a monoethanolamine (MEA) scrubbing system. Temperature (°C) is indicated in boxes; pressure (kPa) appears in circles.

In both systems of generation, products of combustion are first passed through a water-cooled heat exchanger and then through a separator that condenses and discards most of the water of combustion. At this point, the two major systems of generation differ in the methods used for reducing the remaining water vapor and carbon dioxide to very low levels.

Molecular-Sieve Systems. A flow diagram of a typical molecular-sieve system is shown in Fig. 11. The flow diagram for a specific generator may differ significantly depending on the design of components, although overall results are the same.

After products of combustion have passed through the heat exchanger and separator, they are piped to one tower of a dual-tower system, in which both towers are filled with molecular-sieve material. While process gas is passing through the tower that is on the line, molecular-sieve material in the other tower is being reactivated. Switching between towers is controlled by a timer that automatically triggers control valves that direct the flow. In some systems, the time for a complete cycle of a tower from on the line through reactivation is about 10 min.

As the gas passes through the molecularsieve material, both carbon dioxide and water vapor are adsorbed to the extent that typically the dew point of the discharge gas is -40 °C (-40 °F) or lower, and the carbon dioxide content is below 0.15%.

Molecular-sieve systems may function either at low or high operating pressures. In a low-pressure system, reactivation is accomplished by a strong vacuum and purging with some of the discharge gas of the tower that is on the line. Discharge pressure of this system is about 3 kPa (0.5 psig). In a high-pressure system, operating pressure is about 585 kPa (85 psig). Reactivation consists of depressurizing to atmospheric pressure plus purging with some of the discharge gas from the tower that is on the line.

With either type of molecular-sieve generator, heat of combustion is transferred to the water used to cool the combustion chamber. This heated water is sometimes used in other plant processes.

Because of the comparative simplicity and relative absence of operating problems, the molecular-sieve system is often preferred over the monoethanolamine system. Nevertheless, in many installations, the maintenance problems incurred with vacuum pumps are often as troublesome as the total variety of problems encountered in monoethanolamine systems.

Monoethanolamine Systems. Figure 12 presents a flow diagram of a typical monoethanolamine system. The flow diagram for a specific generator may differ significantly depending on design of the components, although overall results are the same.

The combustion process is much the same as previously described except that the combustion chambers are contained in a unit identified as the reboiler-stripper. Heat of combustion is used to boil a recirculating solution of monoethanolamine. Most of the water of combustion in the gas is removed by heat exchangers and separators as described earlier. Gases are then piped to the bottom of the absorber tower, where they pass upward through a counter flow of cooled monoethanolamine solution from the reboiler-stripper, which is introduced at the top of the absorber. Intimate contact between the gas and monoethanolamine is attained with Raschig rings packed in the absorber tower. The upper portion of the reboiler-stripper shown in Fig. 12 is also packed with Raschig rings.

Because cool monoethanolamine, which is basically a water solution containing 12 to 18% monoethanolamine, absorbs carbon dioxide, the CO_2 content of the gases leaving the absorber tower is typically below 0.015%.

The monoethanolamine from the absorber is pumped through a monoethanolamine heat exchanger to the top of the reboiler-stripper. In the reboiler, the heat of combustion from the retort strips the CO_2 from the monoethanolamine. CO_2 and steam from the top of the reboiler-stripper pass through a water-cooled condenser to condense the steam before the CO_2 is vented (Fig. 12).

To reduce the moisture in the gas stream from the top of the absorber, the stream is passed through water-cooled and refrigerant-cooled heat exchangers and then through a dual-chambered desiccant drying system. While one chamber is on the line, the other is being reactivated. Reactivation is accomplished by a separately valved recirculating gas circuit. The volume and pressure of the circuit is maintained by feeding the circuit with a small portion of the discharge gas from the chamber that is on the line. Before being passed through the chamber to be reactivated, the recirculated gas is heated to about 230 °C (450 °F) either electrically or by way of a gas-heated retort. After having passed through the desiccant material in the chamber being reactivated, the water vapor that is picked up by the recirculated gas stream from the desiccant is partially condensed by way of water-cooled heat exchanger. At this point in the closed circuit, a separate gas pump is employed to ensure adequate volume and rate of flow in the recirculated gas stream.

Water vapor of the finished atmosphere is typically lower than 0.02%, or a dew point of less than -40 °C (-40 °F). Accordingly, the prepared nitrogen-based atmosphere is virtually free of carbon dioxide and water vapor, with carbon monoxide and hydrogen contents determined by the air-to-gas ratio fed to the combustion process.

Precautions. In the monoethanolamine process, it is essential that the air-to-gas ratio be maintained on the reducing side to avoid free oxygen in the prepared atmosphere and oxidation of the monoethanolamine. When oxidized, monoethanolamine is much more corrosive than a normal inhibited solution. Antifoaming agents are sometimes necessary in the monoethanolamine to avoid operating problems. Because of the very low surface tension and corrosiveness of monoethanolamine solutions, special care should be given to maintenance of monoethanolamine pumps to avoid leakage through pump-shaft seals.

Generator Maintenance. Rigid adherence to a cookbook recipe for maintenance of any mechanical, electrical, chemical, or electronic system is frequently neither efficient nor effective. A better method is accurate observation of prescribed system performance and adequate records of observations. The following schedules suggest minimum observation and maintenance for each of the two major systems. An adequate schedule of appropriate lubrication of all normal moving components is presumed, as well as a daily review of operator records by the immediate supervisor to detect trends and any need for corrective actions.

The following is a typical generator maintenance schedule for molecular-sieve systems:

Twice per 8-h operating shift

- Observe and record variables such as temperatures, pressures, flow rates, and liquid levels
- Observe and record details of abnormalities such as improper functioning of traps, safety switches, and excessive pump noises or leakage. Where appropriate, consult supervisor regarding the need for immediate corrective actions
- Drain designated nonautomatic traps

Monthly, or as prescribed by standard operating procedures

- Clean or replace all filters and strainers as required
- Lubricate all plug-type valves with appropriate lubricants
- Check operation of fuel safety shutoff valve and all pressure switches
- Clean all traps, unless safety considerations override
- Check the lens of the safety flame detector and clean as required

Complete annual overhaul of the system

- Cleaning heat exchangers, for which chemical cleaning is preferred over mechanical cleaning
- Cleaning, repair, or replacement of all valves, including the safety shutoff valve and the pressure-control relief valve; pressure switches; manometers; sensing lines; traps; and flame scanner and relay
- Replacement of burner block and holder
- Rebuilding of vacuum pumps and compressor as required
- Checking accuracy of all meters, pressure controllers, and pressure switches

Do not overheat the molecular-sieve desiccant. In general, maintenance schedules for monoethanolamine generator systems coincide with those for the molecular-sieve systems except for the following major differences:

- Control amount of foaming in the absorber tower. Use antifoaming agent in monoethanolamine solution as required
- Check monoethanolamine concentration monthly and include additions when required, along with additions of the recommended corrosion inhibitor (typically sodium metavanadate)
- The refrigerator system (for the refrigerant-cooled heat exchanger) should be checked and serviced monthly, also
- Annual servicing should include a check of corrosion characteristics of the monoethanolamine solution. If solution needs to be replaced, the monoethanolamine circuit should be cleaned and boiled out with an appropriate caustic solution
- Although the foregoing statements concerning vacuum pumps and molecularsieve desiccants are not applicable here, a drying tower should not be used beyond its design cycle, contamination should be avoided, and the activated alumina desiccant should not be overheated

Safety Precautions. In general, safety precautions outlined for exothermic-based atmospheres apply equally to prepared nitrogen-based atmosphere generators and usage. Safety precautions as outlined for endothermic-based atmosphere generators and usage are also applicable.

Atmospheres with less than 4% combustibles are underwriter approved for purging, and are approved for furnace operating temperatures below 760 °C (1400 °F) without the requirement that the furnace system be designed for automatic purging in case of electrical power failure or the absence of adequate furnace-atmosphere pressures.

Operating Economics. The following list indicates representative utility requirements for 28 m^3 of atmosphere under so-called standard temperature-pressure conditions (1000 ft^3 under standard temperature-pressure conditions, which is uniformly abbreviated in the English system of units as 1000 scf) for class 201 lean prepared nitrogen-based atmosphere. The following table compares the requirements for a typical molecular-sieve system with a typical monoethanolamine system, with both systems using an air-to-gas ratio of about 9.5 to 1.

Requirement	Molecular sieve	Monoethanolamine

Natural gas, m^3 (scf)	3.77 (133)	3.77 (133)
Electric energy consumption, MJ (kW · h)	28 (7.8)	14.5 (4.0)
Cooling water, L (gal)	2780 (735)	2500 (660)

Commercial Nitrogen-Based Atmospheres

Industrial gas nitrogen-based atmospheres have found technical acceptance in most metalworking applications. The shift of many heat-treating operations to nitrogen atmospheres on some or all of the furnaces accelerated in the late 1970s as a result of shifting economics of hydrocarbon fuel supplies.

Commercial nitrogen-based atmosphere systems employed by the metalworking and heat-treating industry use gases and equipment that are common among all applications. In most instances, the major atmosphere component is industrial gas nitrogen, which is supplied to the furnace from a system consisting of a storage tank, vaporizer, and a station controlling pressure and flow rate. The nitrogen serves as a pure, dry, inert gas that provides an efficient purging and blanketing function within the heat-treating furnace. The nitrogen stream is often enriched with a reactive component, and the resulting composition and flow rate are determined by the specific furnace design, temperature, and material being heat treated. Although there is similarity in the components of commercial nitrogen-based atmosphere systems, the flexibility of controlling atmosphere composition and flow rate independently over a wide range provides very different end-use characteristics.

Types of Commercial Nitrogen-Based Atmospheres. Therefore, the classification of commercial nitrogen-based atmosphere systems is appropriately made according to three major categories of atmosphere function--protection, reactivity, and carbon control--rather than by gas or equipment components.

Protective Atmospheres. The atmosphere systems required for these applications must prevent oxidation or decarburization of the metal surface during heat treatment. Such detrimental reactions normally would occur because of residual oxygen or water vapor present in the furnace as a result of air leaks or inadequate purging. Typical applications include batch and continuous annealing of most ferrous and nonferrous metals. Atmosphere systems employed may be pure nitrogen or nitrogen blended with small quantities (usually less than 5%) of a reactive gas such as hydrogen, methane, propane, or methanol vapor. Reactive gases reduce gaseous oxides present in the furnace atmosphere or reduce surface metal oxides. These systems are best employed to prevent oxidation of relatively clean metal surfaces rather than to remove gross oxidation of hot-worked or forged materials.

Reactive Atmospheres. These atmosphere systems require a concentration of reactive gases greater than 5% to reduce metal oxides or to transfer a small amount of carbon to ferrous materials. The reactive components are generally hydrogen and carbon monoxide. The concentrations depend on the amount of oxide to be removed and the level of reaction products, water vapor, and carbon dioxide, that are formed in the furnace atmosphere. Typical applications include brazing, powder-metal sintering, and powder-metal reduction.

Carbon-Controlled Atmospheres. The main function of these nitrogen-based atmosphere systems is to react with steel in a controlled manner so that significant amounts of carbon can be added to or removed from the steel surface. Significant change in the surface chemistry of the steel occurs in these heat-treating applications. These atmosphere systems are characterized by high concentrations of reactive gases in nitrogen and by the requirement that the rate and amount of carbon transfer must be controlled by the atmosphere composition. Typical atmosphere components may include 10 to 50% hydrogen (H_2), 5 to 20% carbon monoxide (CO), and trace amounts (up to 3%) of carbon dioxide (CO_2) and water vapor (H_2O). The most common applications using a carbon-controlled atmosphere include carburizing and carbonitriding of machined parts, neutral hardening, electrical-lamination decarburization annealing, powder-metal sintering, and carbon restoration of hot-worked or forged materials.

Table 7 describes heat-treating applications that are presently using nitrogen-based atmosphere systems. The major components of the generated atmosphere most commonly used for each application are compared to the nitrogen-based alternatives that are presently in use.

Table 7 Comparison of generated atmosphere systems versus commercial nitrogen-based systems

Type of atmosphere	Application	Generated atmosphere				Nitrogen-based atmosphere				
		Designation	Nominal composition, %			Designation	Nominal composition, %			
			N_2	H_2	CO		N_2	H_2	CO	CH_4
Protective	Annealing	Exothermic	70-100	0-16	0-11	Nitrogen-hydrogen	90-100	0-10	. . .	. . .
						Nitrogen-methanol	91-100	0-6	0-3	. . .
		Dissociated ammonia	25	75	. . .	Nitrogen-hydrogen	60-90	10-40	. . .	. . .
Reactive	Brazing	Exothermic	70-80	10-16	8-11	Nitrogen-hydrogen	95	5	. . .	. . .
		Dissociated ammonia	25	75	. . .					
	Sintering	Endothermic	40	40	20	Nitrogen-hydrogen	95	5	. . .	. . .
		Dissociated ammonia	25	75	. . .	Nitrogen-methanol	85	10	5	. . .
Carbon controlled	Hardening	Endothermic	40	40	20	Nitrogen-methane	97	1	1	1
	Carburizing	Endothermic	40	40	20	Nitrogen-methanol	40	40	20	. . .
	Decarburizing	Exothermic	85	5	3	Nitrogen-	90	10	. . .	. . .

Advantages of Commercial Nitrogen-Based Atmospheres. A nitrogen-based atmosphere system provides a technically viable substitute for generated atmospheres in most heat-treating applications. Although the desired results are often the same with either a commercial nitrogen-based system or a conventional atmosphere generator, there are some significant differences in equipment, operation, and function among these systems that should be understood before making the conversion from a generator to commercial nitrogen.

A generated atmosphere provides a fixed composition of output, which is determined by the input ratio of air to hydrocarbon, the scrubbing and purification process equipment of the generator, and the relative condition of the equipment and catalysts. The commercial nitrogen-based system generally starts with elemental components stored in

separate vessels, blends the desired atmosphere composition, and introduces it into the furnace. The resulting composition can be varied at different times during the cycle and at different locations within the furnace.

Most components of commercial nitrogen-based atmosphere systems are produced either by cryogenic processes or by chemical refining. As a result, the impurity levels are low, usually less than 20 ppm total impurity for liquid nitrogen, as an example. Further, because there are no by-products of air-fuel mixtures, the resulting atmosphere blend often has a dew point of less than -60 °C (-80 °F) and oxygen or carbon dioxide impurity levels of less than 10 ppm.

The reducing or carburizing potential of an atmosphere is determined by several reactions and their associated equilibrium constants. Included among these are:

$FeO + H2$ € $Fe + H_2O$ **(Eq 34)**

$Fe + 2CO$ € $FeC + CO_2$ **(Eq 35)**

$Fe + CO + H_2$ € $FeC + H_2O$ **(Eq 36)**

Because commercial nitrogen-based blends significantly reduce the amount of water vapor and carbon dioxide in the furnace atmosphere, the level of the reactive gases can also be reduced while maintaining acceptable thermodynamic potentials in the above ratios. The net result is that generated atmospheres that contain as much as 60% combustible products are often replaced with nitrogen blends containing less than 10% hydrogen and carbon monoxide. Many heat-treating atmosphere applications can be converted from combustible to noncombustible compositions in conjunction with the switch to a commercial nitrogen-based system.

Because elemental components are available, commercial nitrogen-based heat-treating practice may start with a pure nitrogen purge to eliminate oxygen from the surface. During the heat-treating cycle, a very reactive blend may be used to bright anneal heavily oxidized parts, during cooling, a less reactive protective atmosphere, and finally a pure nitrogen purge to eliminate combustibles before opening the furnace.

Because the composition of a nitrogen atmosphere may be varied with time, it may also be controlled according to the functions of different zones of the heat-treating furnace. For example, in a three-zone powder-metal sintering furnace, a pure nitrogen purge curtain may be used on both ends to reduce air infiltration. The presintering zone may be supplied with a reducing atmosphere with controlled ratio of H_2 and H_2O. Dew-point control supplies sufficient water vapor for efficient breakdown and removal of vaporized lubricants from the powder compact. The sintering zone may use a nitrogen-hydrogen-carbon monoxide blend to provide a highly reducing atmosphere with a slight carbon potential to provide the required sintered strength and metal composition. In the cooling section, it may be necessary to add only a nitrogen protective atmosphere to bring the parts back to room temperature in a clean, nonoxidized condition. In a single-zone sintering furnace, this same ability can be used to expand the range of processes that can be utilized.

The ability to control composition also allows flexibility of the overall flow rate during the heat-treating cycle. The most common advantage of this characteristic is the use of a high flow rate during charging of furnaces equipped with doors. When the door is opened, a microswitch initiates a purge flow of nitrogen to reduce air infiltration into the furnace. After the door is closed, the atmosphere flow rate returns to a level required to maintain adequate pressure in the closed furnace and to perform the required gas-metal surface reactions.

In commercial nitrogen-based applications where the hydrogen content of the atmosphere is significantly reduced from the generated atmosphere composition, it is often possible to achieve a flow rate reduction because of atmosphere density. The most frequent examples of this occur in protective atmosphere applications in which endothermic gas (40% H_2) (Fig. 13a) or dissociated ammonia (75% H_2) (Fig. 13b) is replaced with a nitrogen-hydrogen blend of less than 10% H_2. In these instances, the atmosphere density changes from a specific gravity of 0.295 for dissociated ammonia to 0.595 for endothermic, or to 0.90 for the nitrogen-hydrogen blend. This increase in atmosphere density is responsible for increased furnace pressurization and more efficient purging of impurities from the furnace. Experience shows that an average 10 to 20% flow rate reduction may be achieved relative to the flow rates of generated atmosphere with lower densities.

Components of Commercial Nitrogen-Based Atmosphere System. The basic components of an industrial gas atmosphere system are illustrated in Fig. 14. Figure 14(a) shows a nitrogen-hydrogen protective atmosphere system used for annealing, brazing, and sintering. Figure 14(b) is a nitrogen-methanol system typical of those used for carburizing. In both instances, there are three basic parts to the commercial-nitrogen system: the storage vessels containing the elemental atmosphere components, the blend panel used to control the flow rate of each constituent gas, and the piping and wiring required for safe operation compatible with the furnace design.

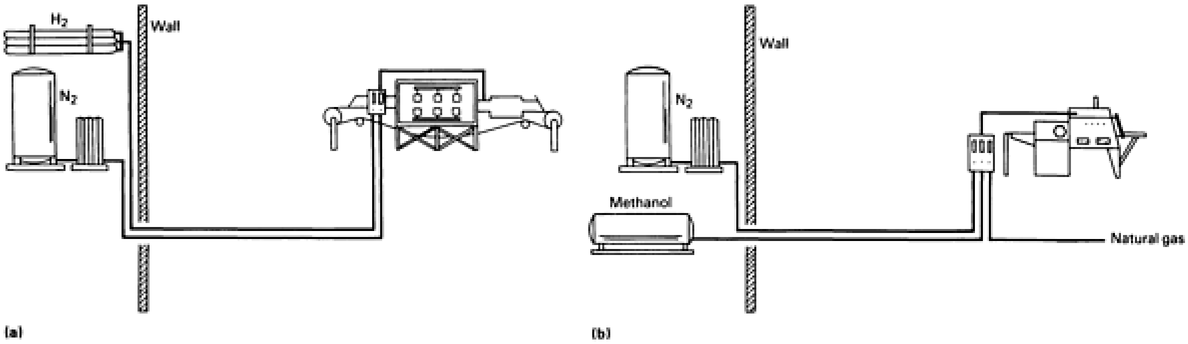

Fig. 14 Industrial-gas nitrogen-based atmosphere processes. (a) Protective atmosphere using H_2 and N_2. (b) Carbon-controlled atmosphere using methanol and natural gas

Nitrogen is the main component of most commercial nitrogen-based systems. Because nitrogen is noncorrosive, special materials of construction are not required, except that they must be suitable for the temperatures of liquid nitrogen. Tanks may be spherical or cylindrical in shape. Figure 15 illustrates a typical liquid nitrogen tank. Sizes range from 2270 to 37,850 L (600 to 10,000 gal).

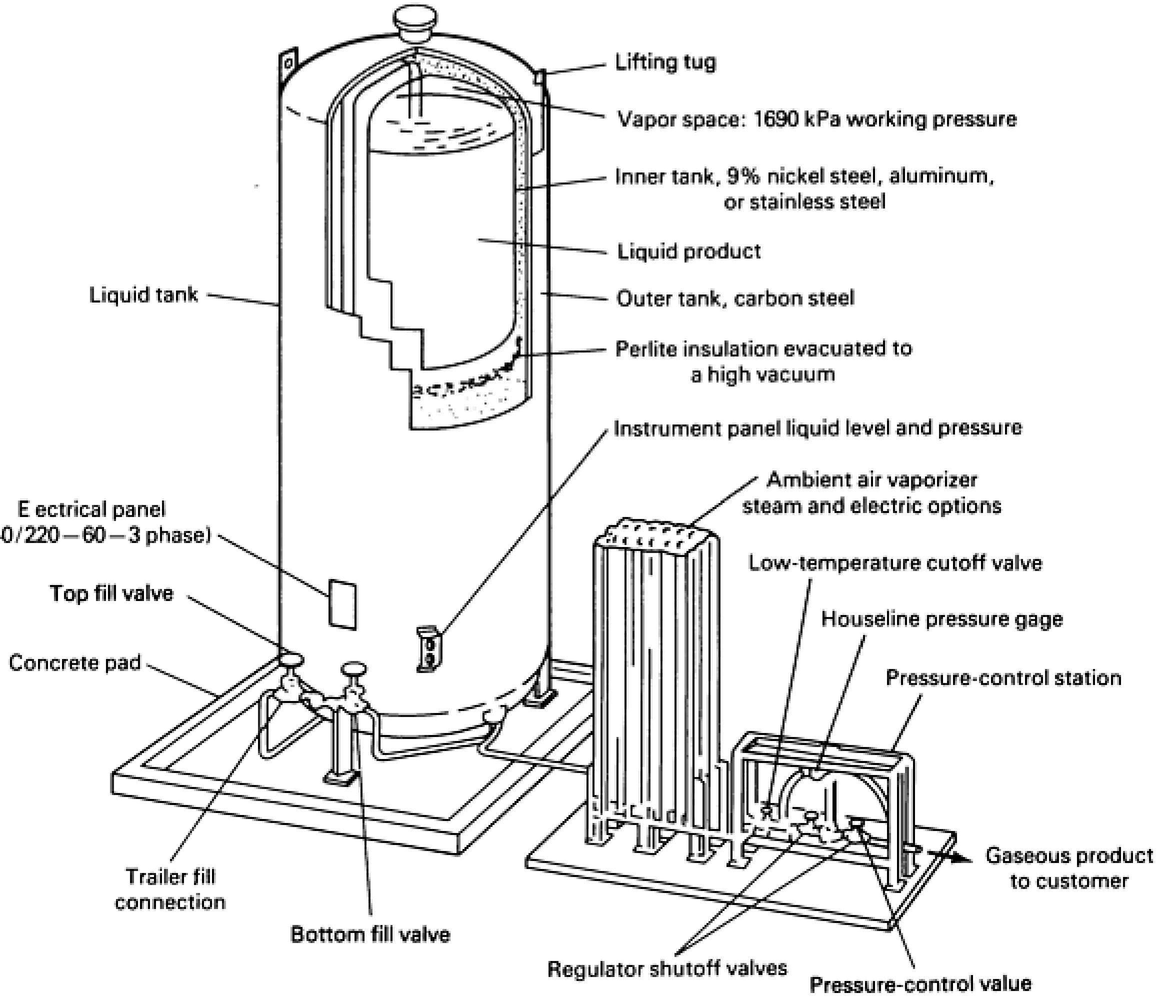

Fig. 15 Typical liquid nitrogen storage facility

Hydrogen is used as a reactive reducing gas for many heat-treating atmosphere applications. In commercial nitrogen-based systems, it is normally blended as a gas with nitrogen to form an atmosphere composition of 90% nitrogen, 10% hydrogen.

Liquid hydrogen is normally stored in tanks from which it is vaporized and used as a gas. Hydrogen may also be delivered and stored as a gas. Tube trailers are available in capacities to 3570 m^3 (126,000 scf) of hydrogen with up to 16,960 kPa (2460 psig) pressure. Modules are available in 3- to 18-tube configurations with capacities to 4250 m^3 (150,000 scf) of hydrogen.

In commercial nitrogen-based atmospheres, methanol is used as a source of hydrogen and carbon monoxide for reactive and carbon-controlled atmosphere systems. Methanol is delivered to the furnace as either a liquid or a vapor. When it is exposed to furnace temperatures greater than 760 °C (1400 °F), the methanol dissociates according to the following reaction:

$$CH_3OH \rightarrow 2H_2 + CO \qquad \textbf{(Eq 37)}$$

Methanol is classified by the U.S. Department of Transportation (DOT) as a flammable liquid. When shipped by rail, water, or highway, it must be packaged in authorized containers, and shippers must comply with all DOT regulations regarding loading, handling, and labelling.

Before any connection or contact is made between the tank truck and the unloading line or other unloading equipment, the tank truck should be electrically grounded. *Caution: All containers filled from the truck should be bonded (electrically connected) and grounded to the truck before filling operations are started.*

Air pressure should never be used for unloading tank trucks of methanol. Nitrogen pressure can be used as long as the methanol tank is a pressure vessel. Because the bulk storage of methanol in above- and below-ground tanks requires consideration of such factors as size of vents, diking, and separation distances, which in turn depend on other variables such as nature of the tank contents, tank-wall thickness, or protection, it is recommended that tank storage requirements be determined through consultation with qualified fire-protection engineers. (For guidance, refer to National Fire Protection Association pamphlet NFPA 30 or Factory Mutual Handbook of Industrial Loss Prevention.) Figure 16 shows an example of underground methanol storage.

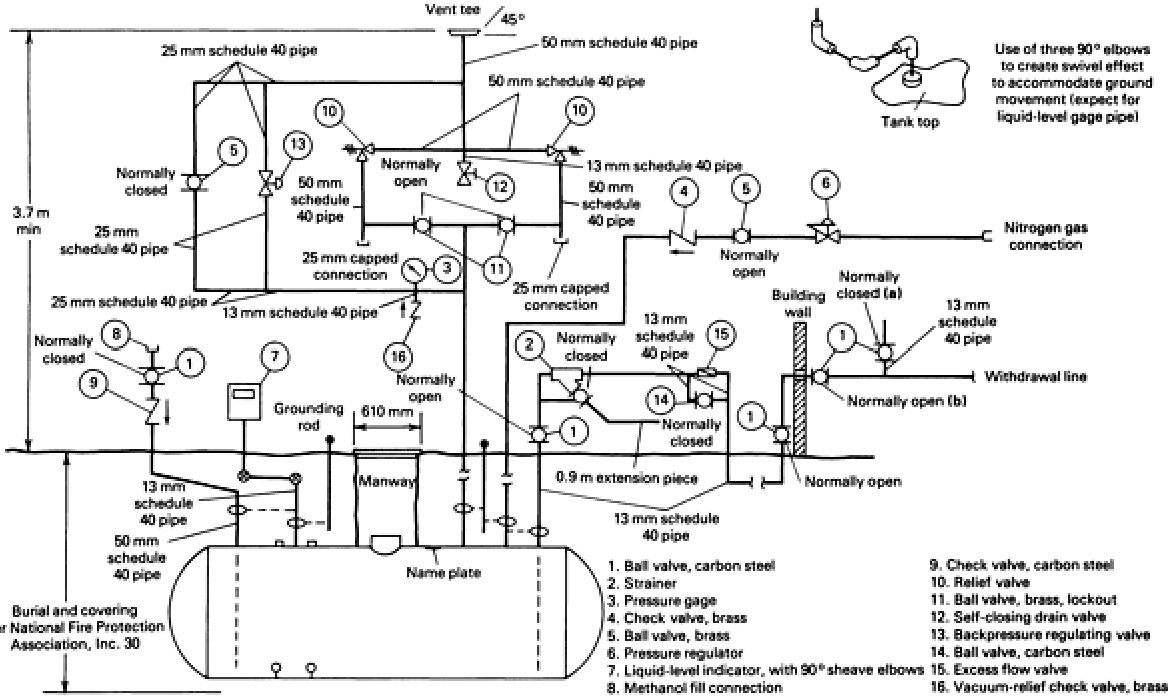

Fig. 16 Flow diagram of typical underground methanol storage. (a) Vapor bleed valve to be located at the high point of the houseline piping. (b) This valve can be eliminated if methanol piping between tank withdrawal connection and inlet to building is less than 6 m (20 ft) long.

Blending Equipment. Blending and flow-control systems for commercial nitrogen-based atmospheres are designed to be consistent with NFPA guidelines for generated atmospheres as well as with Factory Mutual guidelines. However, because gaseous components of the commercial nitrogen atmosphere system are independent with regard to storage, pressure, and flow rate, certain differences exist compared with atmosphere generator operation. The blending system ensures safe operation in both normal and emergency situations compatible with furnace design and processing conditions. Figure 17 illustrates generalized blending equipment schematics for two types of commercial nitrogen-based atmospheres. These schematics are consistent with the storage supply illustrations for protective and carbon-controlled atmosphere systems shown in Fig. 14.

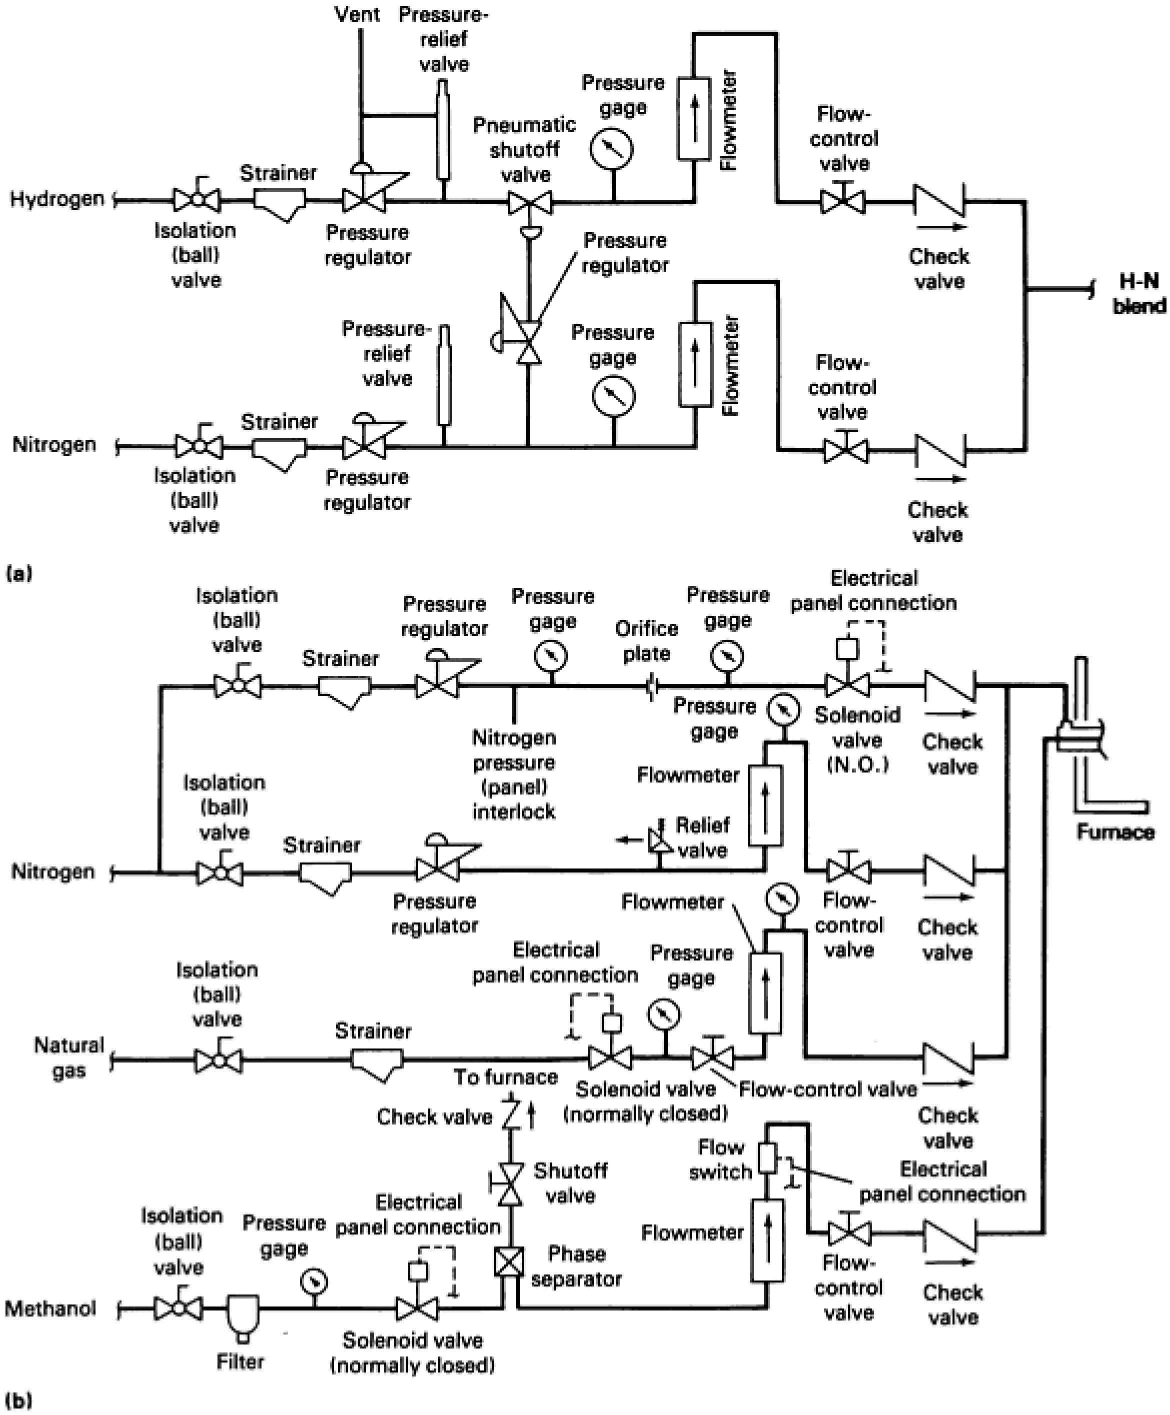

Fig. 17 Flow diagrams of commercial nitrogen-based atmosphere-blending equipment. (a) Two-component blend system. (b) Three-component blend system

In most applications, nitrogen is the predominant component, comprising 50 to 100% of the atmosphere. The enriching gas is typically hydrogen, but it may also be methane, propane, or liquid methanol. Figure 17 shows a two-component blend system. Each leg consists of a pressure regulator, relief valve, pressure gage, flowmeter, control valve, and check valve. Nitrogen pressure is used to open a normally closed pneumatic valve on the hydrogen leg. It is, therefore, not possible for the combustible gas to flow into the furnace until the nitrogen is also available for flow. If nitrogen pressure is lost for any reason, flow of the combustible component will be interrupted automatically. An alternative method of interlocking combustibles to the nitrogen is through use of a nitrogen flow sensor. Typically this will be done by a flow switch or by a magnetic sensor on the nitrogen flowmeter. The hydrogen-shutoff solenoid also should be interlocked to

furnace temperature to prevent the flow of the combustible component into a furnace at less than 760 °C (1400 °F) to prevent the formation of an explosive mixture.

Figure 17(b) shows a nitrogen-methanol-methane blend panel typically used for carburizing applications. The design is more complex than the protective-atmosphere system because of the number of components and the more involved nature of the batch-carburizing process for which this methanol panel is designed.

Each leg typically consists of the same major components as the two-component system in Fig. 17(a): pressure regulator, relief valve, pressure gage, flowmeter, flowcontrol valve, and check valve. Because the combustible components are interlocked to nitrogen pressure, a loss of nitrogen pressure will shut off the methanol and methane. The combustibles are also interlocked to furnace temperature and to the electrical power supply to the furnace and panel. A drop in furnace temperature below 760 °C (1400 °F) or a loss of electric power will shut off the combustibles.

This panel typically includes a separate nitrogen-purge system that is preset with a pressure regulator orifice plate flow control. In the event of low furnace temperature or electric power loss, an alarm sounds, the nitrogen purge commences, and flow of combustibles is shut off. The nitrogen purge is also interlocked to the inner furnace doors through a microswitch circuit so that charging or quenching a load will initiate the high-flow purge. In this mode, the purge will last from 5 to 60 min.

Commercial Nitrogen-Based Atmosphere Applications. Tables 8, 9, and 10 compare commercial nitrogen-based atmospheres with comparable generated atmospheres used in relevant heat-treating processes. Shown are the generated atmospheres typically in use and the nitrogen-based alternative. Protective atmosphere applications in Table 8 indicate the potential of commercial nitrogen-based atmospheres as alternatives to exothermic, endothermic, and dissociated ammonia atmospheres in a broad range of annealing operations. The nitrogen-based alternatives illustrated are pure nitrogen, nitrogen-hydrogen, nitrogen-methanol, and nitrogen-hydrocarbon.

In most instances, the nitrogen atmosphere has a lower level of combustible components, carbon monoxide and hydrogen. The nitrogen atmosphere also will normally contain lower trace impurities, carbon dioxide and water vapor. In some applications, more than one system is applicable, depending on the furnace design and the grade of material processed.

Reactive atmospheres are required for such heat-treating applications as brazing and powder-metal sintering. The atmosphere reacts with the metal surface to remove all metal oxides. In brazing, a chemically clean metal surface is required to ensure proper filler-metal flow and diffusion of the filler metal into the base metal. In powder-metal sintering, reduction of powder surface oxides is necessary to promote diffusion and thus to obtain effective bonding within the powder compact. The reactive nature of these atmospheres also applies to carbon transfer. In brazing, residual carbonaceous lubricants on the materials and organics in the brazing paste must be removed by the atmosphere for proper flow of filler metal. In carbon steel powder-metal sintering, lubricants must be removed in one section of the furnace and carbon made available to the steel in another section to achieve proper part chemistry. Table 9 summarizes the compositions of reactive atmosphere alternatives, both with respect to major constituents and to trace impurities.

Carbon-controlled atmospheres transfer carbon from the atmosphere to the surface of the metal part ($\overline{C}$) through controlled gas-metal reactions. The two most common reactions are:

$$2CO \text{ € } \overline{C} + CO_2 \quad \textbf{(Eq 38)}$$

$$CO + H_2 \text{ € } \overline{C} + H_2O \quad \textbf{(Eq 39)}$$

Because carbon transfer is required of many of these applications, it is common to find higher concentrations of carbon monoxide and hydrogen in these atmospheres than in the protective and reactive atmospheres. The compositions of typical carbon-controlled atmosphere systems are provided in Table 10.

Carbon-controlled atmosphere systems are used in surface carburizing steel parts, in neutral hardening, and in decarburize annealing of steel motor laminations. The essential requirement of all applications using these atmospheres is control. In neutral hardening, the atmosphere carbon potential must match the surface carbon of the steel to prevent decarburization or carburization. The surface carburization of steel parts requires not only the desired carbon potential in the atmosphere, but also the correct carbon availability to provide the proper case depth. Decarburization of motor and transformer laminations requires controlled carbon removal from the steel without unwanted oxidation of the steel surface. The systems presently employed in these applications are exothermic- and endothermic-generated atmospheres, and nitrogen-hydrocarbon and nitrogen-methanol blended atmosphere systems.

Dissociated Ammonia-Based Atmospheres

Dissociated ammonia (class 601) is a medium-cost prepared furnace atmosphere providing a dry, carbon-free source of reducing gas. Typical composition is 75% hydrogen, 25% nitrogen, less than 300 ppm residual ammonia, and less than -50 °C (-60 °F) dew point.

Principal uses of dissociated-ammonia furnace atmosphere include bright copper and silver brazing; bright heat treating of selected nickel alloys, copper alloys, and carbon steels; bright annealing of electrical components; and as a carrier mixed gas for certain nitriding processes, including the Floe system of nitriding, which is a method of controlling white layer formation.

The high hydrogen content affords a strong deoxidizing potential, which is an advantage in removing surface oxides or preventing oxide formation during high-temperature heat treatment. Care should be exercised, however, in selecting heat-processing applications that might result in unwanted hydrogen embrittlement or surface-nitriding reactions.

Other less general uses involve dissociated ammonia fully or partially burned with air in a slightly modified exothermic-gas generator. These secondary atmospheres fall into two general classifications: lean combusted ammonia (class 621), which is considered inert and nonflammable with from 0.25 to 1.0% hydrogen and the remainder nitrogen, and rich combusted ammonia (class 622), which is a moderately reducing atmosphere usually containing from 5 to 20% hydrogen

and the balance nitrogen. A very high moisture content is present following combustion and primary cooling. It is often necessary to further dehydrate these gases with additional equipment in the form of refrigerant and desiccant dryers. These treated gases provide very high-quality atmospheres of low-to-moderate reducing ability. Practical uses, however, are restricted because the process requires consumption of relatively costly anhydrous ammonia as the primary feedstock and because added investment is required in addition to operating costs of exothermic generators and dryers.

Required Equipment. Dissociated ammonia ($N_2 + 3H_2$) is produced from commercially supplied anhydrous ammonia (NH_3) with an ammonia dissociator. This equipment raises the temperature of ammonia vapor in a catalyst-filled retort to approximately 900 to 980 °C (1650 to 1800 °F). The gas is then cooled for metering and transport as a prepared atmosphere. At these reaction temperatures in the presence of catalyst, ammonia vapor dissociates into separate constituents of hydrogen and nitrogen. The simplified reaction is:

$$2NH_3 + \text{heat} \rightarrow N_2 + 3H_2 \qquad \textbf{(Eq 40)}$$

where two volumes of ammonia vapor yield four volumes of dissociated ammonia.

The basic ammonia dissociator (Fig. 18) consists of either an electrically heated or gas-fired chamber containing one or more catalyst-filled alloy retorts, followed by a water-cooled indirect heat exchanger. Operation is simple and continuous, incorporating a product gas flowmeter with either manual or automatic process flow control, and suitable automatic heating-chamber temperature controls. Safety devices include items such as pressure switches, temperature-monitoring instruments, and pressure-relief valves. Periodic checks of operation consist of observing pressures, temperature, and flow rate, and occasional analysis of product gas for unreacted ammonia content.

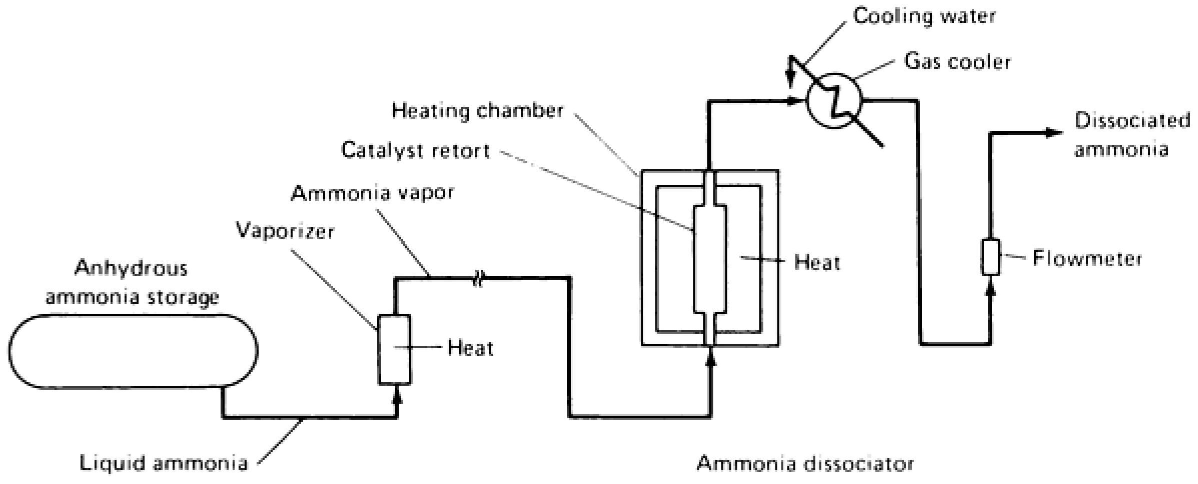

Fig. 18 Simplified process schematic of ammonia dissociator system

Liquid anhydrous ammonia as a feedstock material is obtained by commercial delivery in pressurized cylinders, by pressurized tank truck, or by rail tank car. The ammonia is transferred to a stationary on-site bulk storage vessel. Because liquid ammonia is supplied at high pressure, only pressure and flow regulation are required for conveyance to points of use.

To ensure suitable and efficient dissociator operation, liquid ammonia should first be converted to vapor, usually with a tankmounted vaporizer. This is a chamber using an immersion-type electric heater or steam coil. Some smaller dissociators may have a self-contained vaporizer using residual process heat, thus permitting operation directly from cylinder supplies.

Operating Economics. Typical operating consumptions to produce 28 m^3 (1000 ft^3) of dissociated ammonia are:

Consumption	Value
Anhydrous ammonia, kg (lb)	10 (22.0)
Dissociator electric energy, MJ (kW · h)	75 (21)
Vaporizer electric energy, MJ (kW · h)	14 (3.9)
Cooling water, L (gal)	284 (75)

To obtain the highest-quality furnace atmosphere and to minimize possible dissociator maintenance, an oil-free metallurgical grade of ensured dry anhydrous ammonia should be used.

Safety Precautions. *Caution: Ammonia vapor and dissociated ammonia are flammable when mixed in certain proportions of air.* They should be treated with any combustible gas relative to handling or to its use as a furnace atmosphere. Ammonia vapor also is extremely corrosive to certain materials such as copper and copper-bearing alloys. Care should be taken in the selection of piping materials and other devices in contact to prevent corrosion failure and resultant leaks. *Caution: Additionally, because ammonia is stored at high pressure and has a high rate of expansion, stored cylinders should not be exposed to temperatures exceeding 50 °C (120 °F), otherwise dangerously excessive pressures will result.* Ammonia piping above 25 mm (1 in.) diam should have welded steel joints with adequate pressure rating, and extra-heavy (schedule 80) steel pipe should be used.

Ammonia may also cause certain physiological effects in air concentrations over 100 ppm, resulting in eye and respiratory irritation (see Table 11). It is extremely pungent, however, and the strong odor will generally give adequate warning of any leak.

Table 11 Physiological effects of contamination of air by ammonia in various concentrations

Ammonia concentration in air, ppm	Physiological effect
53	Smallest concentration at which odor can be detected
100	Maximum concentration allowable for prolonged exposure
300-500	Maximum concentration allowable for short exposure ($\frac{1}{2}$-1 h)
408	Least amount causing immediate irritation to the throat
698	Least amount causing immediate irritation to the eye
1720	Least amount causing coughing

2500-4500	Dangerous for short exposure ($\frac{1}{2}$ h)
5000-10,000	Rapidly fatal for short exposure

Caution: Dissociated ammonia with its high percentage of hydrogen makes it necessary to establish furnace operating practices appropriate for hydrogen atmospheres, and these should be carefully observed. Particularly important are safety procedures associated with nitrogen purging to prevent air infiltration. Adequate internal furnace circulation should be used to avoid entrapment of the low-density gas in upper portions of furnace chambers. Most ammonia dissociators are monitored with safety devices, which should be periodically tested to ensure fail-safe operation.

Hydrogen Atmospheres

Commercially available hydrogen is 98 to 99.9% pure. All cylinder hydrogen contains traces of water vapor and oxygen. Methane, nitrogen, carbon monoxide, and carbon dioxide may be present as impurities in very small amounts, depending on the method of manufacture. Hydrogen is produced commercially by a variety of methods, including the electrolysis of water, the catalytic conversion of hydrocarbons, the decomposition of ammonia, and the water-gas reaction. It is also obtained as a by-product in the electrolytic manufacture of sodium hydroxide and the catalytic cracking of petroleum oils.

Hydrogen is a powerful deoxidizer, and its deoxidizing potential is limited by moisture content only. Its thermal conductivity is approximately seven times that of air. Its principal disadvantage is that it is readily absorbed by most common metals, either by occlusion or by chemical combination, at elevated temperature. Absorption of hydrogen can result in serious embrittlement, especially in high-carbon steels. It may also reduce oxide inclusions in steel to form water, thus building sufficient pressure at elevated temperature to cause intergranular fracture of the steel. Dry hydrogen will decarburize high-carbon steels at elevated temperature by reacting with carbon to form methane.

Impurities. The hydrogen best suited for metallurgical purposes is made by the electrolysis of distilled water. In most heat-treating procedures requiring hydrogen, water vapor and oxygen are objectionable, and the hydrogen must be purified before it can be used. Oxygen is removed by a room-temperature catalytic process that combines the oxygen with hydrogen to form water vapor. Essentially all water vapor is then removed by means of activated-alumina dryers, yielding a gas with a dew point of -50 °C (-60 °F). See Fig. 19 for a curve relating dew point and moisture content.

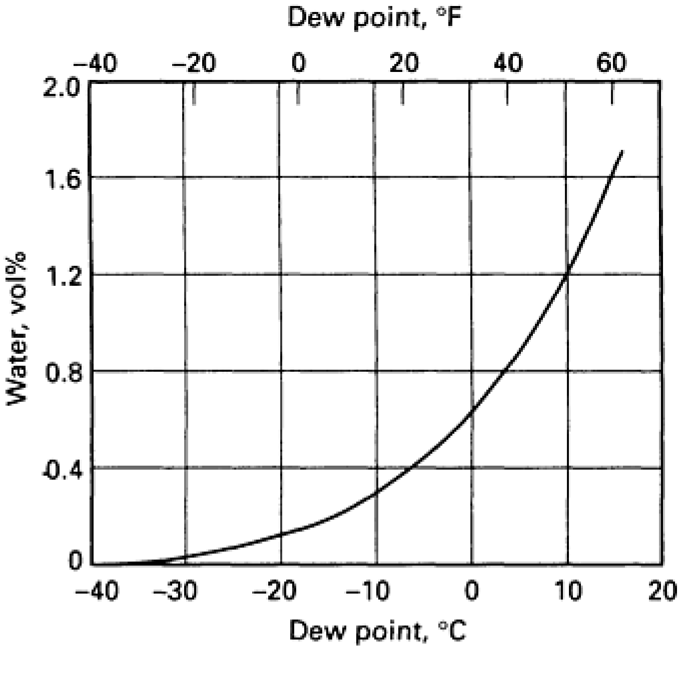

Fig. 19 Relationship between dew point and moisture content of gases

Applications. Dry hydrogen is used in the annealing of stainless and low-carbon steels, electrical steels, and several nonferrous metals. It is used also in the sintering of refractory materials such as tungsten carbide and tantalum carbide, in the nickel brazing of stainless steel and heat-resisting alloys, and in copper brazing, direct reduction of metal ores, annealing of metal powders, and the sintering of P/M compacts. Data relating to metal-oxide equilibriums in hydrogen atmospheres are given in Fig. 20.

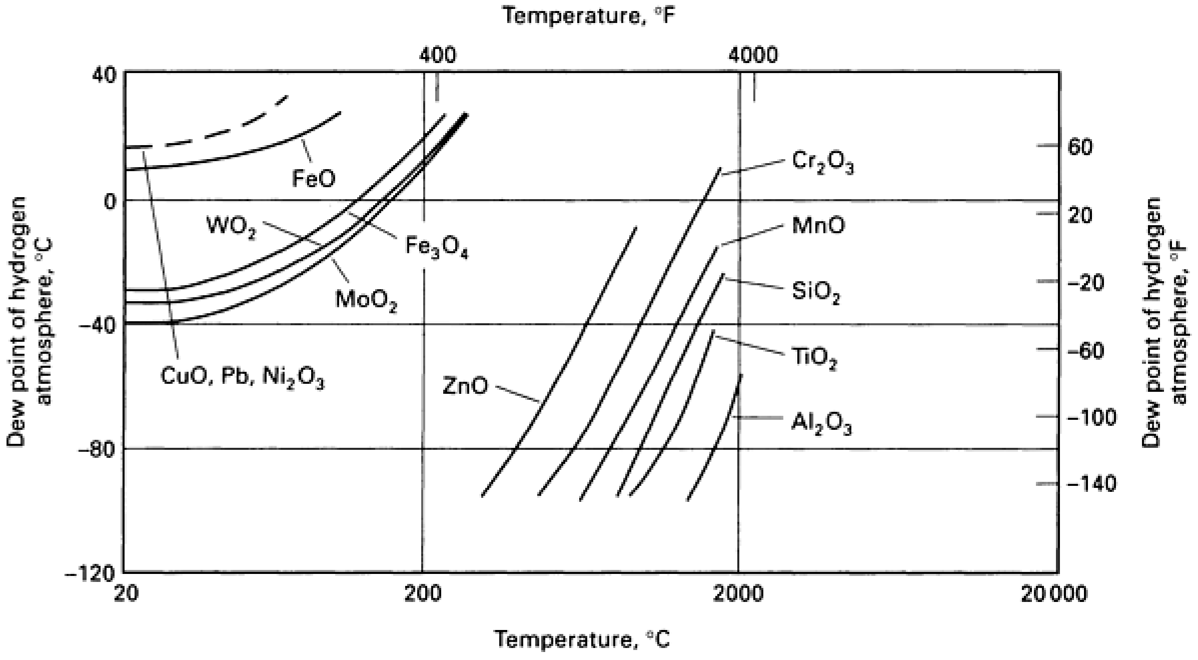

Fig. 20 Metal-metal oxide equilibriums in hydrogen atmospheres

Example 1: Sintering of Stainless Steel P/M Parts in Hydrogen.

Stainless steel powder parts are sintered in a dry (-40 °C, or -40 °F dew point) hydrogen atmosphere at 1275 °C (2325 °F), following preheating in dissociated ammonia at 425 °C (800 °F). Electric furnaces are used for both preheating and sintering. Details of the equipment used are given in Table 12.

Table 12 Equipment requirements for sintering stainless steel powder metallurgy parts in hydrogen

Production requirements	
Load weight, kg (lb)	9 (20)
Heating cycle, min	40
Output per hour, kg (lb)	14 (30)
Equipment requirements

Atmosphere, m^3/h (ft^3/h)	Dissociated ammonia, 4.2 (150)
High-heat furnace	Open chamber, electrically heated; front push, rear pull
Size of hearth, mm (in.)	255 by 610 (10 by 24) (preheating) 255 by 915 mm (10 by 36 in.) (high heating)
Length of cooling chamber, mm (ft)	2.4 (8)
Power, hp (kW)	47 (35)
Operating temperature, °C (°F)	1275 (2325)
Atmosphere, m^3/h (ft^3/h), °C (°F)	Dry hydrogen, 9.9 (350); dew point, -40 (-40)

Supply. Hydrogen is usually obtained in cylinders. Small quantities are supplied at a pressure of 14 MPa (2 ksi) in steel cylinders that contain 5.5 m^3 (193 ft^3) of hydrogen measured at standard conditions of 20 °C (68 °F) and atmospheric pressure. Larger quantities can be supplied in banks of about 12 interconnected cylinders that are mounted on portable dollies and contain a total of about 90 m^3 (3200 ft^3) of gas. For even larger requirements, trailers are used, containing a total of 810 m^3 (28,600 ft^3) of hydrogen at 17 MPa (2.5 ksi); the capacity of a railroad tank car is 5665 m^3 (200,000 ft^3).

In-Plant Generators. Large amounts of hydrogen are supplied by generators that decompose ammonia or partially burn hydrocarbon fuels. Purification is accomplished by adsorption of unwanted gases or by diffusion of raw hydrogen through molecular filters that are capable of producing a gas of 99.5% purity.

Safety. *Caution: The explosive range of hydrogen in air is so great that it should be considered explosive in all ranges.* Whenever hydrogen is used in a furnace, an adequate supply of inert gas for purging should be readily available, either from storage or from a generator. Nitrogen and products of combustion are commonly used for purging.

Steam Atmospheres

Steam may be used as an atmosphere for scale-free tempering and stress relieving of ferrous metals in the temperature range of 345 to 650 °C (650 to 1200 °F). The steam causes a thin, hard, and tenacious blue-black oxide to form on the metal surface. This oxide film, which is about 0.00127 to 0.008 mm (0.00005 to 0.0003 in.) thick, improves certain properties of various metal parts.

Effects of Steam Treating. The service life of cutting edges of high-speed steel tools such as drills, reamers, taps, and milling cutters is increased from 50 to 100% when the tools are steam treated after being tempered and finish ground. During machining operations, the oxide film prevents metal chips from welding to the tool and retains cutting oil to reduce heat of friction.

Steam treating decreases the porosity of sintered iron compacts and provides increased compressive strength and resistance to wear and corrosion. Steam penetrates the pores of compacts and forms the oxide internally as well as on the surface. The oxide seals the pores and partially fills the voids, thus increasing compressive strength. The hardness of the film, in addition to its ability to hold oil, increases wear resistance. The density of the film, coupled with its ability to retain oil, increases corrosion resistance.

Cast iron and steel parts steam treated at 345 °C (650 °F) or higher have increased resistance to wear and corrosion. Steam-treated cast iron valve bodies also have less porosity.

Processing Considerations. Before parts are processed in steam atmospheres, their surfaces must be clean and oxide-free, to permit the formation of a unique coating. To prevent condensation and rusting, steam should not be admitted until workpiece surfaces are above 100 °C (212 °F). Air must be purged from the furnace before the temperature exceeds 425 °C (800 °F), to prevent the formation of a brown coating instead of the desired blue-black coating.

Charcoal-Based Atmospheres

Charcoal-based atmosphere generators (AGA classes 402 to 421), which are on the way to becoming obsolete, are now used mainly by small-scale manufacturing plants that desire a generator of low initial cost for intermittent operation. The principal uses of charcoal-based atmospheres at present are for the manufacture of malleable iron castings and for providing atmosphere in small toolroom heat-treating furnaces.

Composition and characteristics of a class 402 charcoal-based atmosphere are given in Table 3. These gases are produced by passing air through a bed of hot charcoal. The air is supplied by a blower and measured by a flowmeter. Incoming air burns with the charcoal at the bottom of the combustion chamber to form a mixture of nitrogen, carbon dioxide, and water vapor. This reaction heats the charcoal in the upper portion of the combustion chamber to incandescence. The incandescent charcoal converts carbon dioxide to carbon monoxide and water vapor to hydrogen. These hot, dry gases pass around the charcoal storage hopper, heating the charcoal and driving off the moisture and volatile matter through a burnoff can at the top of the hopper. The hot, dry atmosphere is taken off at the side of the generator and passed through a filter to remove fly ash.

Charcoal-based atmosphere is produced by the reaction:

$$2C + O_2 + 3.8N_2 \rightarrow 2CO + 3.8N_2 \qquad \textbf{(Eq 41)}$$

Theoretically, this reaction would produce 34% CO and 66% N_2. Actually, however, the following mixture is normally obtained because of moisture and volatiles in the charcoal and the less-than-100% efficiency in converting all of the carbon dioxide:

Atmosphere constituents	**Concentration, %**
CO_2	1.0-2.0
CO	30.0-32.0

H_2	1.5-7.0
CH_4	0.0-0.5
N_2	bal

Although the generator may operate at as low as 50% of rated capacity, lower percentages of carbon dioxide and water vapor are attained at the rated output because of the hotter charcoal bed. The type of charcoal used also influences hydrogen and water-vapor content of the atmosphere.

Normally, the atmosphere is neutral to higher-carbon steels, but the carbon potential may be increased by additions of about 0.5% of natural gas in the furnace, causing further breakdown of carbon dioxide and water vapor in the atmosphere. Channeling of gases through the incandescent charcoal bed or excessive moisture content of the charcoal can cause high carbon dioxide and water-vapor contents that will decarburize high-carbon steels.

Charcoal-based atmospheres may be used for hardening, annealing, and normalizing high-carbon steels without scale formation or decarburization. A gray-green oxide forms on steels containing appreciable amounts of chromium. At high temperatures, the great affinity of chromium for oxygen causes a breakdown of carbon monoxide. The relatively low hydrogen content of these atmospheres makes them particularly suitable for making malleable iron castings.

The principal disadvantages of charcoal-based atmospheres are the high operating cost, the absence of suitable means for automatic control, the intermittence of operation imposed by the need to recharge charcoal and remove ashes, and the corrosion of alloy furnace parts in the area of high-temperature combustion.

Exothermic-Endothermic-Based Atmospheres

These atmospheres (classes 501 and 502), the compositions and characteristics of which are previously described in the section "Classification of Prepared Atmospheres" of this article, are re-formed exothermic-based atmospheres that are less reducing than conventional endothermic-based furnace atmospheres.

Applications

Potentially, exothermic-endothermic-based atmospheres could be substituted for exothermic, endothermic, and nitrogen-based atmospheres in virtually every application for which any one of these three atmospheres is recommended. They may also be used as a carrier gas in carburizing and carbonitriding. In practice, however, it is not practical to mix exothermic-endothermic atmospheres in existing headers with straight endothermic atmospheres because of the differences in specific gravity and chemistry. This limitation may not apply to the use of the combination exothermic-endothermic type of generator, provided one generator for one furnace can be economically employed to produce both exothermic and endothermic atmospheres for use at the same time.

Generation

Generation of exothermic-endothermic atmospheres begins with the combustion of a mixture of air and fuel gas in a refractory-lined combustion chamber. This reaction supplies the external heating required to maintain a satisfactory temperature in a secondary, or endothermic-stage, reaction. Products of combustion from the first stage are dehydrated, and a predetermined quantity of a hydrocarbon fuel is added to them. This mixture is then reacted in contact with a catalyst contained in an externally heated alloy tube.

The primary air-fuel mixture yields very close to perfect combustion. For normal operations, 0.5% CO or O_2 in the generated gas is satisfactory. This reaction, using natural gas as the fuel, yields 11 volumes of combustion products. Removal of the water formed in the reaction reduces the total to 9.225 volumes. In the secondary reaction, 7.3 volumes of combustion products and 1 volume of natural gas react to produce 10.5 volumes of atmosphere of the following nominal composition:

Composition	Concentration, %
CO_2	0-0.2
CO	17
H_2	20
N_2	bal

Equipment. Figure 21 is a flow diagram of a typical exothermic-endothermic generator. In operation, the flow rates of air and gas are regulated by fixed and variable orifices and balanced pressure ratio regulators to maintain the mixture at a predetermined ratio. A gas pump introduces the mixture into a refractory-lined combustion chamber (exothermic unit A in Fig. 21). The products of combustion then pass through a water spray cooler (atmosphere cooler B). After the combustion products have cooled, a measured volume of a hydrocarbon fuel is blended with them. The ratio of the products to the hydrocarbon fuel is controlled by fixed and variable orifices and balanced pressure-ratio regulators, and the mixture is introduced under pressure by a gas pump into a catalyst-filled U-shaped alloy retort (endothermic unit C in Fig. 21), which is contained in the refractory-lined combustion chamber and is heated by the primary-stage combustion. From the retort, the gas mixture passes into atmosphere cooler D. From here, it is piped through an atmosphere outlet and into the furnace.

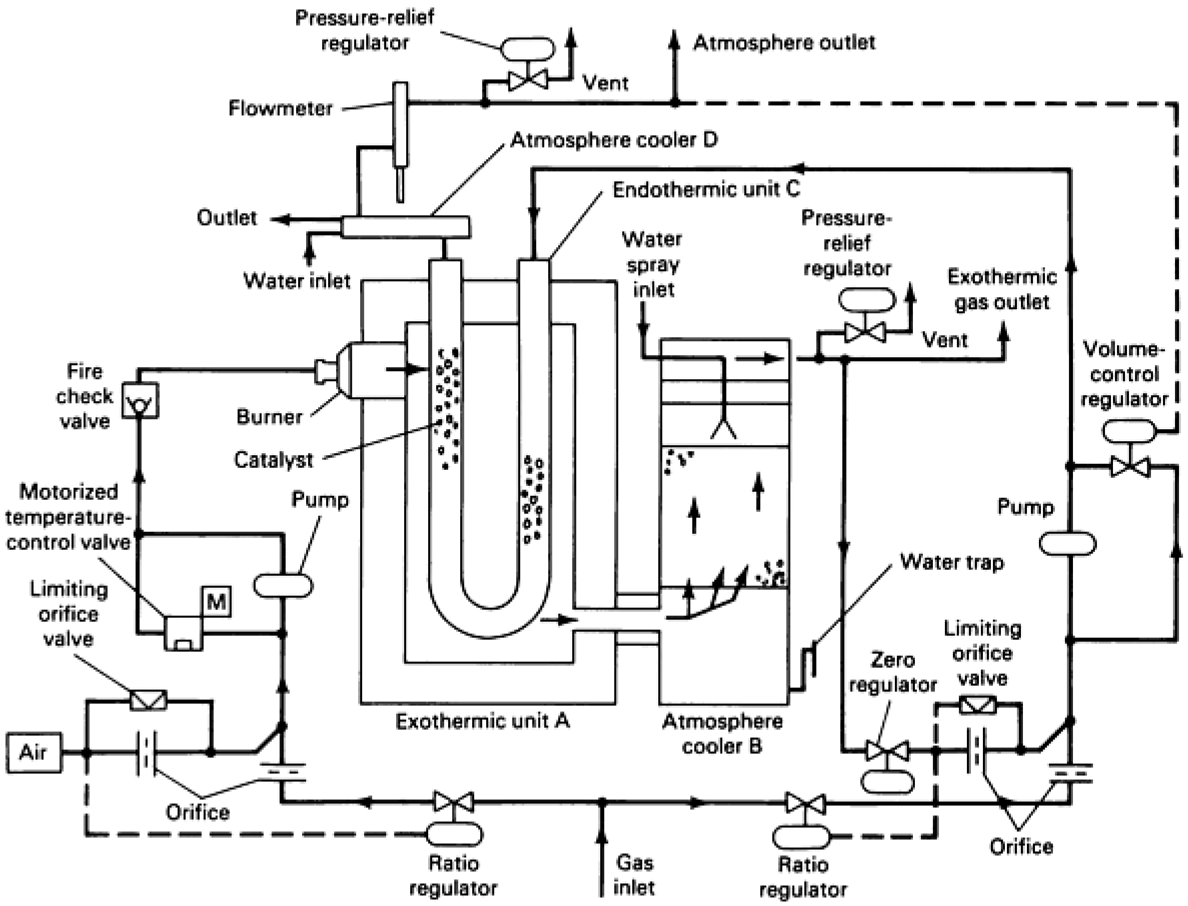

Fig. 21 Flow diagram of an exothermic-endothermic gas generator

The volume of atmosphere needed for a given work load is influenced by the size of workpieces comprising the total work load and the type of furnace used for heating. See Table 13 for production and equipment requirements for hardening small parts made of 1070 steel in an exothermic-endothermic-based atmosphere.

Table 13 Equipment requirements for hardening small parts made of 1070 steel in an exothermic-endothermic atmosphere

Production requirements	
Number of parts per load	2625
Weight of each part, kg (lb)	0.0069 (0.015)
Maximum net weight of load, kg (lb)	18 (40)
Production rate, kg (lb)	7.5 loads (135, or 300) per h
Equipment requirements	
Hardening furnace	Gas-fired radiant-tube single-row pusher type with automatic quench
Size of hearth, m (ft)	0.9 (3) wide by 2.9 ($9\frac{1}{2}$) long
Heat input, W/h (Btu/h)	2.2×10^5 Watts (7.5×10^5)
Operating temperature, °C (°F)	900 (1650)
Capacity of generator, m^3/h (ft^3/h)	68 (2400)
Type of atmosphere	Class 502
Capacity of oil-quench tank, L (gal)	1250 (330)
Type of oil, °C (°F)	Fast, 180 (360) flash point
Temperature of oil, °C (°F)	70 (160) (controlled)
Oil agitation	Medium

Operation of Generator. When the generator is used for the manufacture of endothermic-based gas, it should be operated at approximately 1010 °C (1850 °F). If the temperature is too low, reaction will be incomplete; if the temperature is too high, life of the retort will be greatly shortened. All of the previously described precautions to be observed when operating an endothermic generator should be adhered to when endothermic-based atmosphere is being produced.

When the same generator is used for producing an exothermic-based gas, there is no need to change the operating conditions. Therefore, by closing the gas valve in the secondary stage, the unit purges itself of endothermic gas by producing exothermic gas. When used as an exothermic generator, with about 90% perfect combustion, it will produce a gas having the following approximate composition:

Composition	Concentration, %
CO_2	10.0-11.0
O_2	0-1.0
CO	0-2.0
H_2	0-2.0
N_2	86.0-89.0

When the generator is producing endothermic gas, it can, at the same time, supply an exothermic-gas volume of approximately 25% of its rated endothermic capacity.

When changing over from production of exothermic to endothermic gas, it is recommended that a period of about $\frac{1}{2}$ h be allowed to establish equilibrium in the generator. Gas-analysis equipment, either manual or automatic (as described in the section "Analyzing Atmosphere Requirements" of this article), should be employed to determine when equilibrium conditions for the desired atmosphere have been established.

Generator Maintenance. A typical maintenance schedule for exothermic-endothermic atmosphere generators includes:

Daily

- Check flow of cooling water
- Check dew point and secondary gas analysis, and make adjustments as necessary
- Check instruments

Weekly

- Check primary gas analysis and make adjustments as necessary
- Check operation and linkage of temperature-control valve
- Lubricate as required

- Check drive belts

Monthly

- Check for leaks
- Check operation of combustion and fuel safeguard equipment, such as manual reset shutoff valves, pressure switches, and firecheck
- Check and clean air filter as required
- Check cooling distribution on atmosphere cooler B (Fig. 21)
- Check atmosphere cooler D (Fig. 21) for water leaks by dew point before and after, and excessive soot deposits in the aftercooler by taking readings of pressure of atmosphere before and after it passes through the cooler

Atmospheres for Backfilling and Quenching in Vacuum

Backfilling a vacuum furnace with a cooling gas is performed to induce a more rapid cooling rate. Backfilling also is used to suppress vaporization of oil in integrated oil-quenching vacuum furnaces and to provide an atmosphere for carburizing and nitriding.

Quenching. Inert gases, nitrogen, and, in rare circumstances, hydrogen, are used for cooling. If surface integrity of workpieces is to be maintained and damage to furnace parts avoided, contaminants in the cooling gas must be kept at a low level. Commercial gases are readily available with contaminant level below 0.01%.

Backfilling and forced circulation accomplishes a more rapid cooling rate, facilitates hardening, and, in some requirements, produces annealing of metal alloys. It also enhances efficient use of the equipment. Cooling gas is usually introduced into the vacuum chamber at the end of the high-temperature soaking period. When internal pressure reaches some predetermined level, either slightly negative or positive relative to atmospheric pressure, the gas is circulated through the load and then through appropriate heat exchangers located outside the heating zone. Design of the furnace and its structural strength dictate the maximum pressure level.

Figure 22 shows the effect of gas selection. Because cooling rates were established with identical loads and equipment, differences are attributed to differences in heat conductivity, heat capacity, viscosity, and density of the gases tested.

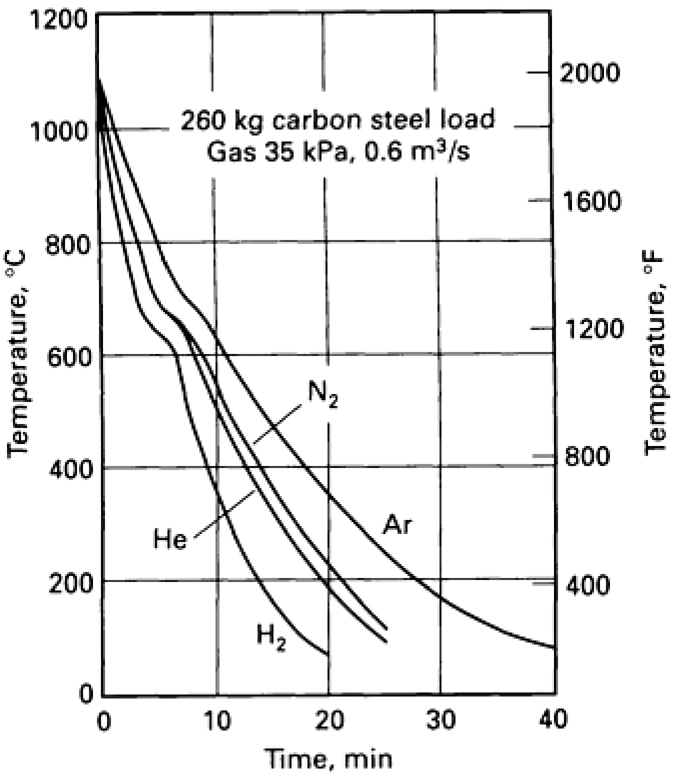

Fig. 22 Effect of four gases on cooling rate

Figure 23 illustrates the effect of pressure when the same cooling gas, load, and equipment are used. Slightly negative pressure provides sufficient cooling to harden air-hardening materials such as air-hardening stainless steels and tool steels. Positive pressure provides a sufficient cooling rate to harden materials such as M2 tool steels. The mass of the load and part cross-section dimensions also govern the cooling rate and must be recognized as cooling-rate factors.

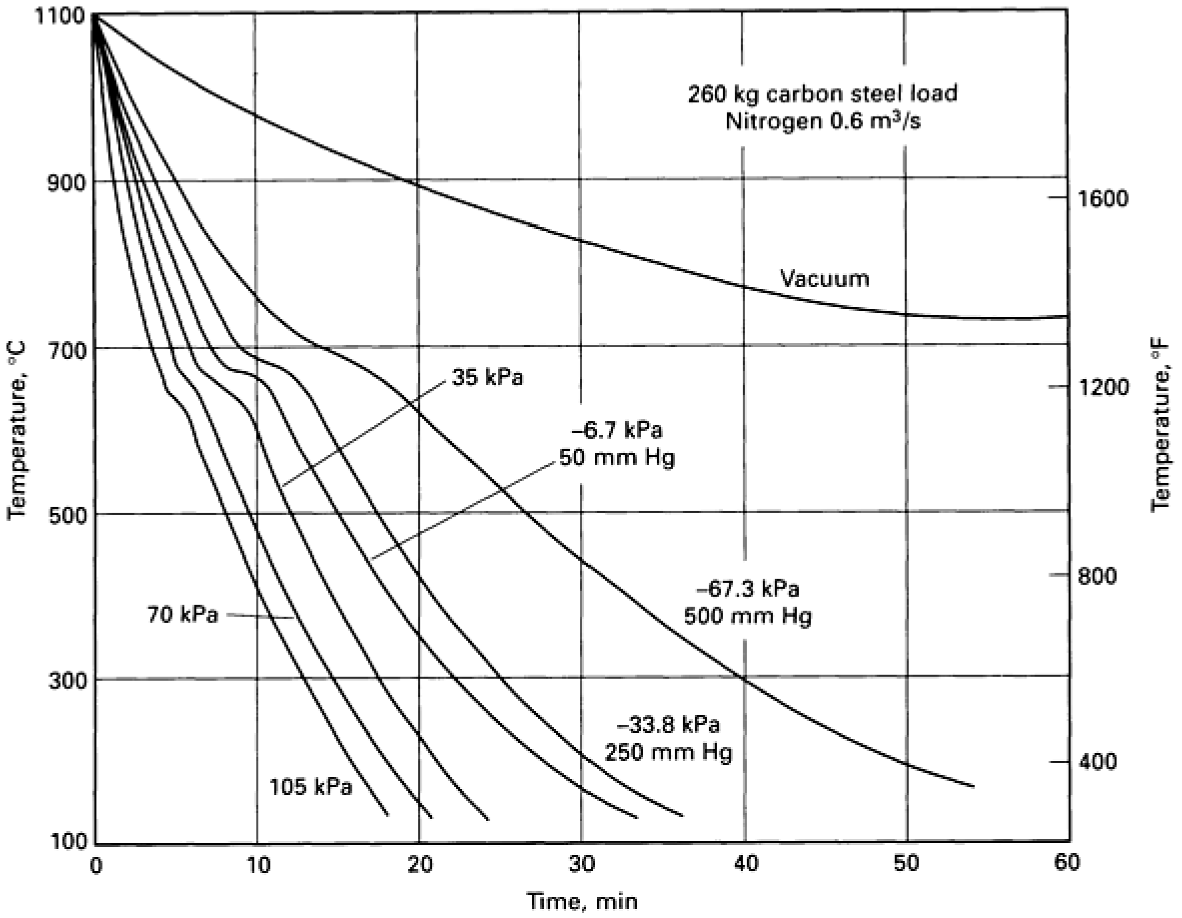

Fig. 23 Effect of circulating gas pressure on cooling rate

Vacuum Furnace Gas-Carburizing Atmospheres. Vacuum furnaces may be used for carburizing by the injection of any one of several atmospheres that will induce carburizing at appropriate temperatures. Nitrogen enriched with a hydrocarbon gas is most frequently employed.

Vacuum furnace carburizing is normally carried out in the temperature range of 870 to 980 °C (1600 to 1800 °F). In the carburizing and diffusion process, surface-carbon contents of 1% or more are formed initially. The high-carbon case is then diffused in vacuum until the surface-carbon content and case depth are acceptable.

The diffusion process may be carried out in a series of interrupted periods during the carburizing cycle or at the end of the carburizing portion of the cycle. An interrupted carburizing cycle produces a less severe drop in carbon content and a higher hardness relative to case depth. Surface-carbon content and surface hardness remain comparable in both diffusion processes.

Vacuum carburizing entails some problems with sooting and distribution of the carburizing atmosphere. Soot monitoring with subsequent enrichment control can minimize the soot problem, and forced circulation of the carburizing atmosphere assists in minimizing the distribution problem. Additional information is available in the article "Vacuum Carburizing" in this Volume.

Ion-Carburizing Atmospheres. A hydrocarbon gas that is ionized by a high-voltage system in a vacuum is a suitable atmosphere for ion carburizing. Methane is a good source of carbon and is frequently employed. With a voltage differential between an anode, which may be chamber walls, and the work load serving at the cathode, a plasma will be generated at a critical vacuum pressure (Fig. 24). Migration and impingement of the resulting ions on the surface of the load produce the carburizing potential. Ion carburizing is much more rapid than conventional atmosphere carburizing, and the surface-carbon content approaches saturation. Other diluting gases are added for carbon control.

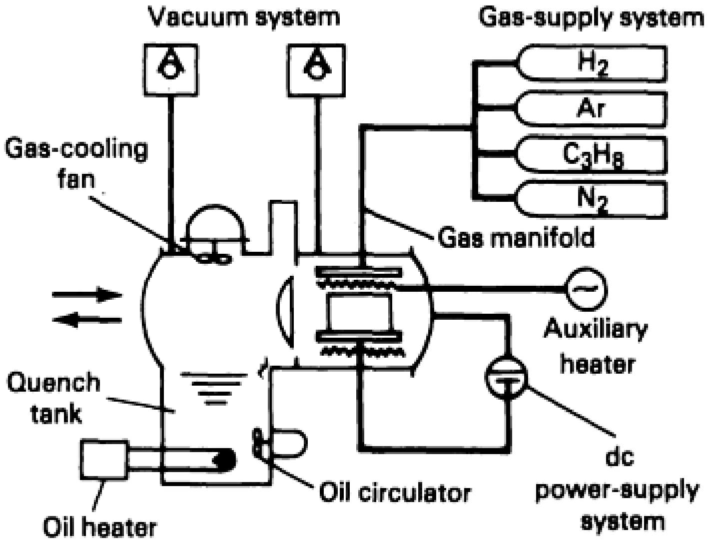

Fig. 24 A two-chamber plasma-carburizing furnace that consists of a plasma-carburizing chamber and an oil-quenching chamber

An AISI 1018 steel can be ion carburized to a depth of 1.0 mm (0.040 in.) with a 10-min cycle in an atmosphere of methane at 1.3 to 2.7 kPa (10 to 20 torr) and a temperature of 1050 °C (1925 °F). Carburizing is followed by a 30-min diffusion cycle in vacuum at the same temperature. Approximately 400 V is required to produce the plasma.

Additional information is available in the article "Plasma (Ion) Carburizing" in this Volume.

Ion-Nitriding Atmospheres. Ion nitriding is similar to ion carburizing, with the exception that the atmosphere gas generates nitrogen ions, and the process is carried out at lower temperatures (Fig. 25). Ammonia or mixtures of hydrogen and nitrogen are suitable sources for the nitrogen ions.

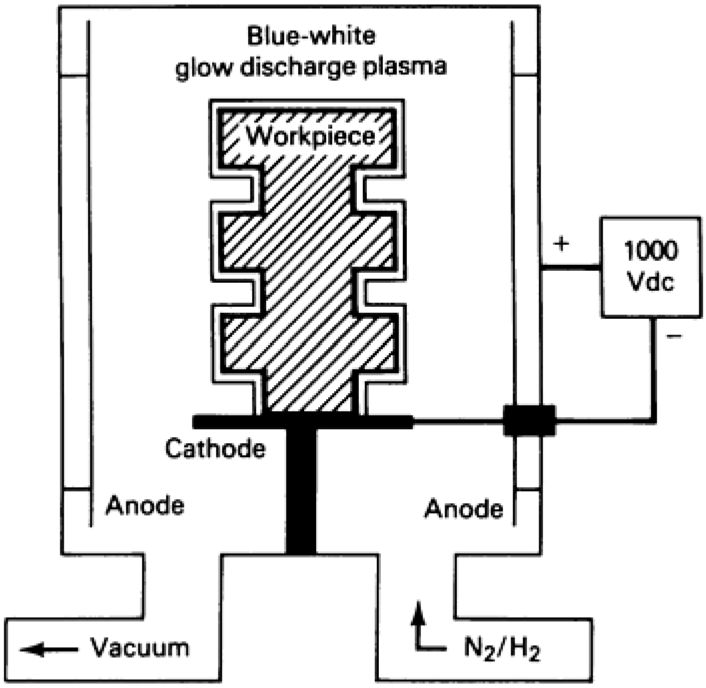

Fig. 25 Schematic showing basic elements of an ion-nitriding system. High-kinetic-energy nitrogen-ion

bombardment on workpiece surface is indicated by blue-white glow discharge around the components.

A typical cycle of 8 h at 510 °C (950 °F) with a mixture of 75% hydrogen and 25% nitrogen at a pressure of 0.9 kPa (7 torr) and a current density of 0.8 mA/cm^2 will produce a nitrided case of 0.30 mm (0.012 in.) in AISI 4140 steel. Approximately 400 V is required to generate the plasma. Other alloys, such as 300 series stainless steels, M2 tool steels, and nitralloy, respond to the ion-nitriding process.

Additional information is available in the article "Plasma (Ion) Nitriding" in this Volume.

Partial Pressure. Nitrogen and inert gases are used in vacuum furnaces at partial-pressure vacuum levels to suppress vaporization of a constituent in the composition of the load. A gas is injected in small quantities by a needle valve. The deliberately leaked gas raises the pressure to some stable level between the ultimate vacuum of the pumping system and atmospheric pressure. For example, the vaporization of copper during the brazing of heat exchangers is suppressed by the leaking of nitrogen into the furnace and maintaining a level of 0.27 kPa (2.0 torr). For more information, see articles "Plasma (Ion) Nitriding" and "Plasma (Ion) Carburizing" in this Volume.

Analyzing Atmosphere Requirements

Analysis of the atmosphere requirements of heat-treating furnaces is influenced by several factors. Cost of operation is always one of the main considerations in selecting an atmosphere system. Another prime factor is the capital investment required to purchase the hardware, make the installation, and satisfy the associated safety requirements. Certain circumstances dictate that all cost considerations be subordinated to achieve high levels of heat-treating accuracy to satisfy stringent metallurgical specifications.

The degree of validity of any analysis is determined by the thoroughness of investigation and the definitive parameters placed on the project.

Influence of Required Processes. Many installations are built in which multiple processes are anticipated. In such instances, the atmosphere system must be capable of a reasonable response time. For example, a batch furnace may be used for carburizing in one cycle, followed by clean hardening of medium-carbon steel in the next, without a long delay between heats. This processing schedule means the carbon potential will vary from 0.9 to 0.3% C. With an endothermic-based atmosphere, this variance means a dew point change from -12 to 18 °C (10 to 64 °F). With a nitrogen-based atmosphere, the carburizing cycle can be completed with additions of carbon-bearing material and an oxidant, and the hardening cycle can be accomplished by eliminating the additives.

In some installations, the volume of atmosphere is based on the process requirements rather than on the amounts of atmosphere required to overcome air infiltration to the furnace chamber. This volume basis is used when the atmosphere provides an element in carburizing parts with large surface areas; for example, in sintering, the amount of hydrogen required becomes a function of the amount of oxide or sulfur to be reduced.

Thus, distinctions need to be made between the need of an atmosphere to exclude unwanted air and the requirement that it enter into a precise chemical reaction. As the process specifications become more exacting, the need for precision of the chemical reaction increases and the need for reliable atmosphere control becomes more urgent.

Influence of Furnace Design. Furnace design and the selection of atmospheres are interdependent. In any atmosphere furnace the degree of tightness is a critical factor, and among the various types of atmosphere furnaces--pusher tray, batch tray, cast link belt, roller hearth, mesh belt, rotary retort, bell, gantry, and others--the furnace designer basically has only three ways to load and four ways to unload the work.

Slot-Opening Loading. The first way of loading and unloading an atmosphere furnace is through a slot. Sufficient atmosphere must be provided to prevent air from entering through the slot, and the amount can be significantly reduced by the use of curtains or flame screens, and by elevating the working hearth above the slot opening when possible.

Vestibule or Cold Chamber Loading. The second way of loading and unloading is through a cold chamber vestibule linked with the furnace. The most common use of a vestibule is with a pusher tray or batch tray furnace. A loaded tray is placed in the vestibule and the outer vestibule door is closed. The vestibule remains closed until sufficient time has elapsed to purge the vestibule of air. This purging occurs either by atmosphere leakage from the furnace around the inner

furnace door or by admission of atmosphere gas through a direct line that is opened for a predetermined time. Sufficient atmosphere for approximately five volume changes must pass through the vestibule to be ensured that contamination will be minimized when the inner furnace door is opened to admit the work tray. Any mechanism that operates through the vestibule wall must be equipped with packing glands, and these must be maintained. The atmosphere in the vestibule also undergoes a temperature change when the inner door is raised and lowered, subjecting the vestibule gases to rapid volume increases followed by decreases. The furnace door closing must not be so rapid as to cause a contraction of the gases in the vestibule greater than the flow of gas to the vestibule for normal purging.

Stationary- or Movable-Base Loading. The third way of loading and unloading is to place the work on a stationary or movable base and to raise the work into the furnace or place the furnace over the base. The furnace chamber over the work is purged with atmosphere, and the furnace is taken through a time-temperature cycle. When that cycle is completed, the work is uncovered and removed.

Quench Tank Unloading. The fourth way of unloading a furnace is to have the work fall directly into a quench tank at the discharge end (see Fig. 24). To protect the atmosphere, an eductor must be installed to draw atmosphere from the quench chute just above the fluid line. If the quenching medium has a water base, the eductor will prevent water vapor from contaminating the atmosphere. If the quenchant is oil, the eductor will prevent oil splash and fumes from unbalancing the atmosphere. One mechanism that has been successfully used in direct-quenching applications is a laminar-flow quench-fluid spray between the quench-tank eductor and the liquid quenchant in the quench chute.

Fans to Increase Atmosphere Uniformity. An additional furnace design consideration having a direct influence on the atmosphere is the use of fans. By increasing the flow of atmosphere gas across the faces of the work being processed, fans increase the effective concentration of the gases and accelerate chemical reactions in applications where the atmosphere is the source of a desired chemical ingredient. This is particularly significant in case hardening. A properly designed fan thoroughly mixes the atmosphere as the various chemical reactions take place, and improves temperature uniformity in dense loads. The result is more uniform part-to-part response to a process within a load.

Influence of the Availability and Dependability of Utilities. The availability and dependability of utilities influence the location of industrial plants. In heat-treating operations, large amounts of energy are consumed. As the cost of energy increases, energy cost and availability receive more management attention and planning, particularly in heat-treating operations that have had their energy supplies curtailed.

In the past, heat-treating operations required a supply of natural gas, which was inexpensive; electricity, which was readily available; and water, which was needed for cooling purposes. These utilities not only were required for the furnaces, but also were the required ingredients for the generation of heat-treating atmospheres. In many instances, natural gas was the preferred form of energy. It was used not only as fuel for furnaces but also as an acceptable feedstock for the atmosphere generators.

As energy supplies have become more expensive and less available, it has been relatively simple to go to alternate or dual fuels to heat furnaces. Finding substitute atmosphere feedstocks has been somewhat more complicated, but solutions are available. Commercial nitrogen produced by air-reduction plants provides an alternative in two forms. For large volumes, the air-reduction plant can be located at or near the using site, or nitrogen from a central air-reduction plant can be transported and stored as a liquid, at the using site. With the developing technology of utilizing methanol with nitrogen, it is now possible to establish a heat-treating operation requiring carburizing atmospheres without dependence on natural supplies.

Influence of Estimating Atmosphere Quantities. As energy costs increase, the customary practice of employing an atmosphere generator of greater capacity than required adversely affects operating costs. This is especially true of endothermic atmosphere generation. The atmosphere feedstock is passed through a catalyst-filled heated reaction tube, which requires considerable energy to reach gas-cracking temperature. Little energy is required to maintain the reaction tube temperature over the range of minimum flow to maximum flow of reactive gases through the tube. For instance, a 68 m^3/h (2400 ft^3/h) endothermic generator at full flow will require a little over 1 m^3/h (36 ft^3/h) of natural gas per 3 m^3/h (100 ft^3/h) of produced gas. The same generator operating at one-third capacity or 23 m^3/h (800 ft^3/h) output will require a little over 1.3 m^3/h (47 ft^3/h) of natural gas per 3 m^3/h (100 ft^3/h) of produced gas. The differences on a 102 m^3/h (3600 ft^3/h) generator were even more pronounced. At 102 m^3/h (3600 ft^3/h) output, the required natural gas is 0.8 m^3/h (28.7 ft^3/h). At 68 m^3/h (2400 ft^3/h) output, the required natural gas is 0.937 m^3/h (33.1 ft^3/h), and at 34 m^3/h (1200 ft^3/h) output, the required natural gas is 1.2 m^3/h (40.9 ft^3/h). Because natural gas is the major cost factor in producing endothermic atmosphere, a 30% variation in operating cost is significant.

Furnace Atmosphere Control in Heat Treating

Revised by John G. Rowe, Union Carbide Industrial Gases Inc., Linde Division

Introduction

THE PURPOSE of atmosphere control is to maintain consistent levels of the various constituents that make up the atmosphere and to determine if changes in those levels are required in order to produce a desired result under a given set of conditions. Controls are required for various heat-treating operations that use a variety of different atmospheres. All methods of atmosphere control can effectively be divided into two groups: those involving control of the atmosphere once it is inside the furnace and those involving control of the atmosphere supply before it is introduced into the furnace. Such control is achieved through the use of atmosphere control devices.

Atmosphere Control Devices

The control devices available for the wide variety of furnace atmospheres used can be categorized into three major types: oxygen probe, infrared, and dew point. Direct oxygen or dew point monitoring devices are also often used for applications such as bell furnace annealing. The oxygen probe is an *in situ* type device; that is, it directly samples the atmosphere to be measured. The electrical signal generated by an oxygen probe is directly proportional to the carbon potential of the atmosphere. Infrared control measures a sample drawn from the furnace. Infrared control is usually used to measure carbon monoxide and/or carbon dioxide levels. Dew point control also analyzes a drawn sample external to the furnace.

These control devices can effectively control endothermic, exothermic, nitrogen-methanol, nitrogen-hydrocarbon, and nitrogen-hydrogen-type atmospheres. Infrared control is most often utilized for endothermic and exothermic generator operation and, in some cases, for exothermic furnace atmospheres as well. Nitrogen-hydrogen atmospheres are typically controlled by dew point.

It is good practice to regularly compare the carbon potential determined through an analyzer to the actual carbon potential of the atmosphere as determined through shim analysis. A shim is a thin low-carbon metal sample that, when placed in the furnace, will quickly carburize to a level equal to the furnace carbon potential. Adjusting the control system to match the carbon potential indicated by a shim test will improve the accuracy of the entire system.

The above-mentioned control devices can be modified and incorporated together to form an automatic control system for any given set of conditions, utilizing normal instrumentation and final control devices. The system is ultimately a product of the needs of the user and justifiable economics. As metallurgical reproducibility of any given process becomes more important, the need for atmosphere control to produce chemical stability becomes a necessity. A second imperative not to be overlooked in the application of atmosphere-control devices is the safety aspects of operating atmosphere supply systems and industrial furnaces.

Oxygen probes have been extensively used for control of carburizing furnaces. Accuracy of carbon-potential control through use of oxygen probes is estimated to be approximately ±0.05% carbon in actual practice because of the limitations of temperature control and temperature variations in typical heat-treating furnaces. Because of the fast response rate, on/off control systems utilizing solenoid valves for regulating propane, natural gas, or liquid enrichment are adequate for batch furnaces. *In situ* probes or probes exposed directly to the furnace atmosphere control carbon potential by adjusting the set point on the control instrument to the carbon level desired in the furnace. The oxygen probe supplies to the control station an electrical signal related to the carbon potential. High-and low-deviation contacts are adjusted throughout the control instrument and either contact is made by the electrical signal from the probe. The low-deviation contact controls the solenoid valve that supplies enriching gas or liquid to the furnace. The high-deviation contact can be made to control the solenoid valve to add air or an oxidizer to the furnace. Carbon-concentration reproducibility of ±0.02% is frequently achieved using systems of this type, provided that the cycle, temperature, and furnace conditions remain constant.

The oxygen probe is based in theory on a hot ceramic electrochemical cell. The probe will respond to oxygen, hydrogen, carbon monoxide, water, and carbon dioxide and thus can determine the oxidization potential of a gas. The output of the oxygen probe is a direct measurement of the oxidation potential of the atmosphere at the process temperature of the furnace. Therefore, when the probe temperature is close to the furnace temperature, the response of the probe is a direct indication of whether the atmosphere will oxidize or reduce steel, provided that the composition of the atmosphere with

regard to the proportions of carbon gases and hydrogen is known. Under such conditions, the probe will give a reliable indication of the oxidation/reduction situation for all furnace temperatures.

The oxygen probe is a closed-end tube usually constructed of lime-stabilized zirconia or yttria-stabilized material for temperatures up to 1600 °C (2900 °F). When such a probe is subjected to elevated temperatures, the nonporous sheath material acts as a solid electrolyte that permits the passage of oxygen ions when the inner and outer surfaces are subjected to atmospheres of different oxygen partial pressures--for example, a reference gas such as air, because its O_2 content is constant at 20.9% by volume at sea level, and the process furnace atmosphere, respectively. The electromotive force (emf) thus generated, and measured via the electrodes attached to the sheath, is related directly to, and provides an accurate quantification of, atmosphere characteristics in terms of its oxidizing/reducing, or, in some endothermic-atmosphere applications, carburizing/decarburizing tendencies at a known temperature (Ref 1). The electrodes mentioned above are in physical contact with the zirconia on both the inside and outside of the tube and usually are constructed of platinum because of its high chemical resistance at elevated temperatures. When the probe is subjected to elevated temperatures, there is a difference between the oxygen partial pressures on the two sides of the probe, and electricity will flow through a circuit connecting the two sides. This flow of electricity is from the higher pressure to the lower. If the oxygen pressure on one side is known, the oxygen pressure on the other side can be determined:

$$E = K\ x\ t \log \left\{ \frac{[O_2]_{known}}{[O_2]_{unknown}} \right\}$$

where T is absolute temperature, $[O_2]$ is oxygen partial pressure, K is a constant, and E is the electromotive force generated. This measurement can be made using a simple panel meter without electronics (Ref 2).

Continuous carburizing furnaces and straight hardening furnaces usually use proportional control in conjunction with the oxygen-probe control. Experience in control of continuous furnaces has shown that proportional control is normally required in order to cope with on-going disturbances involving movement of work, opening of doors, and the like. Compensation for these disturbances is rapid because of the rapid response rate of the oxygen probe. In the proportional-control system, the output voltage is supplied to a two-mode controller, and the controller positions a motorized or pneumatic control valve that regulates the flow of enriching gas to the furnace. Such carbon control is advantageous when short treatment cycles of 20 min or less are used, because compensations of 2 to 3 min or less are required for disturbances in such applications.

Oxygen probes often are used to monitor a furnace atmosphere while control is accomplished manually by adjusting flowmeters on enriching lines to the furnace. This is often used when the cost of control systems cannot be justified. The cost of replacing the consumable probe and the cost of simple on/off control systems must be weighed against human error, process accuracy, and reproducibility.

Endothermic generators also can be controlled by use of the oxygen probe. In this case, because of the difficulty of placing an *in situ* probe in the retort of the generator, the probe is used to sample atmosphere from the output line of the generator. The electrical signal from the probe is then wired to the control instrument that activates the solenoid valve located on the air-bypass line to the mixer. Thus, the air/gas ratio is automatically adjusted to give the desired properties of the endothermic gas.

Infrared Analyzer. An infrared-type analyzer can be utilized for specific analysis of simple or complex mixtures of vapors and liquids and can be used to detect any components that absorb infrared energy. Carbon monoxide and carbon dioxide are the most common gases measured by infrared control. An infrared-type analyzing system could be of a design utilizing two separate or twin infrared radiation cells. One is referred to as a reference source and gives a known signal in response to the reference gas. The other cell is used as a sample cell and would vary from the known reference cell depending upon the elements in the gas contained inside that cell. When the gases in both cells are the same, they are in balance.

If the gas-absorbing infrared radiation in the sample cell is increased, more infrared radiation is absorbed, and consequently the beams become unequal. Movement of a membrane within the detector varies the electrical capacity of the condenser, resulting in an electrical signal proportional to the difference between the two beams. This signal is amplified and fed into an indicating meter.

These same principles are utilized for both furnace control and atmosphere-generator control. Infrared analyzers may be used to control systems other than carbon monoxide and carbon dioxide in furnace applications. However, because many heat-treating systems are based on carbon dioxide analysis, infrared carbon dioxide control is very common. Carbon dioxide control and/or dew point control can be used for determining carbon potential in carburizing atmospheres. Infrared analyzers can also be used to monitor ammonia in nitriding atmospheres and carbon monoxide in other applications.

Dew Point Instrument. Use of a dew point measuring device is another method of controlling the carbon potential of a furnace atmosphere. It can also be used to determine the moisture content of any given atmosphere.

One type of dew point instrument utilizes an aluminum oxide sensor to generate an electrical signal that is proportional to the moisture content of the sample stream. The sensor consists of an aluminum base material with an aluminum oxide etched on its surface. The oxide is then covered with a thin permeable metal layer (see Fig. 1). The inner aluminum base and the outer metal layer form two electrodes in what is basically a capacitor. Moisture passes through the outer metal layer and is absorbed on the oxide. This changes the capacitance of the entire assembly proportionally to the moisture content in the atmosphere (Ref 3 and 4).

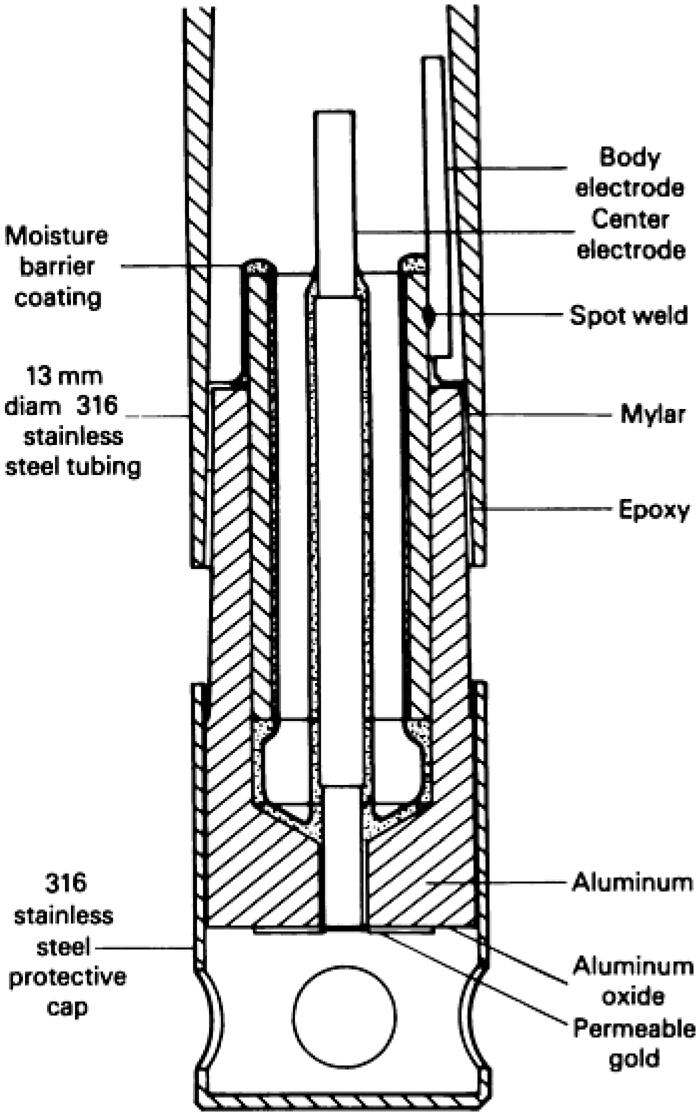

Fig. 1 The aluminum oxide sensor, a type of dew point instrument, measures water content of an atmosphere by change in capacitance between two electrodes. Source: Ondyne Inc.

Oxygen Analysis. Some applications involving heat processes require the use of analyzers to determine the oxygen content of a given processed gas. The most common practice for oxygen analysis in heat-treating furnaces is to determine the lack of oxygen. Depending on the level of oxygen desired or permitted in the process gas, specific ranges of concentration may have to be determined.

The magnetic oxygen analyzer is a common analyzing system used with heat-treating systems. Oxygen has an affinity for magnetic fields; most other gases do not. By adding a sample gas to a magnetic field and a detector, the change in resistance can be measured in a cell. The output from this cell is fed to a meter or a recorder and quite often is used as a permissive circuit in an atmosphere-control system.

Atmosphere Control

For success in metallurgical atmosphere control, gas analysis instrumentation must be applied at the furnace and at the gas generator. This is true for endothermic as well as exothermic atmosphere applications. Analyzers and associated control systems applied to a furnace should never be expected to correct deficiencies in the basic atmosphere produced by the gas generator. Instrumentation dedicated to the furnace is designed to provide information and control relative to operation of the furnace and to the product being processed. Likewise, instrumentation dedicated to the generator is designed to provide information and control relative to operation of the generator and to the atmosphere produced by it.

Furnace Atmosphere

When controlling furnace atmospheres, it is important to control atmosphere composition, that is, the percentages of individual gases such as carbon monoxide, hydrogen, and so on. It is also frequently important to control atmosphere stability, the tendency of the atmosphere to move within, and out of the furnace.

Composition. The complexity of the furnace atmosphere control system is directly related to the degree of control required. For less critical applications, no active control system may be needed. Atmosphere supply adjustments can be made through occasional analysis of the atmosphere with portable instrumentation. With carburizing and hardening applications, a carbon probe and control systems are common. When greater precision is required, an infrared carbon monoxide instrument is added.

Stability. For atmosphere control of continuous (belt, roller hearth, and so forth) furnaces, atmosphere stability is an important factor. Room winds and drafts, caused by open doors in the plant for example, can cause the atmosphere inside the furnace to shift. In most cases, door curtains are sufficient to contain the atmosphere within the furnace. However, there are circumstances where curtains are ineffective, especially when large parts are frequently entering and leaving the furnace. In this case, blanketing the furnace doors with an inert gas flow can reduce or eliminate air entering the furnace. In some cases, a system capable of reacting to atmosphere changes may be needed.

Supply Atmosphere

Because the heat-treated product is treated in the furnace, there is a tendency to emphasize furnace atmosphere control and to overlook the generator. In many cases, automatic atmosphere control of the gas generator will resolve heat-treating atmosphere problems, simplify control of the furnace atmosphere, and in some cases reduce furnace monitoring to occasional spot checks.

There are two basic types of atmospheric supply systems: generated atmospheres (both endothermic and exothermic) and nitrogen-based atmospheres. The primary difference between generated and nitrogen-based atmospheres is the method of producing the final atmosphere composition. Generated atmospheres are produced by reacting natural gas, usually, and air inside a retort with a catalyst. The final product can be modified by downstream filtration. Nitrogen-based atmospheres, on the other hand, are produced by mixing one or more gases or liquids in the desired ratio. With nitrogen-methanol atmospheres, the alcohol dissociates inside the furnace to produce an atmosphere similar to endothermic.

Nitrogen-Based Atmospheres. Nitrogen-based atmosphere supply systems consist of a fluid supply source, normally a tank for each fluid component, and a flow control panel. The tank or tanks are located outside the plant, and the panel is normally situated inside the plant at the furnace. Figure 2 shows a typical supply arrangement. The flow control panel usually includes pressure regulation and flow control devices to ensure consistent supply. The atmosphere composition required in the furnace is mixed at the panel. Atmospheres similar to endothermic, exothermic, and dissociated ammonia are easily produced.

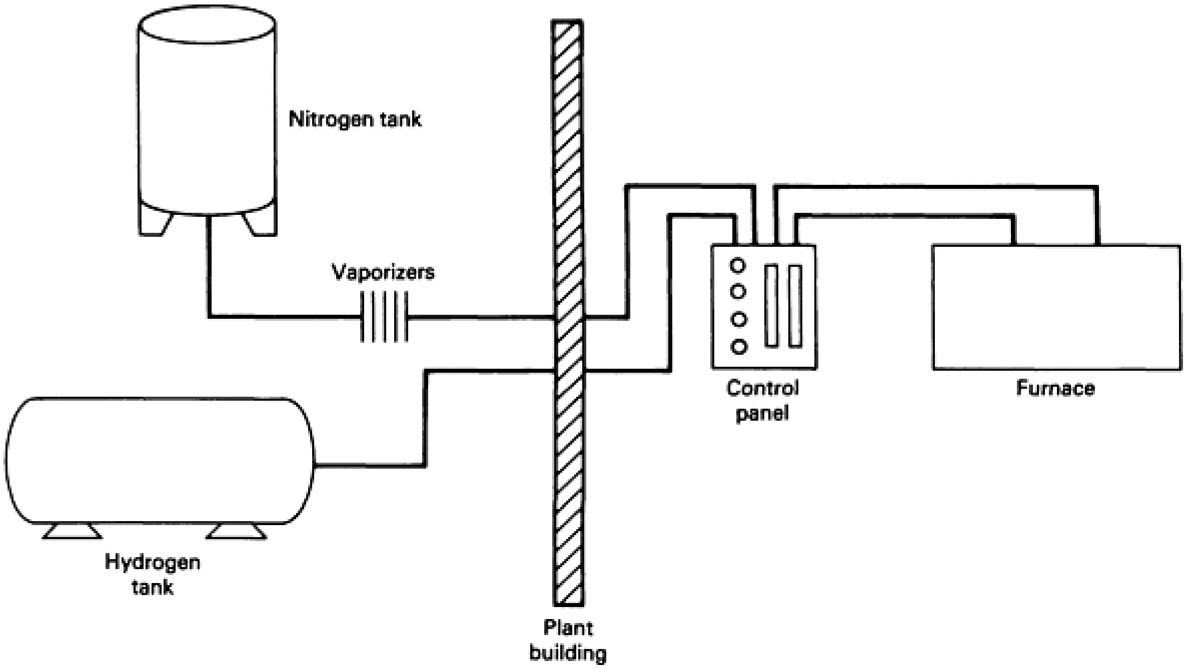

Fig. 2 Typical nitrogen-based supply system

No reaction or combustion takes place outside the furnace with a nitrogen-based system. This fact, along with the consistent, very high purity of the supply fluids, eliminates the need for supply analytical instrumentation.

Nitrogen-methanol atmospheres are used for carburizing and hardening applications as well as for some annealing and brazing operations. Nitrogen-propylene and nitrogen-hydrogen atmospheres are commonly used in annealing, brazing, and sintering. Pure hydrogen atmospheres are increasingly used in bell annealing furnaces.

Generated Atmospheres. Generated endothermic atmosphere is used in heat-treating furnaces for hardening, stress relieving, carbon restoration, and carburizing. The most recognized guides to endothermic generator operation are CO_2 and dew point. Any deviation from the relationship between the two indicates a generator problem, such as a leak or a carbon-coated catalyst. Figure 3 shows a proper carbon dioxide/dew point relationship.

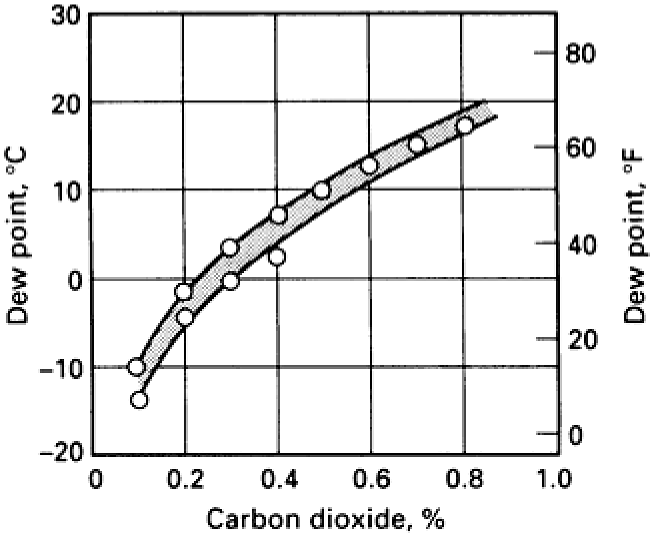

Fig. 3 Variation in the relation between dew point and carbon dioxide in the generation of an endothermic atmosphere, as obtained from four plants. The generator in each plant was operated at a different temperature, in the range of 1005 to 1095 °C (1840 to 2000 °F).

The nominal operating ranges for endothermic-atmosphere generators are -7 to 16 °C (20 to 60 °F) dew point and 0.2 to 0.7% CO_2. Generally, maintenance of an endothermic generator can be reduced by operating the generator near the lower end of the CO_2 range or near the higher end of the dew point range within the limits required by the furnace process. As a rule of thumb, the dew point will rise approximately 6 °C (10 °F) between a sample taken at the generator and a sample taken at the furnace before enriching gases are admitted to produce the desired carbon potential within the furnace chamber.

The following list describes typical endothermic generator problems that can be identified, corrected, or avoided through application of proper analysis and control:

- Carbon on catalyst
- Worn or clogged carburetor or mixer
- Poor temperature control
- Combustion products leaking into retort
- Barometric pressure change
- Humidity change
- Hydrocarbons from quench oil or engine exhaust drawn into generator with air
- Change in natural gas composition
- Sticking regulators
- Dirty flowscope orifices

When it is determined that carbon is present on the catalyst, a "burnout" procedure is followed to restore catalyst activity. Burnout is accomplished by turning off the natural gas and allowing air to pass through the catalyst. Oxygen combines with the excess carbon to form CO_2. Using the CO_2 analyzer to track the CO_2 buildup and decay, the entire burnout procedure can be monitored to completion efficiently. Operators often allow burnout to continue for excessive periods of time. By following the CO_2 readings on the analyzer, burnout usually can be completed in less than one hour. The necessity for burning out a generator is greatly reduced when the generator is controlled by CO_2 or dew point analysis, because large upsets commonly induced by manual adjustments are eliminated. In some cases, endothermic generators have been controlled at 0.20% CO_2 (dew point of -4 °C, or 25 °F) for one year without requiring burnout; this is exceptional and largely contingent on generator design, controls used, and manufacturing cycles in operation.

Generated exothermic-type atmospheres are used where inert atmospheres are required. Applications are common in the metal-treating industry for bright annealing of copper, decarburization annealing of motor laminations, processing of aluminum, and ferrous and nonferrous annealing of coils, wire, and strip. Exothermic atmospheres are also used as an inert blanket in production of glass, in food processing, and in rubber curing. Various chemical processes and storage facilities employ inert atmospheres produced by exothermic-gas generators.

Analyzer Recommendations

Typical analyses of various exothermic atmospheres are listed below, along with recommended analyzers. Total combustibles analyzers are applied most frequently to monitor and/or control exothermic atmospheres. Very rich (20% or higher total combustibles) and very lean (less than 1% total combustibles) exothermic atmospheres are most accurately monitored and/or controlled by an infrared analyzer sensitized to an appropriate range of carbon monoxide.

Rich exothermic atmospheres typically consist of 10 to 25% combustibles (approximately equal parts CO and H_2), 5% CO_2, 3% H_2O, with the remainder N_2. Recommended analyzers to control and/or monitor rich exothermic atmospheres are:

- Infrared analyzer calibrated for 0 to 10 or 20% carbon monoxide
- Total combustibles analyzer (catalytic type) calibrated for 0 to 15%, 20 or 25% combustibles

Lean exothermic atmospheres consist of 1 to 10% combustibles (approximately equal parts CO and H_2), 12% CO_2, 3% H_2O, with the remainder N_2. Recommended analyzers to control and/or monitor lean exothermic atmospheres are:

- Total combustibles analyzer (catalytic type) calibrated for 0 to 1, 2, 5 or 10% combustibles
- Infrared analyzer calibrated for 1, 2, 5, or 10% carbon monoxide
- Oxygen analyzer for 0 to 1.0% or 2% oxygen to monitor lean atmospheres to ensure minimum oxygen

Nitrogen (lean exothermic) atmospheres typically consist of 0.2% combustibles, 0.1% oxygen, 12% CO_2, 3% H_2O, with the remainder N_2. Recommended analyzers to control and/or monitor nitrogen atmospheres are similar to lean exothermic analyzers but with lower ranges specified for greater accuracy; infrared analyzers calibrated for 0 to 0.1% or 0 to 0.5% carbon monoxide are generally preferred over total combustibles analyzers when best accuracy is required.

Exothermic atmospheres with CO_2 and H_2O removed may be produced by passing exothermic atmospheres through a MEA (monoethanolamine) or a molecular sieve scrubber to remove CO_2 (<1000 ppm) and H_2O). The atmosphere can be a N_2 or a N_2 + combustibles atmosphere. In addition to applying the above analyzers, an infrared analyzer calibrated for 0 to 0.1% carbon dioxide provides an excellent means of monitoring CO_2 scrubber efficiency as well as prompt indication of carbon dioxide buildup or variation.

Control Valve and Motor Adjustment Procedure

Figures 4 and 5 summarize application of analyzers to exothermic- and endothermic-gas generators, indicate analyzer sample take-off locations, and show proper locations for installation of control valves for automatic atmosphere control. The effectiveness of an automatic atmosphere analysis control system is directly related to the proper setup of the control valve and motor. Proper control valve port size and driven-motor speed are important to system success. In both Fig. 4 and 5, the control valve should drive open when analysis point is below set point. If set point is moved below analysis point, valve should drive closed.

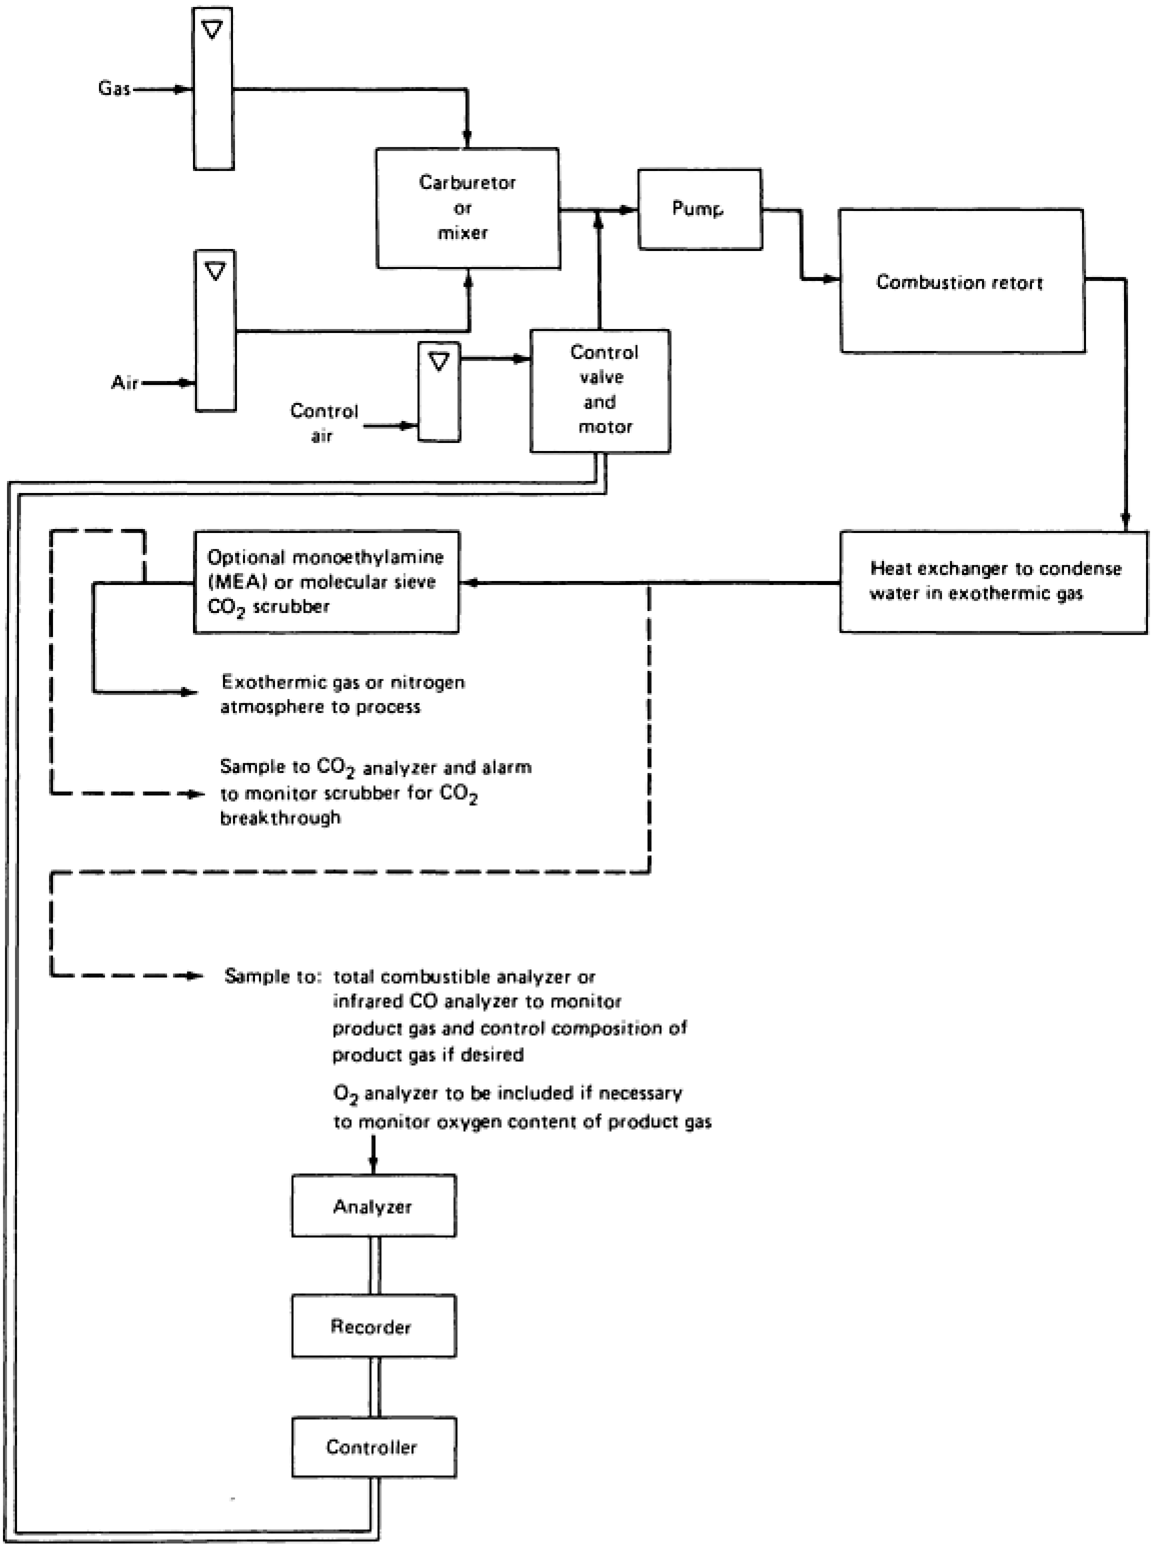

Fig. 4 Typical analyzer and controller applied to exothermic-gas or nitrogen generator

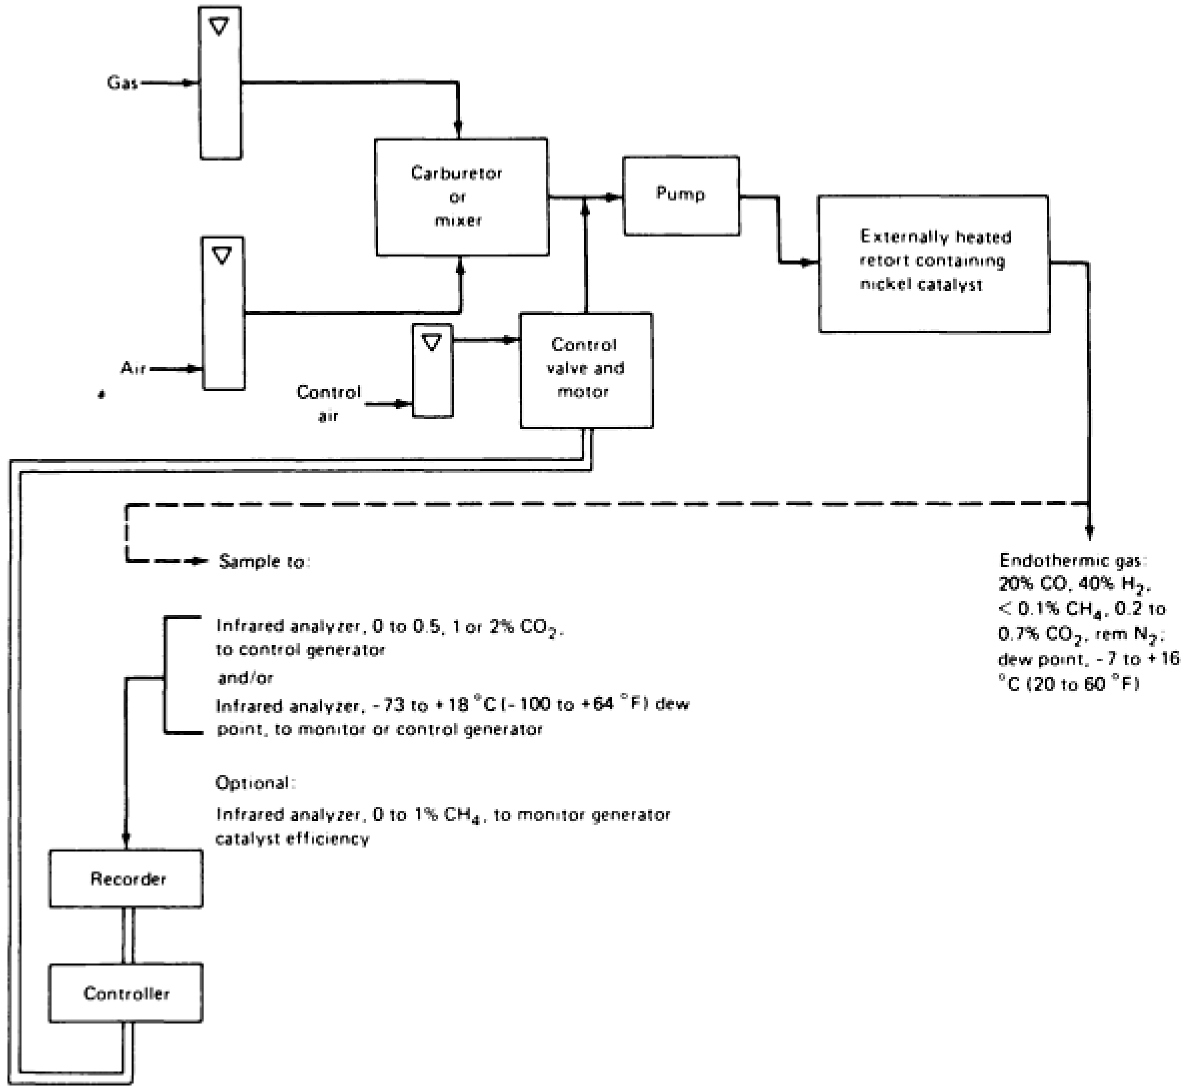

Fig. 5 Typical analyzer and controller applied to endothermic-gas generator

Increasing air to the endothermic generator (Fig. 5) increases CO_2 and dew point. Increasing air to the exothermic generator (Fig. 4) decreases CO or total combustibles. During the first week or two of operation, the control valve on the endothermic generator may keep seeking a position at full motor travel, and it will be necessary for the operator to manually reset to midposition, adjust carburetor or mixer to obtain desired set point, and switch back to automatic. This is a normal sequence caused by gradual cleaning and conditioning of catalyst in the endothermic generator.

Control of Surface Carbon Content in Heat Treating of Steel

Revised by the ASM Committee on Control of Surface Carbon Content*

Introduction

MOST HEAT-TREATING ATMOSPHERES are gaseous mixtures containing carbon monoxide, carbon dioxide, methane, nitrogen, hydrogen, and water vapor. The relative amounts of these gases depend on the type of generator gas used, the processing temperature, and the amount of gas added during processing. For example, endothermic generator gas produced by catalytic reaction of natural gas with air results in the following composition (approximate percentages by volume): 20 CO, 40 H_2, 40 N_2, 0.1 to 0.5 CO_2, 0.2 to 1.2 H_2O, and 0.2 to 0.8 CH_4. A synthetic endothermic atmosphere may be obtained by injecting 40% N_2 with 60% CH_3OH into the furnace at the heat-treating temperature. In

gas carburizing, a common commercial practice is to use an endothermic gas as a carrier and to enrich it with natural or propane gas additions.

Gas Reactions

There are several possible gas reactions that can occur in a heat-treating atmosphere because of the presence of many gas species. The most important reactions are described briefly:

$$H_2 + CO_2 \;\text{€}\; H_2O + CO \qquad \textbf{(Eq 1)}$$

$$H_2 + \frac{1}{2}O_2 \;\text{€}\; H_2O \qquad \textbf{(Eq 2)}$$

$$CO + \frac{1}{2}O_2 \;\text{€}\; CO_2 \qquad \textbf{(Eq 3)}$$

Equations 1, 2, and 3 are homogeneous gas reactions that are generally assumed to be in equilibrium in furnace atmospheres above 790 °C (1450 °F).

Equations 4, 5, and 6 are gas-solid reactions, where *C* represents carbon in solution in the steel:

$$2CO \;\text{€}\; C + CO_2 \qquad \textbf{(Eq 4)}$$

$$CO + H_2 \;\text{€}\; C + H_2O \qquad \textbf{(Eq 5)}$$

$$CH_4 \;\text{€}\; C + 2H_2 \qquad \textbf{(Eq 6)}$$

The carbon potential in the gas phase determines the carbon concentration at the surface of the steel parts being processed. Equations 4 and 5 are much faster reactions than Eq 6, as discussed in the section off kinetics. Thus, to maintain a given carbon potential in the gas atmosphere, the following reactions are important for replenishing CO and H_2 and for maintaining the appropriate low concentration levels of CO_2 and H_2O because they introduce methane (enriching gas) into the furnace:

$$CH_4 + H_2O \rightarrow CO + 3H_2 \qquad \textbf{(Eq 7)}$$

$$CH_4 + CO_2 \rightarrow 2CO + 2H_2 \qquad \textbf{(Eq 8)}$$

Equations 7 and 8 are usually considered to be nonequilibrium reactions.

Control of Carbon Potential

Traditionally, control of carbon potential has been achieved, in principle, by controlling either water vapor concentration (dew point), carbon dioxide concentration, or oxygen partial pressure. It is accomplished by the addition of methane or air to the furnace atmosphere.

The principle of carbon-potential control can be shown by the following equilibrium reaction:

$$2CO = C + CO_2 \quad \textbf{(Eq 9)}$$

The equilibrium constant for Eq 9 (K_1) is given by the relationship:

$$K_1 = \frac{a_c P_{CO_2}}{P_{CO}^2} \quad \textbf{(Eq 10)}$$

where a_c is the activity of carbon, and PCO_2 and P_{CO} are the partial pressures of CO_2 and CO, respectively. The expression:

$$a_c = \frac{K_1 P_{CO}^2}{P_{CO_2}} \quad \textbf{(Eq 11)}$$

can be derived from Eq 10. The quantity a_c is related to the carbon potential by the equilibrium relationship shown in Fig. 1, where a_c is plotted against weight percentage of carbon in austenite for various isotherms between 815 and 1040 °C (1500 and 1900 °F). Because K_1 is temperature dependent only and P_{CO} in the carrier gas remains essentially constant (20 kPa, or 0.20 atm is typical), the carbon potential may be controlled by varying PCO_2. The calculated isothermal equilibrium relationship between percentage of CO_2 and weight percentage of carbon in an endothermic-based-atmosphere containing 20% CO is shown in Fig. 2. The experimentally determined relationship between percentage of CO_2 and weight percentage of carbon has been obtained by several investigators. Although the experimental values determined by different investigators are not in exact agreement with one another or with calculated values, they generally are in close enough agreement so that control of percentage CO_2 can be used as a reliable means for controlling carbon potential.

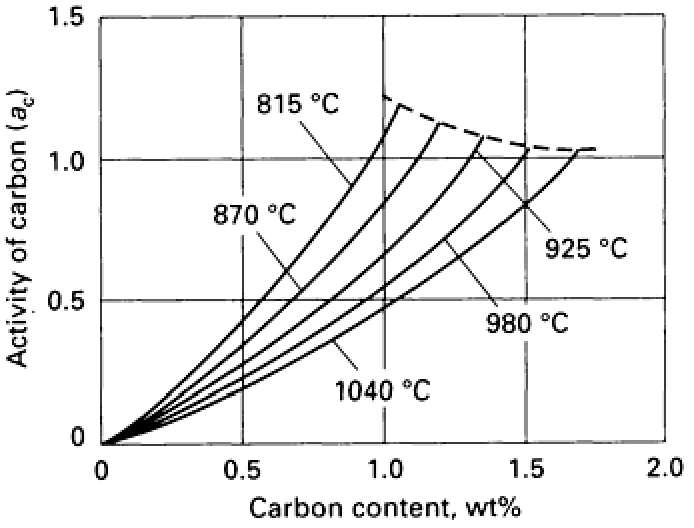

Fig. 1 Isothermal equilibrium relationship between activity of carbon and carbon concentration in austenite for various temperatures

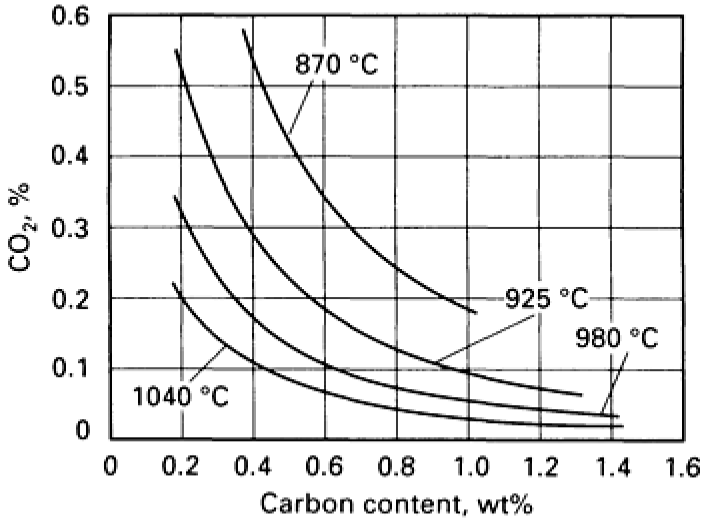

Fig. 2 Calculated equilibrium relationship between carbon dioxide concentration and carbon content in an endothermic-based atmosphere. Carbon monoxide content is assumed to be 20%.

The principle of control of carbon potential by control of H_2O vapor pressure (dew point) may be demonstrated easily by the following equations. Under equilibrium conditions, the partial pressure of H_2O is related to the partial pressure of CO_2. The following well-known water-gas reaction can be used to show this relationship:

$$H_2 + CO_2 \rightleftarrows H_2O + CO \qquad \textbf{(Eq 12)}$$

The equilibrium constant for Eq 12 (K_2) is given by:

$$K_2 = \frac{P_{H_2O} P_{CO}}{P_{H_2} P_{CO_2}} \qquad \textbf{(Eq 13)}$$

and the following expression for P_{CO_2} may be derived from Eq 13:

$$P_{CO_2} = \frac{P_{H_2O}}{K_2 P_{H_2}} P_{CO} \qquad \textbf{(Eq 14)}$$

Substitution of the right side of Eq 14 for P_{CO_2} in Eq 11 gives:

$$a_c = K_1 K_2 \frac{P_{CO}}{P_{H_2O}} P_{H_2} \qquad \textbf{(Eq 15)}$$

Because K_1 and K_2 are temperature dependent only and P_{CO} and PH_2 remain essentially constant in the carburizing atmosphere, the carbon potential can be controlled in principle by controlling the vapor pressure of H_2O (dew point). The calculated equilibrium relationship between dew point and weight percentage of carbon for an endothermic-based atmosphere containing 20% CO and 40% H_2 is shown in Fig. 3. Although the experimental values determined by different investigators are not in exact agreement with one another or with calculated values, they generally are in close enough agreement so that control of dew point can be used as a means of controlling carbon potential.

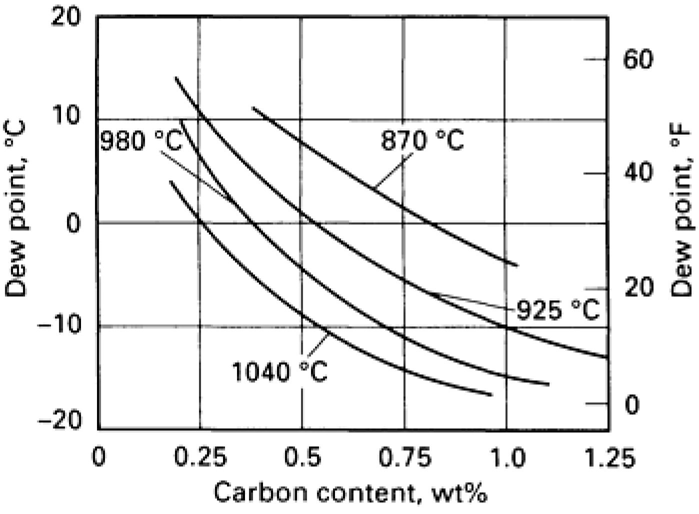

Fig. 3 Calculated equilibrium relationship between dewpoint and carbon content in an endothermic-based atmosphere. Carbon monoxide and hydrogen contents are assumed to be 20% and 40%, respectively.

Based on simple thermodynamic considerations, control of oxygen partial pressure (PO_2) can in principle be used to control carbon potential. Under equilibrium conditions, PO_2 is related to the partial pressure of P CO_2. The following well-known expression can be used to show this principle:

$$\mathrm{CO} + \frac{1}{2}\mathrm{O_2} \text{ € } \mathrm{CO_2} \qquad \textbf{(Eq 16)}$$

The equilibrium constant for Eq 16 (K_3) is given by:

$$K_3 = \frac{P_{CO_2}}{P_{CO}P_{O_2}^{1/2}} \qquad \textbf{(Eq 17)}$$

and the following expression for P CO_2 may be derived from Eq 17:

$$P\ \mathrm{CO_2} = K_3\ P_{O_2}^{1/2} P_{\mathrm{CO}} \qquad \textbf{(Eq 18)}$$

Substitution of the right side of Eq 18 for P CO_2 in Eq 11 gives:

$$a_c = \frac{K_1 P_{CO}}{K_3 P_{O_2}^{1/2}} \qquad \textbf{(Eq 19)}$$

Because K_1 and K_3 are temperature dependent only and P_{CO} remains essentially constant in the carburizing atmosphere, the carbon potential can be controlled by monitoring the partial pressure of oxygen.

Kinetics

As stated, the concept of equilibrium conditions presupposes that an infinite length of time for reaction, necessary to ensure true equilibrium, is available. In actual heat treatment of steel, however, reaction times are important factors. Some reactions are fast and take control of the heat-treating process; these are the reactions of chief concern. Intergas reactions determine the atmosphere composition and the carbon potential it will exhibit. Gas-solid reactions are responsible for the actual carbon transfer and so determine the rate of case formation.

Homogeneous Gas-with-Gas Reactions. Some gas-with-gas reactions, such as those given in Eq 12, 2, and 16, are fast. In a well-mixed atmosphere of uniform composition, fast reactions reach equilibrium and characterize, to a large extent, the gas and its carbon potential.

Other reactions, such as those given in Eq 7 and 8, are comparatively slow. These are endothermic reactions that require considerable energy absorption but that are important as replenishment reactions. They are, however, less important in characterizing the gas, especially in terms of effective carbon potential.

Hetergeneous gas-with-solid reactions, such as those defined by Eq 4, 5, and 6, are relatively slow. These are the reactions by which carbon is transferred to steel surfaces, and carbon potential is displayed and made effective. The reaction in Eq 6 is particularly slow, and this reflects the fact that CH_4 is a relatively stable molecule and does not dissociate readily. The reaction given in Eq 5 is said by some investigators to be the fastest of all carburizing reactions and the most influential in determining the rate of case formation.

Carburization of a surface involves three factors not present in gas-with-gas reactions, and one of these factors becomes rate controlling.

Movement of Molecules to the Metal Surface. Reaction in contact with the metal surface is usually required. Usually reactions occurring away from the metal surface result simply in soot deposition, which hinders carburization. Turbulent mechanical circulation of the gases over the metal surfaces keeps the gases well mixed and uniform in composition, and maintains flow of the supply gases to the main stream of reacting gases. The amount of energy and time required for mixing can be significant, especially where workloads are densely packed in the baskets and gases do not have uniform access to all parts of the load.

Reactions between Gases and Metal Surfaces. Carburization occurs when the proper gas molecules interact with a metal surface and transfer carbon to that surface. As the carbon is released by the gases, it is incorporated (dissolved) into the surface layer of the metal. These reactions are rate controlling with respect to the overall process, especially in the early hours of the process. The concentration of the active species affects the rate at which the proper molecules contact the metal surface and consequently affects the rate at which the gas mixture gives up carbon to the surface. Conversely, the concentration of decarburizing H_2O and CO_2 molecules (relative to equilibrium concentrations) determine whether some of the carbon transferred will be reincorporated promptly into a gas molecule. Such considerations determine whether, at a given temperature, a given gas mixture will carburize steel at the maximum rate or at a considerably lower rate. Consequently, increasing methane concentrations well above equilibrium values (that is, without corresponding decreases in CO_2 and H_2O) will not necessarily result in the expected increase in carburizing rates.

Dilution of the carburizing gas mixture with an inert gas such as nitrogen will slow carburization by reducing the rate at which carbon-donating molecules contact the metal surface. To this reduction is added the effect of the inert diluent on carbon potential. Generally, that effect is a drop in carbon potential. However, in the endothermic-gas technique, concentrations of inert diluent up to at least 40% do not seriously impair the carburizing power or the carburizing rate of a well-prepared gas mixture. Despite these known factors, the mechanisms of reactions between gases and metal surfaces are too complex and conditions at the work surfaces too difficult to evaluate, for accurate mathematical prediction of reaction rates for a given gas composition in a production carburizing furnace.

Diffusion of Dissolved Carbon from the Metal Surface. When carbon has become part of the metal surface, it usually represents an increase in carbon concentration over that of the core, except where the surface has been previously decarburized. With this increased carbon concentration, the carbon begins to diffuse toward the leaner core at a rate that is a function of this concentration gradient, of case depth, and of temperature. Initially, this diffusion rate is high; carbon diffuses inwardly at a rapid rate, and surface concentration increases slowly. As the surface carbon activity approaches equilibrium with the gas carbon activity after about 2 h at 925 °C (1700 °F), the rate of inward transfer diminishes until it becomes rate controlling. Beyond that point, acceleration of carburization requires that either the carbon potential or the carburizing temperature be raised.

Kinetics in Practice. Recognizing that transfer of carbon from the gas to the steel surfaces can be rate controlling for the first several hours of a carburizing cycle, it is advisable to:

- Employ high-power circulating fans in the furnace to move the atmosphere rapidly and to keep it thoroughly mixed
- Direct the movement of gases as much as possible to maximize circulation through the work load and to

minimize short circuiting in the region of the fan

- Allow sufficient space for movement of gas between and around workpieces
- Use atmosphere compositions that initially will provide a carbon potential well above the concentration desired in the work surface. This will facilitate carbon transfer at a maximum rate while the case is shallow and carbon demand is high
- Reduce carbon potential during processing in time to establish carbon concentration in the surface at the desired set point before processing is complete
- Anticipate the total carburizing time required for a given case by referring to published data or by means of calculations based on Fick's law of diffusion. Use this as a guide in evaluating the rates of case formation obtained

Process Control in Gas Carburizing

Control of a gas-carburizing process involves accurate measurement and adjustment of temperature, time, flow of carrier gas or atmosphere, and flow of enriching gas. Initial set points for these parameters are established from equilibrium data or from experience. Set points may be changed as necessary to maintain required properties of the workpieces. In some installations, certain parameters such as temperature and carrier-gas, or base atmosphere, flow are fixed, and the time of exposure and the flow of enriching gas are varied to achieve differences in case depth and surface carbon content.

Control-System Features. Regardless of the variable being controlled or the instrumentation being used, a major feature of every control system should be a set of signal devices that warns operating personnel of major malfunctions. For instance, a power failure normally renders the atmosphere control system inoperative. It also shuts down the furnace heating system. If the furnace temperature drops below 760 °C (1400 °F), there is an increased danger of an explosion. A temperature-activated, battery-powered audible or visible alarm warns of a decrease in temperature in time to allow the furnace doors to be opened and the combustible mixture to be burned out or purged with an inert gas before the temperature drops below the danger point.

If the furnace pressure drops below a predetermined minimum because of loss in atmosphere flow supply, there is again a danger of explosion due to air infiltration. Such a condition should activate an alarm system that triggers a purge system.

The reserve supply of inert gas should be monitored and an alarm system installed that will signal a drop in the gas supply to a predetermined dangerous level. There should always be enough inert gas in reserve to purge the combustibles out of all connected furnaces.

In general, the control system should comply with National Fire Protection Association (NFPA) 86C recommendations.

Under normal operating conditions, control is maintained by periodic checking of the control parameters against set points or specified values, followed by adjustment of heat input, enriching-gas flow, or other process variables as necessary. Case depth often is specified as effective case depth (to 0.40% C, or to 50 HRC), which indicates the hardened case depth. The effective case depth is influenced by steel composition and by process variables: temperature, time at temperature, carbon potential of the atmosphere, and efficiency of the quench.

Accuracy. For a constant atmosphere composition, especially where there is no change in carbon dioxide content, a change in temperature of about 10 °C (18 °F) can produce a change of as much as 0.1% in carbon potential. Therefore, accurate control of carbon potential is achieved only when there is accurate control of temperature.

Normally, an atmosphere-control system must respond to variations of 0.01 to 0.02% in carbon dioxide content; however, this degree of control is not sufficient in high-temperature carburizing, where the set point may be below 0.1% carbon dioxide. Then, reproducibility of ±0.005% or better is usually recommended.

Inherently, carburization is a slow, forgiving process; a part is usually at elevated temperature for several hours. Therefore, periodic fluctuations in temperature or in carbon potential are usually of little consequence. As long as average conditions are maintained, without large or prolonged excursions from set-point conditions, it is unlikely that parts will be adversely affected. Likewise, a few minutes' difference from programmed time in the furnace usually will be of little consequence.

Only carburizing and diffusion times, not total furnace time, should be counted toward the time required to develop a given depth of case. Preheating time is disregarded because little carburizing takes place in this part of the cycle. Any equalizing time following diffusion also may be disregarded; during cooling from the diffusion temperature to the quenching temperature, any diffusion that occurs will not substantially increase case depth.

Controlling the Process. For control of carburization, there is no substitute for alert, vigilant, well-trained operators. There are many ways a carburizing furnace and its controls can malfunction. For instance, failure of a thermocouple or plugging of the atmosphere-sampling tube can cause the process to go out of control. Any soot buildup on the parts will stop continuous carburizing reactions. These and many other relatively common occurrences can be detected by operators, and corrective action can be taken before there is an adverse effect on parts in the furnace.

Moreover, considerable thought and preparation should go into the initial preproduction planning for carburizing a new part or for putting new or renovated equipment into operation. The following is a checklist of items to be considered in setting up for production:

- *Temperature distribution:* Uniformity of temperature throughout the heated zones of the furnace and correct location of thermocouples should be ensured
- *Effects of loading:* Full trayloads of parts may have to be checked and subjected to complete metallurgical examination to determine distribution of case depth, hardness, and other properties in parts throughout the load. Light loading is inefficient in terms of energy usage, but heavy loading can cause nonuniform atmosphere flow through the work. Bulk loading of parts randomly heaped in baskets is likely to cause unacceptable case depth and hardness variability
- *Variations in carbon concentration:* Test bars for carbon determination should be placed in different furnace loads and at varying locations on trays. Results of tests should be analyzed statistically to ascertain the process capability of the furnace
- *Variations in properties:* Effects of the positions of parts in the load on asquenched or quenched and tempered properties should be analyzed statistically
- *Atmosphere introduction:* In continuous furnaces for shallow cases and with fast pushing cycles, most of the enriching gas is piped into the furnace close to the discharge end and possibly flowed countercurrent to the work. For slow cycles and deep cases, the main flow of enriching gas into the furnace should be nearer to the charging end. In either instance, most of the enriching gas should enter at the point where the work load has reached the carburizing temperature
- *Dew-point characteristics:* In continuous furnaces, it should be ascertained whether the last furnace zone (diffusion zone) can develop the required dew point, with some latitude for adjustment. A small measured quantity of air may be introduced to increase the dew point and lower the carbon potential. Some operators prefer to inject exothermic gas instead of air at the discharge end
- *Hardenability of the steel:* Wherever possible, properties of the parts should be determined for heats of steel at both the top and bottom limits of the hardenability band
- *Dimensional variations:* Parts requiring close tolerances should be measured before and after hardening to evaluate dimensional changes

When a furnace is first put into operation, when it has been overhauled or relined with new firebrick, or after a long furnace shutdown, it is usually necessary to dry out and condition the furnace before it is used for carburizing production parts. Conditioning consists of bringing the empty furnace to the operating temperature and then admitting a carburizing atmosphere and allowing the atmosphere to react with the internal components of the furnace for at least several hours to as long as several days. Conditioning ensures that the internal components of the furnace will be essentially at equilibrium with the carburizing atmosphere, so that chemical reactions between the atmosphere and the workpieces will not be slowed because of reactions between the atmosphere and the furnace lining.

Set points for control of the carburizing atmosphere are usually estimated by referring initially to a plot of carbon potential versus dew point (see Fig. 4), or of carbon potential versus carbon dioxide concentration (see Fig. 5). After control has been established and the furnace is conditioned, it may become necessary to adjust set points to ensure that the desired surface carbon content is obtained consistently and reliably. Charts such as Fig. 4 and 5 also may be used to estimate the effect of a given change in set point.

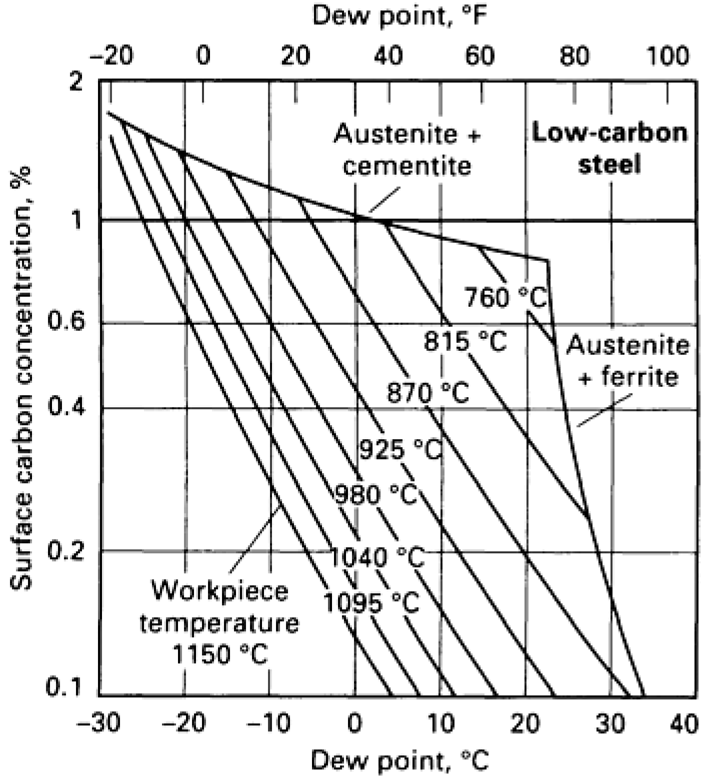

Fig. 4 Variation of carbon potential with dew point for an endothermic-based atmosphere containing 20% CO and 40% H_2 in contact with plain carbon steel at various workpiece temperatures

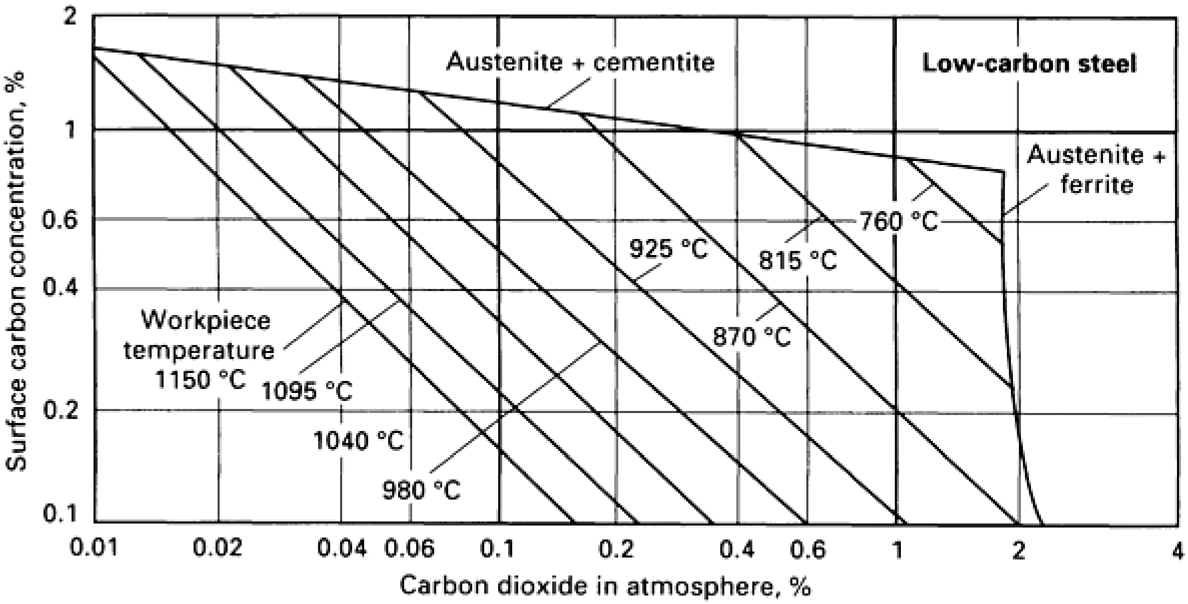

Fig. 5 Variation of carbon potential with carbon dioxide concentration for an endothermic-based atmosphere containing 20% CO and 40% H_2 in contact with plain carbon steel at various workpiece temperatures

Temperature control should be maintained with an average deviation from the control set point of no more than ±3 °C (±5 °F) for good control of results. However, a control cycle of ±6 °C (±10 °F) is usually acceptable. In a continuous four-zone carburizing furnace, thermocouples should be placed near the end of the first (preheat) zone because workpieces should be at carburizing temperature when they enter the second (carburizing) zone. Thermocouples should be placed in the centers of the second zone and the third (diffusion) zone. In the fourth (equalizing) zone, thermocouples

should be close to the discharge end; this will ensure that the workpieces have reached the required temperature for subsequent quenching, which is usually about 815 °C (1500 °F).

There should be provision for two thermocouples in each furnace zone. They should be as close as possible to the workpieces. One thermocouple is for the temperature recorder/controller, and the second is for an overheat potentiometer set at the overtemperature of that zone. If a hole or crack develops in a thermocouple-protection tube, the thermocouple will come in contact with the reducing furnace atmosphere and will malfunction. When this happens, the protection tube and thermocouple must be replaced.

Circulation of the atmosphere influences temperature uniformity throughout the furnace. Without good circulation, there is no effective temperature control, and wide differences in temperature can exist between the outer and inner sections of the work basket. This is true for both continuous and batch furnaces.

Atmosphere Control. Generator gas that contains 0.1 to 0.3% CO_2 and that has a dew point of about -10 to 5 °C (15 to 40 °F) is ideal for use in a carburizing atmosphere. Reactions in the gas generator are controlled by regulation of the gas-to-air ratio in the mixing valve before the hydrocarbon gas is cracked in the retort tubes of the generator. Increasing the air flow increases the dew point, and increasing the natural gas flow decreases the dew point. It is usually preferable to generate a carrier gas with a composition favorable to trouble-free generator operation. Production of carrier gas with a carbon dioxide content of less than 0.1% may cause excessive sooting in the generator, requiring frequent burnouts.

An oxygen probe or infrared control system may be used to automatically control the generated endothermic atmosphere so that it maintains a constant composition.

The atmosphere formed by incomplete combustion of natural gas, propane, or other hydrocarbon is assigned a predetermined set point. When the generated atmosphere is not on the set point, a signal is sent to a motorized valve that either increases or decreases the flow rate of hydrocarbons for a given constant rate. Control could be implemented with either hydrocarbon or an air trim system. The amount of trim should be ±15% of the total flow.

An oxygen probe could be installed using two distinct setups.

In Situ Method. The probe is inserted through the top of the cooling chamber to a point 25 to 50 mm (1 to 2 in.) above the catalyst. At this point, the temperature should be at least 900 °C (1650 °F), although the preferred temperature range is 925 to 980 °C (1700 to 1795 °F). The head of the probe and the lead wire must be cooled with forced air.

Sample-Reheat Method. The probe is inserted into a sample port on the atmosphere exhaust line. This method may require maintenance to remove the deposition of soot from the sample line.

Automatic control of the generated atmosphere, which would maintain a constant composition, could contribute to a more effective process. However, automatic control of the generated atmosphere is not as accurate as an automatic carbon-potential control that monitors the atmosphere of a heat-treating furnace.

At no time should the carburizing atmosphere in the furnace be controlled by varying the dew point or carbon dioxide of the generator gas. If the furnace atmosphere is too rich, raising the generator-gas dew point to decrease the carbon potential will not work effectively. The reactions in the generator will not stay in equilibrium with this method of control.

The carbon potential of a carrier gas is neutral; the actual source of carbon is the enriching gas. Thus, the carbon potential of the furnace atmosphere can be controlled by varying the flow of the enriching gas. Altering the enriching gas will raise or lower the CO_2 or H_2O content, which, in turn, determines the carbon potential of the steel.

It should be noted that the reactions are not in equilibrium with latter stages of a carburizing batch. The enriching gas flow is initially found by experience and subsequently continuously monitored by automatic controls until the cycle is completed.

An oxygen probe or infrared control system may be used in controlling the carbon potential automatically in the batch furnace atmosphere or continuous furnace atmosphere zones. The atmosphere of each zone is assigned a predetermined set point. When the atmosphere is not on the set point, a signal is sent to a motorized valve, which either increases or decreases the flow of the enriching gas. A normally closed on-off solenoid valve may be used instead of a motorized

control valve. The equalizing zone generally is controlled by admission of a predetermined amount of air to keep the carbon potential at its intended value.

Sampling of Atmospheres for Analysis

In the carburizing of steel, three properties of the finished case are important:

- Surface concentration of carbon
- Case depth
- Carbon gradient

Case depth depends primarily on carburizing time and temperature; it often can be presumed to depend only on time because the temperature used in a given plant is often standardized. The other two case characteristics depend strongly on the carbon potential of the atmosphere and on accurate control of carbon potential. Carbon control is difficult unless the amounts of both carburizing and decarburizing constituents present in the atmosphere can be analyzed and controlled. The first requisite of analysis is that a representative sample of the furnace atmosphere be obtained.

The sample of gas should be taken from a point in the furnace chamber as close as possible to the work being treated. This will lessen the likelihood of obtaining a sample of stagnant gas, such as may be present near the furnace wall. The sampling point should also be as far as possible from the atmosphere inlet ports and from burner tubes. When the furnace has forced circulation through the work load, a sample taken from the atmosphere as it leaves the work will most nearly reflect its effective operating condition.

Velocity of Gas Flow. Empirical data indicate that when carbon dioxide or water vapor is to be measured, the velocity of gas flow through the sampling probe should be at least 1.2 m/s (240 ft/min). This velocity almost completely prevents reactions between constituents by reducing the time that the gas is in the intermediate temperature range, which exists mainly in the portion of the tube that passes through the furnace wall. With lower velocities, the water-gas reaction will take place at lower temperatures and thus raise the concentration of carbon dioxide and decrease the concentration of water vapor. If the carbon potential of the atmosphere is high, carbon monoxide will decompose into carbon dioxide and soot. This will further increase the concentration of carbon dioxide and also will affect the water-vapor content through the water-gas reaction.

When sooting occurs in the probe, the sample delivered to the analyzer has a higher carbon dioxide content than actually exists in the furnace. Based on analysis of the sample, the controller would increase the flow of enriching gas, which would put the furnace out of control and compound the sooting problem in the probe. This condition can be detected by observing the flow rate of enriching gas. If it is significantly higher than the normal value for the indicated carbon dioxide content it indicates out-of-control furnace atmosphere. Probe sooting also may be suspected if a manual check of dew point reveals an abnormally low water-vapor content for the indicated carbon dioxide content.

An alternative method of preventing a gas reaction during cooling is water cooling of the sample probe. The water cooling prevents water-gas reaction in the sample probe. This method should not be used with dew-point analyzers when the temperature of the cooling water is below the dew point of the atmosphere. Accurate measurement of dew point will not be obtained until the sampling line is dry. For other types of analyzers, a water trap is required in the sampling line to keep condensed water out of the analyzer. Even with a trap, however, it is good practice to keep the sampling line dry and to ensure that water does not enter the atmosphere analyzer.

Probe sooting also can be prevented by inserting a high-purity quartz liner into the probe to eliminate any catalytic effect of the probe material on chemical reactions within the probe.

If a flow rate below 1.2 m/s (240 ft/min) is used without a water-cooled sample probe, analysis will be sensitive to flow rate. Flow sensitivity can be checked by varying the flow rate from $\frac{1}{2}$ to $1\frac{1}{2}$ times the normal value and by noting any change in analysis that results.

Probe Materials and Design. The probe should be made of a heat-resisting alloy that does not react with the gas sample. Probes made of iron-chromium alloys are preferred to those made of high-nickel alloys because nickel catalyzes the breakdown of carbon monoxide into carbon dioxide and soot.

If the sample flow rate required by the analyzer is known, the internal diameter of the sampling probe that will provide the desired velocity can be calculated. Permanent probes smaller than 6.4 mm (in.) in diameter are not recommended because it is difficult to prevent them from becoming plugged with soot. To facilitate cleaning, a 25 mm (1 in.) diam pipe with tee and cap often is used as the outlet through the furnace wall. When the probe is mounted in a horizontal position, it must be made with heavy-wall tubing or must be placed inside a larger tube for increased mechanical strength.

One of the more effective methods of ensuring proper flow rate is to provide a separate sample pump for each furnace, furnace zone, or carrier-gas generator being controlled. The sample pump pushes the sample gas from the furnace or generator to the analyzing instrument. This minimizes sample contamination due to leaks in the sample line because there is always a positive pressure in the portion of the line downstream from the pump. If a sample pump fails, only one sampling point, not the entire controlled system of a multiple-point recorder-controller, is affected.

Another method for measuring the atmosphere composition of each furnace or each zone of a continuous furnace is shown in Fig. 6. This central sampling installation uses one pump for one sampling port and the analyzing instrument(s), and a second separate pump for all other sampling ports to keep them purging.

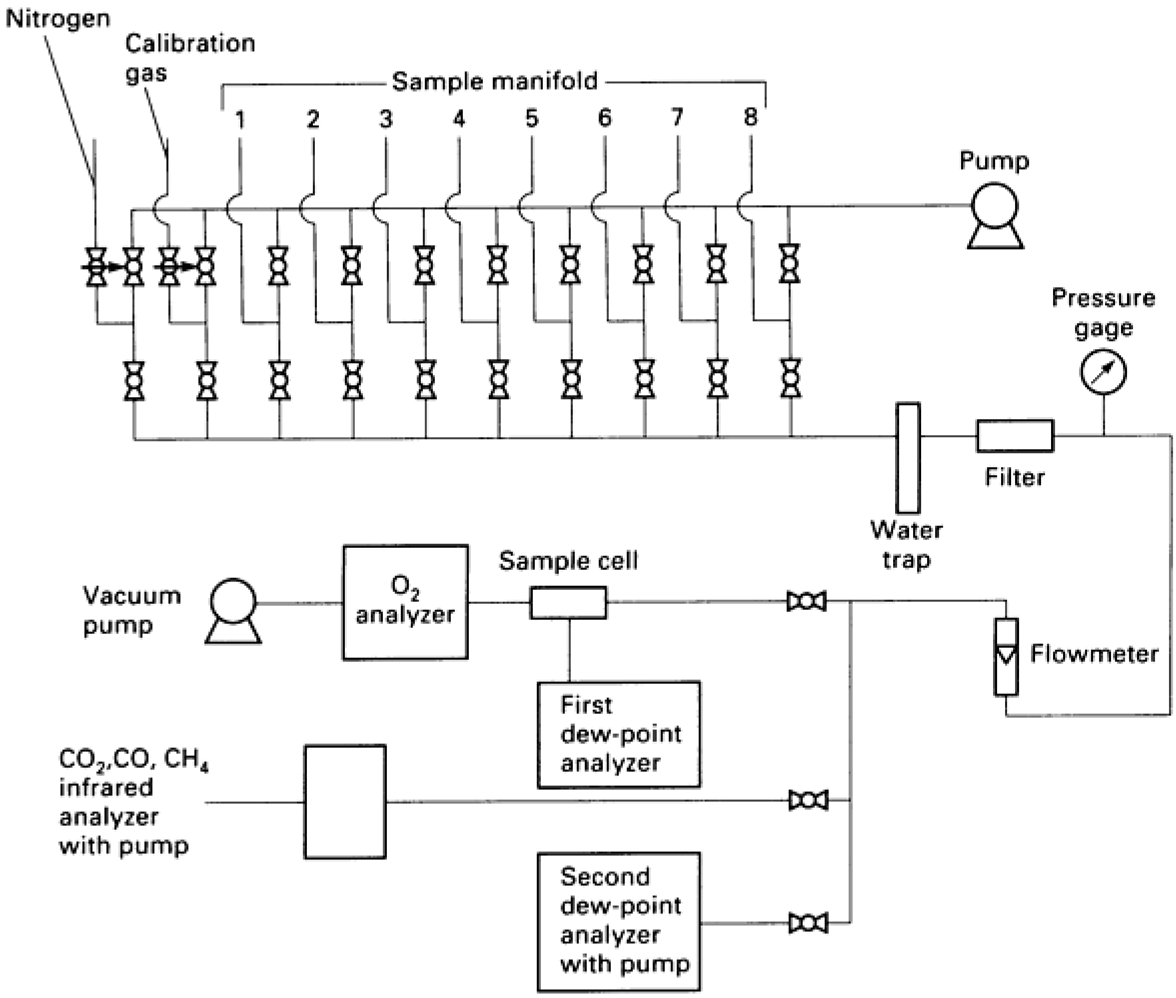

Fig. 6 Central atmosphere-sampling system that incorporates a sample manifold

The sample gases flow continuously through all sample lines. This reduces significantly the time required to purge the individual sample line selected for analysis and increases the accuracy of the entire analysis. Furthermore, the instruments can be purged with nitrogen and used to measure the sample gas when needed.

This central sampling system consists of a manifold with two shutoff valves for each sampling line (see Fig. 6). The two shutoff valves can be replaced with one three-way selection valve for each sampling line.

Permanent sampling probes should have a tee with a cleanout plug. Even though the instrument may have a filter of its own, it is wise to install a separate filter about 0.6 m (2 ft) from the gas-sampling tube in the furnace to collect any soot or dirt. An ideal filter for this purpose is the type used for compressed-air lines, which has a replaceable porous metal filter cartridge and a transparent plastic bowl. Another common type has a glass-wool filter cartridge. The filter cartridge can be inspected periodically and changed when dirty, and any condensate in the filter can be drained off by a petcock on the filter. If condensate is observed in the filter cartridge after draining, the cartridge should be replaced.

The sample line may be of copper, aluminum, or stainless steel tubing, although copper should not be used if ammonia is present in the atmosphere. A plastic tubing that will not absorb moisture also may be used if it is protected from heat. For installations in which the sample line must pass through areas where the ambient temperature sometimes falls below the dew point, steam tracing or electrical heating of the sample line is required.

Procedures and Precautions. Before a gas sample is taken from a batch-type furnace without a charging vestibule or from a continuous furnace from startup, enough time should be allowed for purging of the furnace chamber and porous refractories. Otherwise, high atmosphere dew points will occur at the beginning of a cycle and will cause condensation in the sample line. For batch-type furnaces, this delay can be accomplished automatically with an electrical limit switch operated when the furnace door or cover seal is broken and a time-delay relay set up for the proper purging time. In continuous furnaces, the sample pump should be turned off, or the sample line should be blocked with a manual valve.

In pusher-type continuous furnaces, the periodic opening of the furnace doors may cause large changes in atmosphere composition. When manual instruments are used, samples should be taken at the same time in each push cycle (preferably just before a push), in order to compare results. Use of an automatic analyzer that continuously monitors the atmosphere will permit observation of the effects of venting, resealing doors, and changing the purge flows to the vestibules. With this as a guide, the amount of variation in atmosphere composition can be reduced.

Relationship between Control Systems and Analysis. Usually, automatic equipment for controlling atmosphere-mixture ratios and carbon potential is more reliable than manual equipment, which varies in effectiveness with the skill of the operator. However, regardless of whether the process is controlled automatically, there is no substitute for alert, intelligent personnel on the operating floor. It should not be assumed that automatic process controls are the answer to control problems. Equipment malfunctions have often been noticed by operating personnel in time to switch over to manual control and avoid ruining the parts in the furnace.

Generator output and furnace-atmosphere composition are controlled by recording analyzers. These should have proportioning-type controls rather than on-off or two-position control because of the time lag in the sampling lines and the slow response of some analyzers. The preferred procedure for controlling carburizing atmospheres is to hold the flow of carrier gas constant and to vary the flow of the enriching gas. The normal procedure for generators is to set the carburetor (or mixer) to produce a rich fuel-air ratio and then to control the flow of air in a bypass line around the carburetor.

When the carbon potential of an atmosphere is to be controlled and one constituent of the atmosphere is to be measured, the set point must be determined on the basis of chemical analysis of the carbon content of either shim stock or turnings from test bars. Equilibrium data can be used to determine the approximate set point, but equilibrium conditions do not always exist in furnace atmospheres. By setting the limit on the furnace to obtain the final equilibrium condition required, the enriching gas flow is minimized. The controller will take over the monitoring of the furnace near the end of the cycle to deliver much lower flow rates.

Control of temperature is usually accomplished automatically, with a single-point or multiple-point recorder-controller regulating the heat input to the furnace. When several furnaces or several zones in a single furnace need to be controlled, it may be necessary to use a separate (dedicated) temperature controller for each furnace or each zone, particularly if different set points are used. Location of thermocouples that sense the control point is important, especially in continuous furnaces under zone control or in situations where furnace doors are opened frequently.

Simple elapsed-time controllers frequently are used to trigger successive events in the carburizing cycle, such as successive pushes in a pusher furnace or the end of carburizing and the beginning of diffusion in a batch furnace. In some types of continuous furnaces cycle time is regulated by the speed at which parts are moved through the furnace.

For batch furnaces with programmed temperatures, atmosphere set points also must be programmed. Shims removed at the end of each temperature period will serve as guides in determining correct set points.

When a furnace or generator is first placed under automatic control, it is considered good practice to monitor carbon dioxide content continuously and to correct any variations caused by equipment condition. The following list gives the interdependent variables that must be considered to establish and maintain automatic control of the carbon dioxide content in a carburizing atmosphere:

- Type of furnace
- Condition of equipment, including tightness and ability to maintain uniform temperature
- Size and type of typical work load
- Composition and uniformity of carrier gas
- Composition and uniformity of enriching gas
- Frequency of sampling and controlling
- Type of control: on-off or proportional
- Sensitivity of controller
- Width of proportional band on proportional controllers
- Normal and maximum response times of the motor-driven control valve
- Flow rate through fully open control valve
- Normal time for atmosphere to stabilize following a change in a controlled variable

Dual controls offer certain advantages for improving the stability and responsiveness of automatic control systems when the atmosphere gas is not of uniform composition, or when there are frequent large variations from normal operating conditions. Under these conditions, measurement of a single constituent of the furnace atmosphere will not necessarily lead to the desired level of process control. In these cases, control through analysis of only one atmosphere constituent results in a relatively large percentage of off-quality production. Simultaneous analysis and control of two atmosphere constituents is usually sufficient to overcome the more common problems.

Dual control is most often accomplished by either infrared ratio control of both carbon monoxide and carbon dioxide, or simultaneous independent analysis of carbon dioxide and dew point. In infrared ratio control, a two-column analyzer is used, with one column sensitized to carbon monoxide and the other to carbon dioxide. The output from the two columns is sent by means of a tapped slidewire to a third unit that actually controls the flow of enriching gas. The use of a tapped slidewire allows the output of the analyzers to be read as the ratio $(P_{CO})^2/(PCO_2)$, which is directly proportional to carburizing potential.

A system for simultaneous analysis of both carbon dioxide and dew point normally consists of two independent analyzers connected to a single sampling line. In the usual arrangement, the carbon dioxide analyzer establishes primary control, and the dew-point controller activates an alarm circuit whenever the water vapor content of the atmosphere deviates from prescribed limits.

Infrared Analyzers

Infrared analyzers are based on the principle that any compound present in the mixture will absorb infrared energy in proportion to its concentration in the mixture. The wavelengths absorbed are different for each compound. Elemental gases such as hydrogen and oxygen do not absorb infrared radiation and therefore cannot be analyzed by this method.

Infrared analyzers are normally used to measure carbon monoxide, carbon dioxide, and methane. For automatic control of carburizing processes where the carrier gas and enriching gas are reasonably uniform in composition, infrared analysis of carbon dioxide was considered the most accurate method and was the most widely used. The oxygen probe has recently gained acceptance. Infrared analyzers are normally connected to a recorder-controller or a scanner-programmer-printer of either the single-point or multiple-point type, which actually performs the control function.

In multiple-point control assemblies, a single analyzer is coupled to a system of gas-sample valves and control circuits, one set of sample valves and a control circuit for each point being analyzed and controlled. After each analysis is made and the resulting control signal is transmitted to the appropriate control valve, an automatic switching mechanism disconnects the sample valves and control circuit and energizes the set of sample valves and the control circuit for the next control point. A maximum of eight different furnaces, furnace zones, or carrier-gas generators is usually recommended for a single analyzer.

An infrared analyzer responds rapidly when the analysis function is triggered by the recorder-controller. Even so, time is required for transmittal of the control signal, and for flushing of the sample cell in the analyzer, so that the composition of a new sample will not be altered by remnants of the previous sample. Successive analyses can be made at intervals of about 1 min, allowing approximately 30 s for flushing and analysis and the remaining 30 s for controlling.

Positive-Filtering Analyzer. In this type of analyzer (shown in Fig. 7), an electrically heated helix of nickel-chromium alloy wire is the source of infrared radiation. Radiation from this source is split into two beams by mirrors. Both beams are simultaneously interrupted by a motor-driven chopper. The resulting pulses of radiation cause alternate heating and cooling of gas in the two sides of the detector. A condenser microphone consisting of a movable metal diaphragm and a fixed metal plate is mounted between the two sides of the detector. A measurement of differential pressure can thus be obtained.

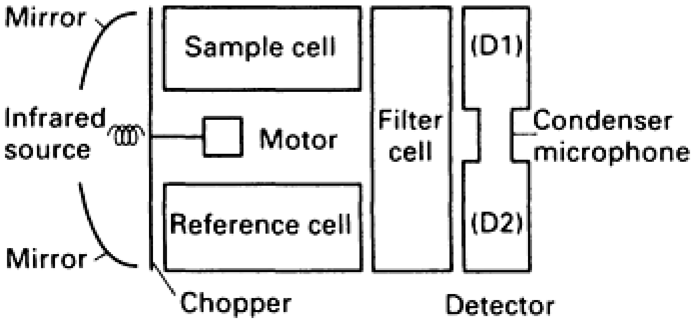

Fig. 7 Components of a positive-filtering infrared analyzer for measuring carbon monoxide, carbon dioxide, and methane contents of an atmosphere

The gas stream to be analyzed is continuously passed through the sample cell. The reference cell is filled with a gas that does not absorb infrared radiation, such as nitrogen or argon. A filter cell common to both beams is filled with a mixture of the background gases present in the sample-gas stream; the mixture should contain all constituent gases that absorb infrared radiation other than the specific gas being measured. The latest instruments on the market do not need to have the reference cell filled with a mixture of the background gases.

To sensitize the analyzer for measurement of carbon dioxide, both sides of the detector (D1 and D2) are filled with carbon dioxide. If the radiation in the two beams is identical, equal pulses of energy will strike both sides of the detector simultaneously, causing identical heating effects that will cancel each other and thereby produce no motion of the flexible membrane. If a gas containing some carbon dioxide is admitted to the sample cell, energy pulses reaching the D1 side of the detector (Fig. 7) will be reduced. The gas in D1 will be heated less than the gas in D2, and the pressure differential will cause a movement of the flexible membrane. The higher the concentration of carbon dioxide in the sample cell, the lower the energy level reaching D1, resulting in a higher signal output.

A positive-filtering infrared analyzer has good sensitivity and accuracy; the usual stated accuracy is 1% of full scale. Its direct-current output is 0 to 20 mA, 4 to 20 mA, or 0 to 100 mA. When a positive-filtering analyzer must be removed from service for repair, it can be returned to service without being conditioned prior to use.

Negative-Filtering Analyzer. In this type of analyzer (shown in Fig. 8), an electrically heated nickel-chromium alloy filament is the source of infrared radiation. Infrared energy passes through the sample cell and a filter cell and is separated into two beams by sensitizing cones. These two beams fall on detectors D1 and D2, which are thermopiles connected in series opposition to measure the difference in energy level of the two beams.

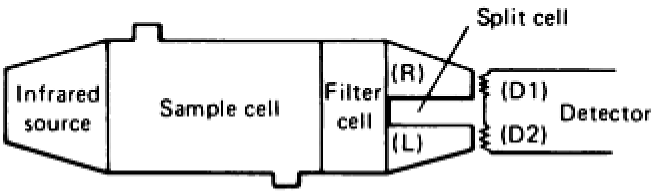

Fig. 8 Components of a negative-filtering infrared analyzer for measuring carbon monoxide, carbon dioxide, and methane contents of an atmosphere

Sensitization of the analyzer for measurement of carbon dioxide is accomplished by filling the right sensitizing cone (R in Fig. 8) with carbon dioxide, the left sensitizing cone (L) with a nonabsorbing gas such as nitrogen, and the filter cell with a mixture of interfering gases. Interfering gases are any gases present in the sample-gas stream that have any absorption lines that coincide with absorption lines for carbon dioxide. The newest such instruments on the market have deleted the filter cell as a component of the analyzer.

When no carbon dioxide is present in the sample flowing through the sample cell, radiation falling on detector D2 is undiminished, but radiation passing through the right sensitizing cone and falling on detector D1 is reduced to nil because of absorption by the pure carbon dioxide in the right cone. As a result, the two detectors produce a net signal that is proportional to the radiation unbalance.

If a gas sample containing some carbon dioxide is now passed through the sample cell, the radiation falling on detector D2 will be reduced by the energy absorbed in the sample cell. There will be no change on detector D1 because the pure carbon dioxide in the right sensitizing cone removes all radiation frequencies characteristic of carbon dioxide. The resulting change in net signal from both detectors is proportional to the concentration of carbon dioxide in the sample cell.

If a gas sample containing other gases that absorb infrared radiation is passed through the sample cell, an equal amount of radiation will be absorbed from the beams reaching both detectors, and the output of the analyzer will remain proportional to the amount of carbon dioxide present in the sample. If an interfering gas is present in the sample, the gas in the filter cell will ensure that its effect cannot be detected and that the output is still proportional to the carbon dioxide content.

A negative-filtering infrared analyzer has good sensitivity, good stability, and no moving parts. It has a nonlinear output so that the scale on the recorder is expanded at the low end of the scale (where most carburizing is controlled) and compressed at the high end. The stated accuracy at the low end of the scale is ±0.002% at a set point of 0.05% CO_2. When a negative-filtering analyzer is removed from service for repair, it must be conditioned for 24 h, after repairs have been made, before it can be put back into service.

Solid-State Detector Analyzer. This type of analyzer is similar in operation to the positive-filtering analyzer, except that the chopper is generally used to alternate the energy through the sample cell and the reference cell. The filter cell and condenser microphone detector are eliminated and replaced by a narrow band-pass interference filter placed on top of a solid-state detector, as shown in Fig. 9. The energy from the sample cell and reference cell is collected by end mirrors and directed to the filter/detector assembly. The band pass of the interference filter is set up in such a manner that the instrument becomes specific for either CO, CO_2, or methane. Because these detectors are very small, they can be stacked side by side, and multiple components can be analyzed in a single instrument. A solid-state detector infrared analyzer has good sensitivity and accuracy. The usual stated accuracy is 1% of full scale. Direct-current outputs are available as required, and repairs tend to be more routine than with either the positive-filtering analyzer or the negative-filtering analyzer.

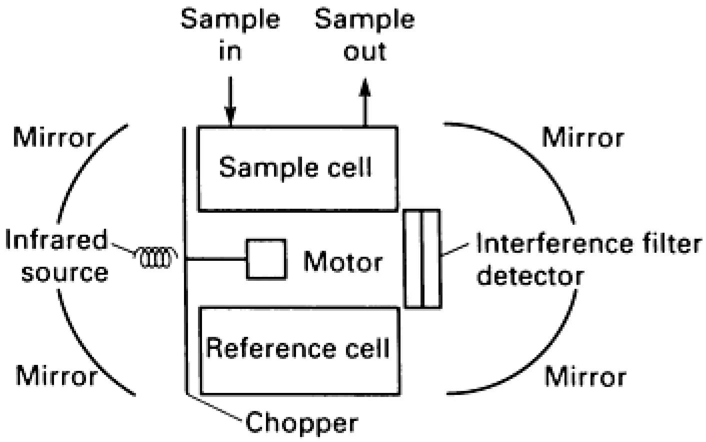

Fig. 9 Components of a solid-state detector infrared analyzer for measuring carbon monoxide, carbon dioxide, and methane contents of an atmosphere

Advantages of Infrared Analyzers. The use of an infrared analyzer-control system on endothermic generators and carburizing furnaces will result in narrower deviations in gas analyses. Such a system provides more uniformity of case depth and helps keep generators and furnaces free of soot.

Examination of the daily charge record of the analyzer will reveal changes in the condition of the atmosphere. For example, work on the natural gas pipelines in the field may cause a variation in the heat content of the natural gas. This will be indicated by the analyzer, and controls automatically restrict the effect of this change.

In one plant the chart revealed that rapid and severe increases in the carbon dioxide concentration and the dew point of the furnace atmosphere occurred with each opening of the discharge door of a continuous carburizing furnace. This problem was eliminated by improving the seal on the inner door and by adding a flame curtain to the outer door.

An infrared analyzer-control system will also compensate for the difference in the volume of natural gas required by a heavily loaded furnace on a short heating cycle and that required by a lightly loaded furnace on a long heating cycle. When a furnace or generator is being started, the system will provide a continuing check of atmosphere conditions so that equipment can be put into service as soon as proper operating levels are reached, without the necessity of frequent manual checking of dew point.

Limitations of Infrared Analyzers. An infrared analyzer is relatively expensive and complex, and its maintenance and repair require the skills of a trained electronics specialist. Malfunctions are not readily detectable; the unit may continue to operate despite failure of several components but will give erroneous readings. However, instruments that incorporate the most recent state-of-the-art technology include microprocessors having self-diagnostic features to announce and to identify analyzer malfunctions. Automatic control valves must be checked to ensure that they are operating properly and are not locked in the completely open or closed positions. The unit must be adjusted frequently to reflect changes in minor variables, such as a change in the energy content of the gas. Therefore, to ensure the accuracy of the system, trained personnel must daily recalibrate the unit against a gas of known composition.

Finally, when very high dew points are encountered, enough moisture may condense in the lines and be carried to the sample cell to damage the cell or render the system inoperative until the cell has been dismantled and cleaned. Damage caused by moisture may be prevented by installation of a moisture trap or an electrical warning system ahead of the sample cell.

Dew-Point Analyzers

Dew-point analyzers measure the partial pressure of water vapor in the furnace atmosphere. Dew point is defined as the exact temperature (at a given pressure) at which a mixture of gases will begin to precipitate its moisture content. When air and gas are mixed in consistent fixed proportions and the mixture is heated to allow chemical reactions to reach equilibrium, the dew point will reflect the chemical balance of the various components comprising the reacted products.

The use of dew point for controlling carbon potential is a fast, inexpensive, and relatively simple procedure. Control of endothermic-based atmospheres by the dew-point method is widely accepted in industry.

Manually operated instruments for measuring dew point are inexpensive, rugged, and simple, and serve satisfactorily under normal operating conditions. Automatic instruments are available also.

Dew-Cup Instrument. The simplest instrument for measurement of dew point is the dew cup, which appears in Fig. 10. The gas sample is drawn from the furnace or generator across the outside of a polished cup made of chromium-plated copper. The cup is enclosed in a glass container so that the moisture can be seen condensing on the cup surface when the dew point is reached. The cup surface is cooled progressively by dropping small pieces of dry ice in acetone (or methanol) inside the cup until the dew point is reached, as indicated by condensation on the cup surface at a temperature indicated by a thermometer in the acetone.

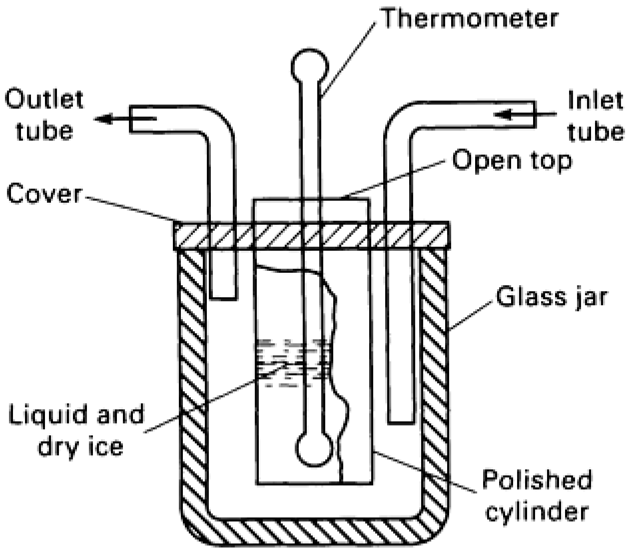

Fig. 10 Components of dew-cup apparatus for measuring dew point

The dew cup is most accurate for measurement of dew points above the freezing point of water. At dew points lower than 0 °C (32 °F), there is the possibility of supercooling, with an attendant low dew-point reading.

Use of the dew cup requires that the operator possess a considerable amount of skill and consistency. However, it is not recommended for close control. Incorrect dew-point readings may result if the atmosphere is sooty, if there are leaks in the dew cup or sampling lines, if the flow of atmosphere is too fast, if the temperature is lowered too quickly, or if the lighting conditions are poor in the area where the dew point is being observed.

Fog Chamber. The fog chamber, shown in Fig. 11, is another instrument for manually measuring dew point. It is used throughout industry because it is portable and gives consistent and accurate readings over an extremely wide range of dew points but requires no external cooling or mechanical refrigeration. The fog chamber operates on the principle that a rapidly expanding gas cooled adiabatically will produce a fog only when specific requirements of pressure drop, ambient temperature, and moisture content in the gas sample are satisfied.

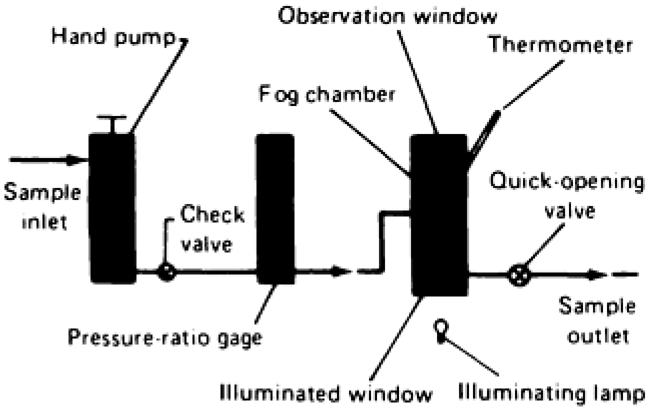

Fig. 11 Components of fog-chamber apparatus for measuring dew point

The atmosphere sample to be tested is drawn into the apparatus and held under pressure in an observation or fog chamber by a small hand pump. A pressure-ratio gage indicates the relationship between the pressure of the furnace atmosphere sample and the ambient atmospheric pressure. The temperature is indicated by a thermometer that extends into the observation chamber. The atmosphere sample is held in the observation chamber for several seconds to stabilize the temperature, after which the quick-opening valve is depressed, releasing the pressure and creating an adiabatic cooling. This may cause a visible condensation or fog to be suspended in the chamber. The fog is easily observed with a lens system that provides a beam of light in the fog chamber when the quick-operating valve is depressed. The procedure is repeated to find the end point, that at which the fog disappears. The dew point is then determined by referring to a chart that is based on the initial temperature reading of the thermometer and the pressure-ratio-gage reading at the point at which the fog disappeared.

Chilled Mirror. One of the first methods devised for automatic control of dew point involves the use of the chilled-mirror instrument, which is presented in Fig. 12. This method uses refrigeration and heating to condense and evaporate moisture from an illuminated mirror while the temperature of the mirror is being monitored. A photoelectric cell is used to detect the intensity of the light that the mirror reflects from the source of illumination. The intensity of this reflection depends on the amount of moisture present on the mirror. When the photoelectric cell registers a reflection that represents a deviation from a desired dew point, it generates an electric signal that in turn actuates appropriate auxiliary equipment at the furnace or atmosphere generator, which restores the dew point to the desired level.

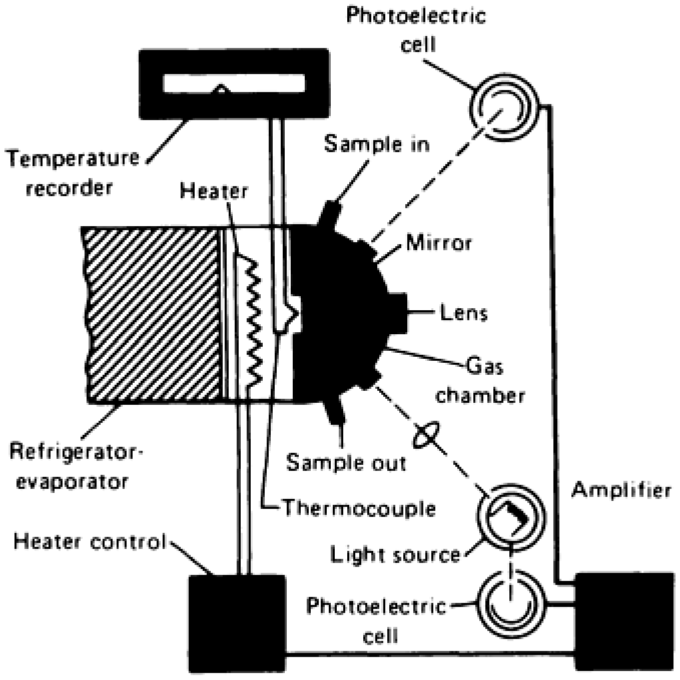

Fig. 12 Components of chilled-mirror apparatus for measuring dew point

This method is satisfactory for controlling relatively clean atmospheres, such as those consisting of mainly nitrogen or hydrogen, but it is not recommended for use with endothermic atmospheres unless maintenance problems created by dust and soot are solved. Chilled-mirror instruments are subject to errors when hydrocarbons or other vapors are present in the sample-gas stream.

Chilled-Metal Instrument. The chilled-metal method of determining dew point uses two refrigerated platinum electrodes that condense the moisture from a gas sample to complete an electrical circuit. The temperature of the electrodes is recorded as the circuit is completed, thus giving the dewpoint temperature. A heater is employed to evaporate the moisture from the sample chamber and electrodes, to prepare the instrument for another determination. Dirt and sooting present problems as with the chilled-mirror instrument. Figure 13 shows a chilled-metal instrument.

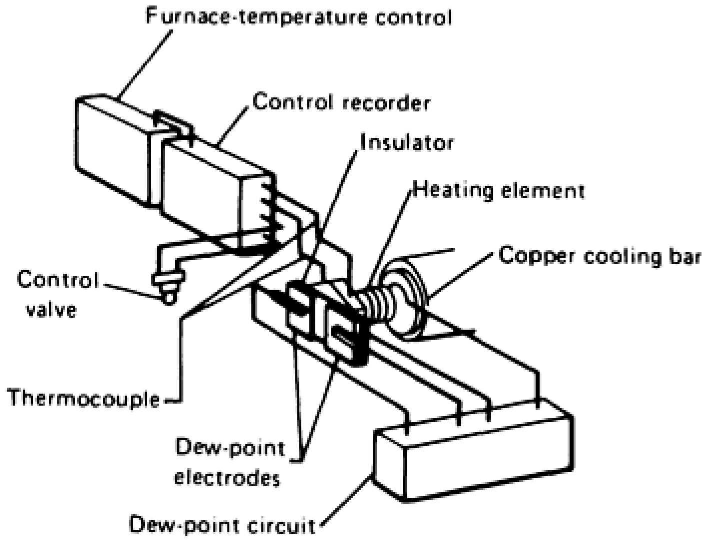

Fig. 13 Components of chilled-metal apparatus for measuring dew point

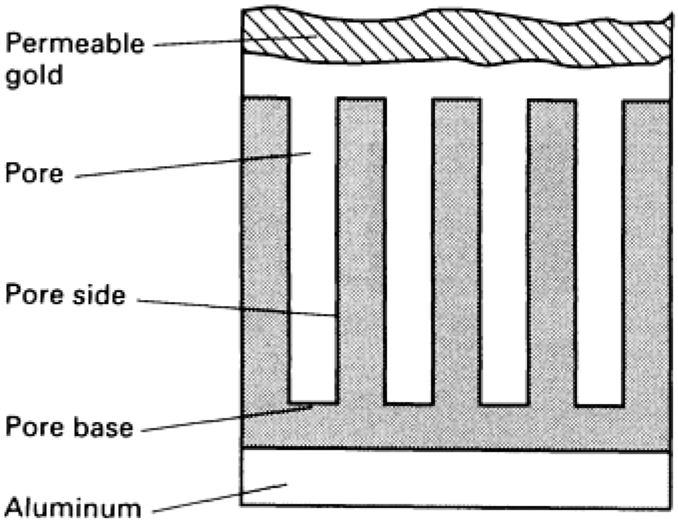
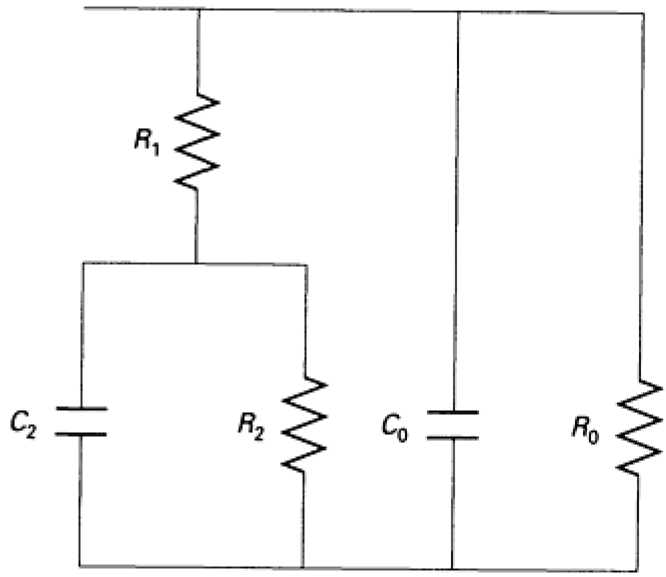
Lithium Chloride. Another type of dewpoint instrument that is widely employed for continuous automatic control uses as its basis for operation the behavior of a hygroscopic salt (lithium chloride) when in contact with water vapor. Dry lithium chloride will absorb water at room temperature and dissolve, forming a saturated solution. This solution may then be heated to the temperature at which the evaporation tendency of the moisture just matches the absorption tendency of the salt. This temperature is directly related to the dew-point temperature.

The instrument used consists of a thin metal tube wrapped with glass tape that is impregnated with dry lithium chloride. The tape is overwound with two silver wires and covered with a perforated metal guard. When the lithium chloride is exposed to moisture and becomes partly saturated, it becomes conductive, and a current is passed through the silver wire, driving off the moisture until equilibrium is achieved. The temperature is read from a sensor inside the metal tube. A limitation of this instrument is its susceptibility to contamination by raw ammonia, which makes it unacceptable for control of carbonitriding atmospheres.

Aluminum-Oxide Dew-Point Analyzer. The sensor in this analyzer consists of an aluminum substrate that is anodized to form a thin porous layer of aluminum oxide over which a very thin coating of gold has been deposited. The aluminum and gold form two electrodes of an aluminum-oxide capacitor (see Fig. 14). Water will diffuse through the gold layer and equilibrate on the pore walls. The number of water molecules absorbed on the oxide structure determines the conductivity of the pore walls. Each value of pore-wall resistance provides a value of electrical impedance that is related to the water vapor pressure, thus producing a dew-point reading.



(a)



(b)

Fig. 14 Aluminum-oxide dew-point sensor. (a) Layered construction. (b) Circuit equivalent. C_0, capacitance of aluminum-oxide layer; C_2, pore-base capacitance; R_0, resistance of aluminum oxide; R_1, pore-side resistance; and R_2, pore-base resistance

The aluminum-oxide dew-point analyzer is used for continuous automatic monitoring and control of heat-treating atmospheres. Because the maximum operating temperature of the aluminum-oxide sensor is 70 °C (160 °F), a sample gas stream must be taken from the furnace and cooled prior to taking the dew-point measurement. Current state-of-the-art liquid oil filters are the most efficient method of removing submicron solid metallic particles that may be deposited on the aluminum-oxide layer and are the source of inaccurate dew-point readings.

The standard furnace gas-sampling system used in an aluminum-oxide dew-point analyzer is shown in Fig. 15. The furnace atmosphere sample stream initially flows into the sample system via a stainless steel needle valve. The sample stream then passes through two filters: an oil filter containing polyethylene in liquid form to remove the solid particles, and a sintered stainless steel filter to entrap particles over 7 μm (280 μin.) in diameter. The sample stream then proceeds

to the sample cell, where the moisture-sensing probe is located, flows through a second needle valve, and finally exits the sample system via the vacuum pump.

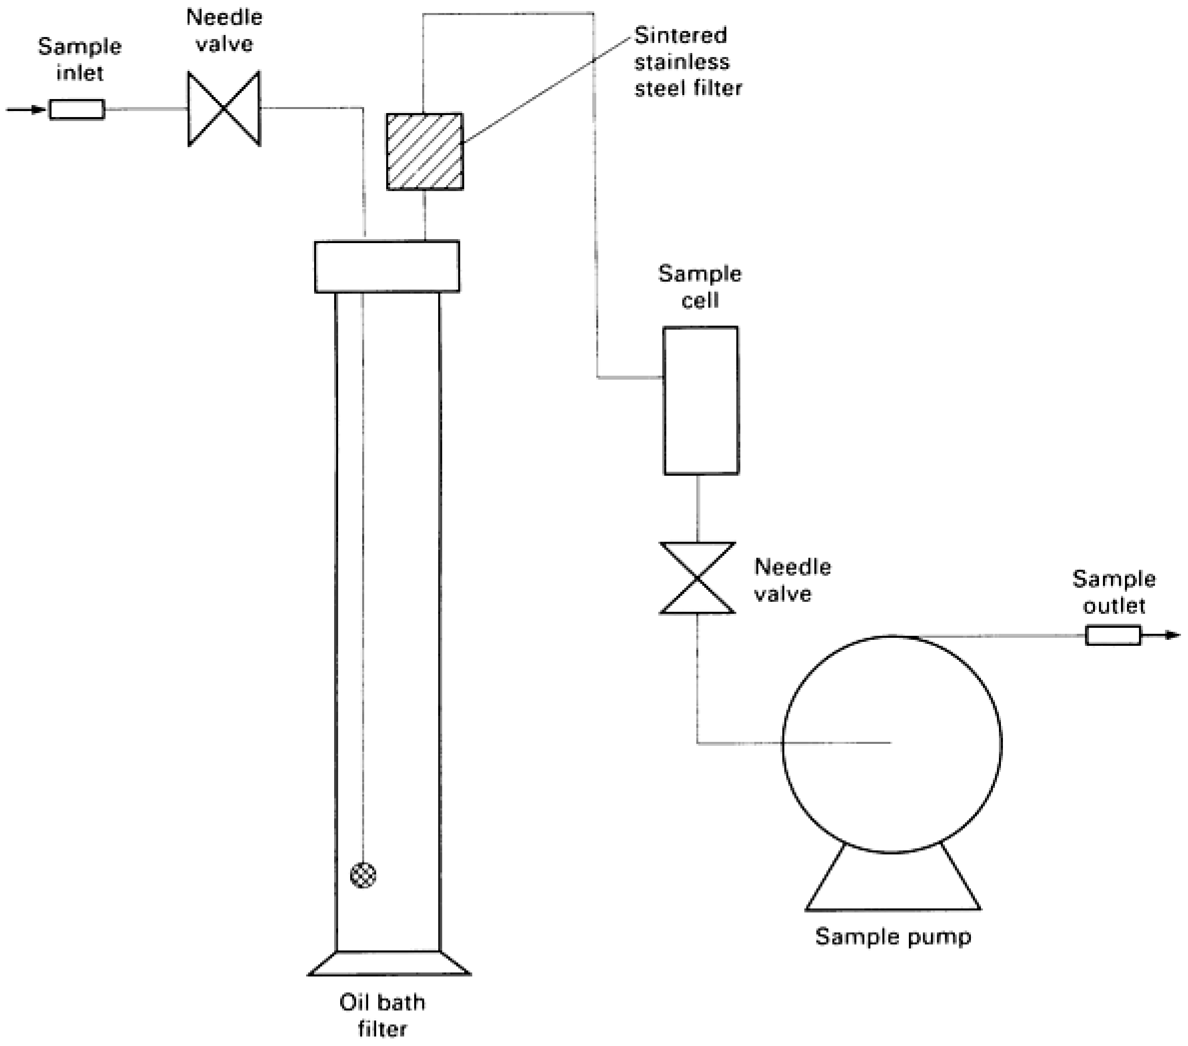


Fig. 15 Standard furnace gas-sample system incorporating an aluminum-oxide dew-point sensor in the sample cell

Limitations of Aluminum-Oxide Dew-Point Analyzer. This instrument cannot be relied upon to provide consistently accurate readings because it tends to drift with ambient and sample-gas temperatures. Furthermore, when exposed to the air or a wet gas atmosphere, it cannot be reused until the sensing probe has been either dried or recalibrated.

Silicon-Chip Dew-Point Analyzer. This instrument uses a capacitive-type sensor of silicon composition. An attached thermostatically controlled heating element maintains the temperature of the sensor in excess of the normal ambient or sample-gas temperatures. Because the sensor is calibrated at the elevated operating temperature of 45 °C (115 °F), the accuracy of the analyzer is unaffected by gas temperature variations below 45 °C (115 °F).

Instrument advantages include:

- Wide operating dew-point range: -80 to 80 °C (-110 to 175 °F)
- No temperature-induced error between -40 to 45 °C (-40 to 115 °F)
- Practically independent of flow rate
- High stability

- Rapid removal of moisture and hydrocarbon contaminants
- Extremely rapid response

Instrument limitations include:

- Does not tolerate gas samples containing oil, ammonia, or corrosive components
- Insufficient data to evaluate analyzer performance in hydrocarbon(s), carbon monoxide, and carbon dioxide atmospheres because instrument is a recent heat-treating innovation

Typical Limitations of Dew-Point Analyzers. Although dew-point analyzers can reflect changes in dew point with a fair degree of accuracy, these changes do not always correlate exactly with changes in carbon potential. An error of only a few degrees Celsius can represent an error of 0.1 to 0.2% C in evaluation of the carbon potential of a given atmosphere, which can be as much as a 25% deviation if the desired carbon content is near the eutectoid composition.

With respect to initial investment, automatic dew-point analyzers and controllers represent one of the lower-cost approaches to automatic control of carbon potential. However, the cost of maintenance of automatic dew-point equipment is a matter of some consequence. The equipment will tolerate virtually no dirt in the sampling system and consequently requires frequent cleaning and replacement. A refrigeration system is generally used to lower the gas temperature so that dew point can be measured, and problems may attend the operation of any refrigeration system.

In any dew-point-analysis system, condensed moisture in the sampling lines or filters will result in erroneous high readings that will continue until all moisture has been evaporated by purging the sampling lines and changing the filters. It is possible for condensate to form if the temperature within the sampling lines at any time falls below the dew point of the gas being analyzed. An efficient filtering system must be used with automatic equipment to keep contaminants out of the sampling system of the instrument.

In most automatic systems used for checking more than one unit, rather long purge times are required between dew-point readings if the dew points of the various units are not reasonably close together. For example, if the dew points in two furnaces differ by 20 °C (36 °F), long purge times between readings may be required for accurate results. In some automatic systems, it might be impossible to record successive dew points of -18 and 10 °C (0 and 50 °F) because formation of excessive moisture on the sensing head might render the system inoperative until the moisture can be purged from the system.

The silicon-chip dew-point analyzer (see the section "Aluminum-Oxide Dew-Point Analyzer" in this article) has a rapid response and removes excessive moisture very rapidly, but there is insufficient data to evaluate its performance in an atmosphere containing hydrocarbon(s), carbon monoxide, and carbon dioxide.

Other disadvantages of a dew-point system are the lack of a method of accurate calibration, such as is available with a system for controlling carbon dioxide, and the fact that calibration is required if the system is to reflect the hydrogen content of the atmosphere.

Oxygen Probes

In an endothermic-based or exothermic-based carburizing atmosphere, one of the reversible reactions, given as Eq 16, is:

$$CO + \frac{1}{2}O_2 \rightleftharpoons CO_2$$

The carbon potential of such an atmosphere is inversely related to the square root of the partial pressure of oxygen, as indicated in Eq 19. Therefore, by monitoring the concentration of oxygen, carbon potential can be defined without considering the concentrations of hydrogen, water vapor, or carbon dioxide. The only atmosphere constituent that directly influences the relationship is carbon monoxide. As long as the carbon monoxide content is reasonably constant, carbon activity can be controlled by controlling oxygen content. The advantage of this method of carbon-potential control is that it is less sensitive to changes in carbon monoxide and/or hydrogen content of the carburizing atmosphere. This can be

easily ascertained by comparing Eq 19, where it is observed that a_c is proportional to P_{CO}; with Eq 11 and 15, in which a_c is proportional to P^2CO and to the product $P_{CO}PH_2$, respectively.

An oxygen probe usually consists of two platinum electrodes separated by a solid electrolyte in the form of a gas-tight zirconia tube closed at one end (see Fig. 16). The probe, which is enclosed in a ceramic sheath or heat-resistant alloy, is inserted into the furnace. The furnace atmosphere enters the probe through a window in the sheath and contacts the outer electrode. The other electrode, inside the zirconia tube, is in contact with air, which serves as a reference gas of constant oxygen content. The difference between the partial pressure of oxygen in the furnace atmosphere and that in air induces an electromotive force (voltage), or emf, across the electrodes. The partial pressure of oxygen in the furnace atmosphere is determined by the voltage output (emf) of the sensor. Thus, carbon potential can be controlled by controlling the temperature in the furnace and the voltage output of the sensor because, as shown in Fig. 17, an isothermal relationship exists between carbon content (wt%) and the emf of the sensor. The voltage output of the sensor is fed directly into an electronic control circuit. The control circuit may be designed to operate in an on-off mode, a proportional mode, or a proportional-plus-reset mode, depending on the smoothness of response desired. The stated accuracy of most control systems based on the oxygen probe is ±0.05 wt% of carbon potential over the temperature range of the sensor.

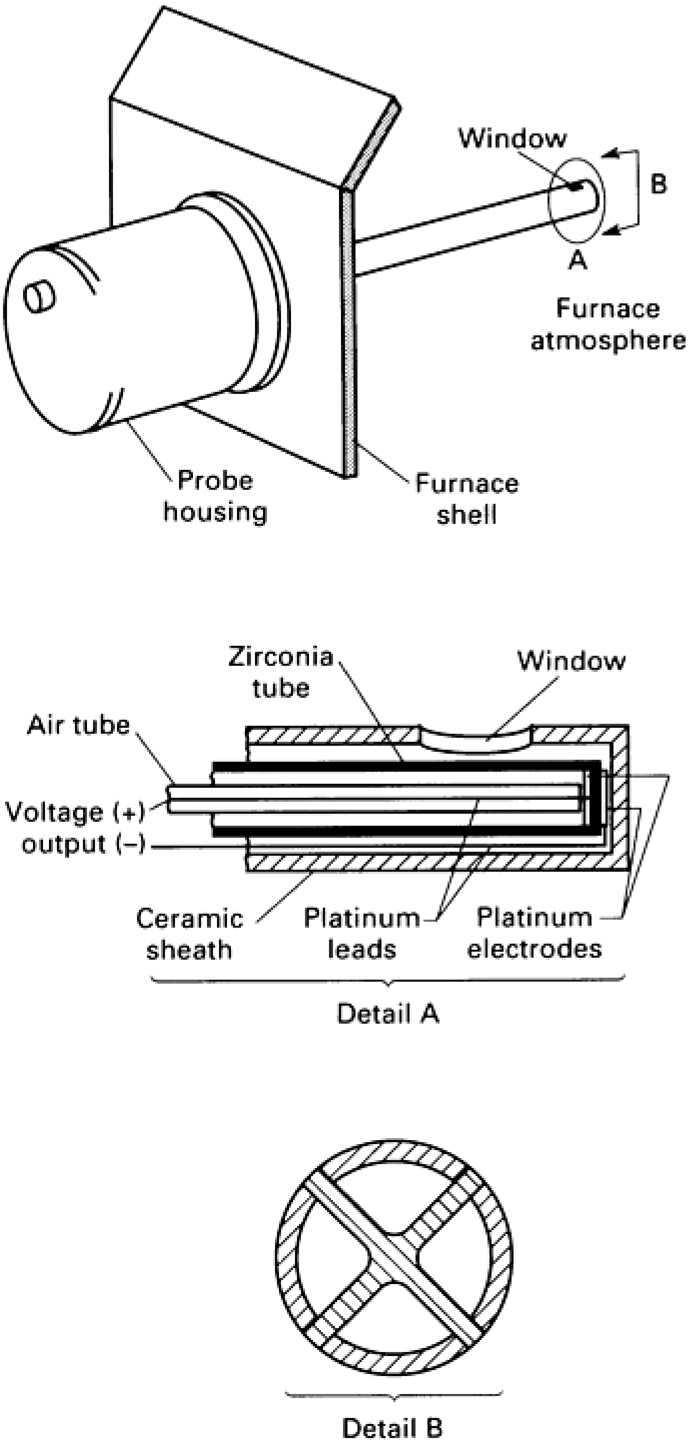

Fig. 16 Components of a typical oxygen probe for controlling carburizing atmospheres. Detail B shows construction of X-cap tip.

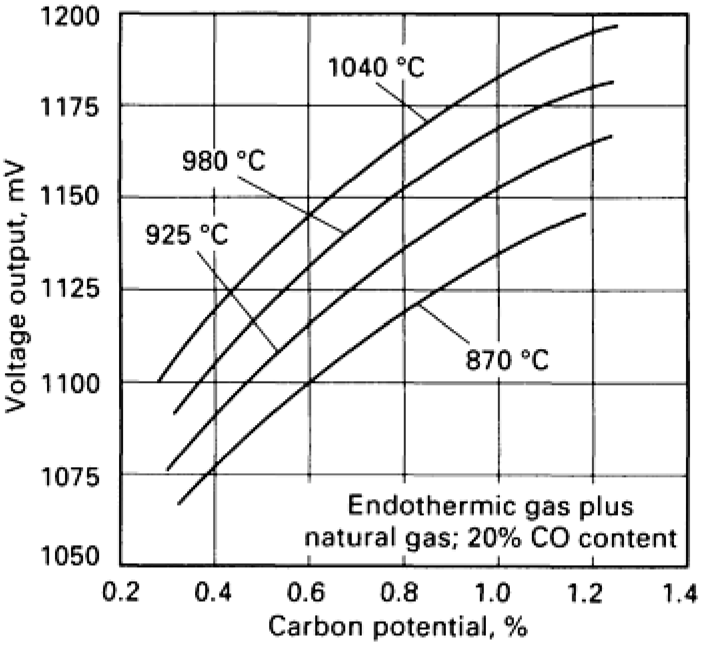

Fig. 17 Voltage across electrodes of a typical oxygen probe as a function of carbon potential at four temperatures, for endothermic gas enriched with natural gas and containing 20% CO

The correlation between the output of an oxygen probe and actual carbon potential has been confirmed experimentally, as shown in Fig. 17.

Advantages. The response of an oxygen probe is almost instantaneous and is directly related to changes in carbon potential. There is no loss in sensitivity at high temperatures, that is, 980 to 1040 °C (1800 to 1900 °F). Calibration, cleaning, and the maintenance associated with gas-sampling systems are not required; the probe is inserted directly into the atmosphere through a hole in the furnace wall. Sudden or substantial changes in the concentrations of carbon dioxide or water vapor do not cause pronounced control problems, as such changes do with infrared analyzers.

Disadvantages. The major disadvantage of oxygen probes is that the ceramic probe element must be replaced periodically, normally at intervals of one year or longer. Detachment of the outer electrode from the zirconia tube causes most probe failures requiring replacement. (The outer electrode is the one exposed to the furnace atmosphere.) Other causes of failure are mechanical and thermal shock, which crack the brittle ceramic components. In most instances, however, the increased reliability and decreased maintenance and supervision costs more than offset the expense of periodic replacement of the probe element.

The catalytic effect of the platinum outer electrode and the nickel alloy tube greatly reduces the accuracy of the probe. This catalytic effect can influence the hydrocarbon enrichment reactions represented by Eq 7 and 8, resulting in the atmosphere at the platinum electrode having a higher carbon potential than the atmosphere in the other portions of the furnace. This creates two problems:

- Because product formed has lower carbon content than expected, the magnitude of the error increases with the percentage of hydrocarbon enrichment
- Platinum electrode is plagued by increasing buildup of soot on its surface

To minimize the problems incurred by the catalytic effect described above, the following steps are recommended:

- Increase the furnace atmosphere flow at the sensing element
- Position the sensor near the circulation fan or in an area with a high furnace atmosphere flow. Note that furnaces lacking circulation fans are poor candidates for *in situ* oxygen probes

- Use an X-cap tip and open porting of the protection tube to maximize atmosphere flow (see Fig. 16)

Heavy sooting will impede atmosphere flow to the cell, thereby causing erroneous carbon-potential readings. Soot deposition usually occurs between the probe window and the furnace-shell portion of the insulating ceramic tube.

The installation of an air-purge system can eliminate the sooting problem. A low but controlled airflow rate of approximately 0.06 m^3/h (2 ft^3/h) can provide a gentle burnoff of the soot deposits without chilling the tube. The control must be set offline during the purge operation. Purge air must originate from a low-pressure source to prevent injection of a dangerously excessive volume of air into the probe. Oxygen probe manufacturers should be consulted for details.

Orsat Analyzer

The Orsat analyzer has long been the principal tool for analysis of furnace atmospheres. However, chromatographic and infrared analyzers have been gradually displacing it because of their greater speed and sensitivity. The Orsat analyzer has a comparatively low initial cost.

Operation of this equipment involves bubbling of a sample of an atmosphere through a series of solutions, each designed to absorb one of the gaseous constituents. Hydrogen, methane, ethane, and sometimes carbon monoxide are determined by controlled oxidation to water and carbon dioxide. The Orsat analyzer employs a fixed sequence of testing for the various constituents, and this sequence must always be followed.

Advantages. The Orsat analyzer has the advantage of low initial cost, simplicity of operation, portability, and ability to analyze accurately all constituents normally encountered in heat-treating atmospheres.

There are no complicated electrical circuits to maintain, and no standardization procedures are required. The operator must be certain only that solutions are reasonably fresh and that all connections are gastight. Although accuracy and reproducibility of results depend largely on the technique of the operator, satisfactory results can be obtained by nontechnical personnel after relatively short periods of training. Accuracy is actually dependent on the scale used. Higher concentrations are more accurate than lower concentrations. The ability to determine concentrations of all normal atmosphere constituents permits detection of air leaks, water leaks, or degeneration of the catalyst in the generator.

Disadvantages. The principal disadvantages of the Orsat analyzer are the long analysis time required compared to that required by the newer methods and the relatively large errors possible in determining the carbon dioxide contents of most furnace atmospheres. Automatic control of the furnace atmosphere is impractical.

Carbon dioxide and oxygen-content determinations can generally be made in about 5 min, whereas a full analysis requires 30 min or more. In contrast, a full analysis for all normal components of an atmosphere can be made in about 5 min with a gas chromatograph (see the subsequent section "Gas Chromatography") or in approximately 30 s using a set of infrared, oxygen, hydrogen, and dew-point analyzers.

To achieve high carbon potentials, carbon dioxide content must be maintained at low concentrations, generally from 0.1 to 0.5%. Hence, a small error in determination of carbon dioxide content will result in a relatively large inaccuracy in the ratio of carbon monoxide to carbon dioxide, which is used for determining carbon potential. Therefore, a method that provides more accurate analysis of carbon dioxide content is preferred whenever the heat-treating process employed requires close control of carbon potential.

Hot-Wire Analyzer

The hot-wire analyzer is based on the principle that carburization of steel (except high-alloy grades) is completely reversible. With the exception of nitrogen, poorly equilibrated atmospheres high in inert gases are a possible exception to this principle. The surfaces of thin and thick pieces of steel eventually come to essentially the same equilibrium with a gas of given composition and temperature. The electrical resistivity of steel is a linear function of carbon content over the range from 0.05% C to saturation. Therefore, a length of fine iron wire will exhibit a resistance proportional to its average carbon content, and at equilibrium, proportional also to the carbon potential of the surrounding gas. This is the potential that would be effective in carburizing loads of production parts.

Basic Design Configuration. The sensor of a hot-wire analyzer is a fine iron or iron-alloy wire, about 0.08 mm (0.003 in.) in diameter and about 32 mm ($1\frac{1}{4}$ in.) long that is shaped like a "U." This wire and its supporting structure are called the sensor tip and are mounted on a long holder that provides for room-temperature connections. The tip can be readily and economically replaced.

The sensor is housed in a protection tube that is a $\frac{3}{4}$ IPS pipe assembly, fitted for gas and electrical connections at the cold end and equipped with a small sampling hole at the hot end. This tube is inserted through the furnace wall or lid so that a sample of gas from the work load can be drawn over the sensor while the sensor is held substantially at work temperature.

The measuring circuit is a Wheatstone bridge equipped with compensators for furnace temperature and for calibration of the sensor. Suitable circuitry for driving an optional recorder is provided. Also included is circuitry for proportionally operating a control solenoid valve or a motorized proportional valve.

A pump and related flowmeters and valves are provided to ensure positive flow of sample gas over the sensor. This gear also provides protection of the sensor when the sample gas is not protective, including during standby periods.

The instrumentation is packaged in a 405 by 510 mm (16 by 20 in.) portable enclosure or in a 485 by 660 by 1650 mm (19 by 26 by 65 in.) free-standing panel. The latter package is also available with a small sensor-heating furnace, in which the sensor in its protection tube can be located and to which the sample gas from any remote point can be brought and then reheated to the preferred temperature before being passed over the sensor for measurement.

Advantages. The hot-wire analyzer can make an *in situ* measurement unaffected by sampling-system disturbances, and the measurement is of carbon potential rather than of gas composition. The readout is directly in terms of percent of carbon. Accuracy is normally ±0.05% C. The equipment is relatively simple and easy to maintain, and replacement components are readily available and inexpensive. The method is broadly applicable to any gas mixture exhibiting carbon potential, and measurements can be made either in the work furnace (*in situ*) or remotely in a small furnace that holds the sensor at constant temperature and reheats the sample gas before measurement.

Limitations of the hot-wire analyzer include:

- The hot-wire sensor cannot function in atmospheres so extensively rich that soot is deposited
- If the sensor is exposed to oxidizing gas above 425 °C (800 °F), it will be damaged (calibration shifted) or destroyed. Therefore, the sensor requires the protection of a good purge gas, such as nitrogen or endothermic generator gas
- If sulfur and some other contaminants are in the atmosphere, they can render the fine wire sluggish and insensitive
- In carbonitriding atmospheres, the sensor responds to nitrogen as well as to carbon, and therefore the readout consists of the sum of carbon and nitrogen
- A response speed below 815 °C (1500 °F) is too slow for automatic control of a short ($\frac{1}{2}$ h) cycle. However, speed of response is always faster than that of the work load; therefore, measurement is always feasible
- In high-nitrogen carburizing atmospheres ($\geq$70 vol% N_2) where equilibration is likely to be poor, the fine sensor wire can sometimes achieve higher carbon concentrations than the more massive workpieces; therefore, the readings might be too high

Economic Considerations. The hot-wire analyzer is among the least complicated single-point carbon-potential instruments and therefore is also one of the least expensive, considering original cost and upkeep. The most expensive component that needs occasional replacement is the alloy-protection tube.

The system requires attention from a trained operator and needs calibration two or three times a week.

Uses. The hot-wire method is useful for measurement and control of any atmosphere capable of transferring carbon to and from steel surfaces. The composition of the gas mixture need not fall into a conventional pattern, and the composition can be varied, such as when nitrogen additions are made or when peak shaving is practiced. The temperature range of application is 790 to 1040 °C (1450 to 1900 °F), and the carbon range is from 0.10% C to saturation.

Operation. The sensor is installed in its work furnace port under a flow of protective gas. Interlocks are usually arranged to activate furnace sampling and furnace control during the at-heat period. Low- and high-limit switches enable the sensor to bypass very lean or very rich sample gas without interruption of furnace control. When the protective purge gas is nitrogen, the sensor need not be withdrawn from its furnace port until it is to be replaced. The sensor is calibrated either by decarburizing it to its minimum reading or by carburizing it with a standard gas mixture. Under ideal conditions, average life of the sensor exceeds one month.

Hot-wire analyzers have been used to control endothermic-gas generators; batch carburizers; continuous carburizers, both pusher and belt; protected quench carburizers; bell carburizers; belt-hardening furnaces; rotary carburizers; and tool-hardening furnaces. They have been used with atmospheres made from drip feed of organic fluids, endothermic gas alone or enriched with natural gas or propane, appropriate combinations of a hydrocarbon fuel gas and an oxygen-supplying agent, and nitrogen modified for use in carburizing applications using suitable additives.

Gas Chromatography

Gas chromatography provides a relatively fast method for measuring the concentrations of practically all the gases present in an atmosphere. A small sample of the gas mixture is inserted into the analyzer, where a steady flow of a carrier gas such as helium carries it through the analyzer column. As the sample goes through the column, individual components are separated by adsorption or partitioning. Measurement of the thermal conductivity or ionization characteristics of the gas leaving the column provides a measure of the concentration of each constituent. Various types of analyzer columns are available by which almost any gas component can be analyzed. A chromatograph is shown in Fig. 18.

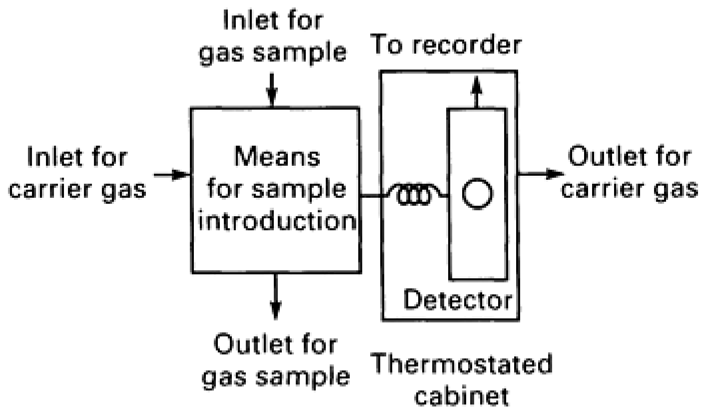

Fig. 18 Chromatograph for atmosphere analysis

Advantages. With present-day chromatographs, an analysis of each constituent, except water vapor, in an atmosphere containing carbon monoxide, carbon dioxide, methane, hydrogen, water vapor, and nitrogen can be made in approximately 5 min. If water vapor is analyzed, an additional 5 to 7 min are required.

The minimum full-scale ranges are 12% for hydrogen, 3% for water vapor, and 1% for each of the other gases listed. Reproducibility is ±1% of the full-scale reading, except for water vapor, for which it is ±2%. Laboratory analyzers are available with more sensitive detectors that can measure concentrations in parts per million. However, they do not have the stability that is needed in an automatic process-control device.

Although several constituents may be analyzed, automatic control usually is applied to only one. Because of the intermittent nature of the analysis, the input signal to the controller can be adjusted only once for each analysis cycle. The length of the cycle limits the analyzer to single-point control.

Limitations. Two limitations of gas chromatography are the fact that it provides only periodic, rather than continuous, analysis of the gas stream; and the difficulty of interpreting the chart record. With respect to the latter, the concentration of each constituent is recorded as a bar on the recorder chart, and each must first be identified from the recording sequence. Moreover, because the full-scale ranges differ for the various constituents, percentage of full scale must then be converted to percentage concentration.

Evaluation of Carbon Control in Processed Parts

Introduction

WHEN FABRICATED STEEL PARTS are heated in an atmosphere that will either carburize or decarburize the surfaces of the parts, an evaluation of the precise effect of the atmosphere on the parts is usually desirable. This is particularly important when the carbon content at the surface, and at significant depths below the surface, is to be controlled by adjusting the composition of the furnace atmosphere. Several methods of evaluating the carbon control of processed parts are considered in the following discussion.

In addition, methods for measuring the case depth produced by carburizing or carbonitriding are described in greater detail in the article "Methods of Measuring Case Depth," in this Volume.

Hardness Tests

Hardness tests for evaluating carbon control should be used with caution. The type of test selected should be one in which the depth of metal affected is properly related to the depth to which carbon control is desired. When hardness tests are used, one of three methods should be adopted only after all possible sources of error in the specific application have been thoroughly investigated:

- Surface hardness measurements taken under at least two conditions of loading (Rockwell C and superficial Rockwell 15N, for example)
- Superficial Rockwell 15N tests on steps ground below the surface to significant depths
- Microhardness measurements, either on steps or, preferably, on a cross section through the carbon control zone

Depth-of-penetration measurements such as those made in Rockwell tests generally do not measure hardness accurately at depths of less than 0.08 mm (0.003 in.) below the surface. Thus, if full hardness is required at the surface, as in wear applications, decarburization less than 0.08 mm (0.003 in.) deep may not be readily revealed by Rockwell testing at the surface. Such a condition would require microhardness testing or perhaps could be revealed by the proper use of a file. Conversely, the surface hardness test is not an accurate indication of carbon control if the carbon control is not effective to sufficient depth to support the penetrator during the hardness test. Lower or higher carbon content at a depth of 0.3 or 0.4 mm (0.010 or 0.015 in.) below the surface can also cause false readings.

Superficial Rockwell 15N testing on steps ground below the surface to significant depths gives a better indication of the depth to which carbon control is effective. For example, if a carbon restoration operation were being performed and the original decarburization were deeper than anticipated, the low carbon in the incompletely restored zone between the carbon-restored zone and the core could be detected by the step grind and hardness test method, whereas it might not affect a surface hardness reading.

Microhardness testing on a cross section through the carbon control zone is the most accurate of the hardness test methods for evaluating carbon control. With this method, each hardness impression is supported by metal of like composition. Variations in carbon content that affect hardness can be detected at any depth up to 0.06 mm (0.0025 in.). This method has the disadvantage of requiring a metallographically prepared cross section and special hardness-testing equipment that is usually available only in well-equipped laboratories.

When hardness testing is used to evaluate carbon control, it should be remembered that maximum quenched hardness is attained at about 0.80% C in plain carbon steels, and at lower carbon contents in alloy steels, depending on types and percentages of alloying elements present. If variations in carbon content above the level required to produce maximum

hardness are significant, hardness measurements are not capable of evaluating carbon control. Also, low hardness in quenched parts or test specimens can be caused by insufficient quenching or by excessive retained austenite, as well as by low carbon content. Therefore, evaluation on the basis of hardness measurements alone might lead to incorrect control measures. In instances where hardness measurements do not give adequate information, the techniques to be used are microscopic examination, analysis of consecutive cuts, analysis of shim stock, analysis of rolled wire, spectrographic analysis, and/or electromagnetic testing.

Microscopic Examination

Microscopic examination is the only method of determining surface carbon variations that shows the effects of such variations on microstructure. Because of this, it will indicate which corrective action must be taken to alter surface carbon concentration. Microscopic examination is also useful for determining whether an improper surface carbon content is detrimental to the part.

The effect of carbon content on microstructure varies from steel to steel. It also varies for a given steel, depending on whether the steel is annealed, unannealed, hardened, or tempered. The microscopic method is best used on steels with which experience has been gained in correlating results with those of other test methods of evaluating carbon control. Microscopic examination should be used to determine the microstructural constituents discussed below.

Ferrite. A layer of ferrite on the surface indicates total decarburization. There is usually partial decarburization below this layer.

Carbide (Cementite). An increase in the amount of carbide indicates carburization, and a decrease indicates decarburization. A fully annealed sample is almost always best for determining depth of carburization or decarburization by observing carbide variations. Size and frequency of carbide particles can be measured in order to estimate more accurately the percentage of carbide in the microstructure. Extreme carburization can result in massive amounts of carbides at the surface.

Pearlite. When the steel is annealed, pearlite indicates eutectoid carbon content. The ratios of pearlite to free ferrite and to proeutectoid carbide can be used to estimate how far and in which direction the structure deviates from that corresponding to the eutectoid composition.

Austenite. Carburization causes some steels to retain excessive amounts of austenite at the surface after heat treating. The proper etchant must be selected so that austenite is distinguished from ferrite and from massive carbide. Because both austenite and ferrite are soft, microscopic examination should be used to distinguish a sample with excessive retained austenite from one that has become decarburized.

Martensite. Variations in procedures used for etching martensitic structures (variations in metallographic preparation and in the etching reagents used) can indicate variations in carbon content. Familiarity with the microstructure of the steel is important for the correct interpretation of variations. Coarsening of martensite near the surface can indicate a variation in surface carbon.

As indicated, annealing of the sample is often desirable in order to obtain the best information; however, annealing must be carried out in the proper atmosphere, or severe errors may result from carburization or decarburization during the annealing cycle. The use of an inert atmosphere or a copper-plated sample is best. A neutral atmosphere tends to correct variations in surface carbon content, which makes it less desirable than an inert atmosphere.

The microscopic method is more sensitive than hardness testing, but it cannot detect very slight variations in carbon content and does not yield quantitative data suitable for plotting curves of atmosphere variables. Also, this type of evaluation is destructive, because cross sections must be cut perpendicular to the surface. When expensive parts are involved, appropriate testpieces should be processed along with the parts.

Analysis of Consecutive Cuts

The consecutive-cuts method of analysis can be used for the accurate evaluation of carbon control at any significant depth below the surfaces of parts. Because of the extremely accurate machining operations required to obtain reliable information, this type of evaluation is usually performed on cylindrical test bars treated with the work. After a test bar has

undergone the heat treatment to be evaluated, consecutive cuts of 0.03 to 0.3 mm (0.001 to 0.020 in.) or more are turned from the surface of the test bar, and the turnings from each cut are analyzed for carbon concentration.

The consecutive-cuts method is used most frequently on carburizing grades of steel to evaluate the control of case carbon content. Other methods of evaluation are usually adequate for medium-carbon and high-carbon steels that have been subjected to annealing, carbon restoration, or hardening.

Considerable doubt has been cast on the reliability of the data representing the first 0.03 to 0.1 mm (0.001 to 0.004 in.) cut from the surface. This reliability, however, is a function of the accuracy with which the test is performed and the care exercised in preparing and machining the test specimen.

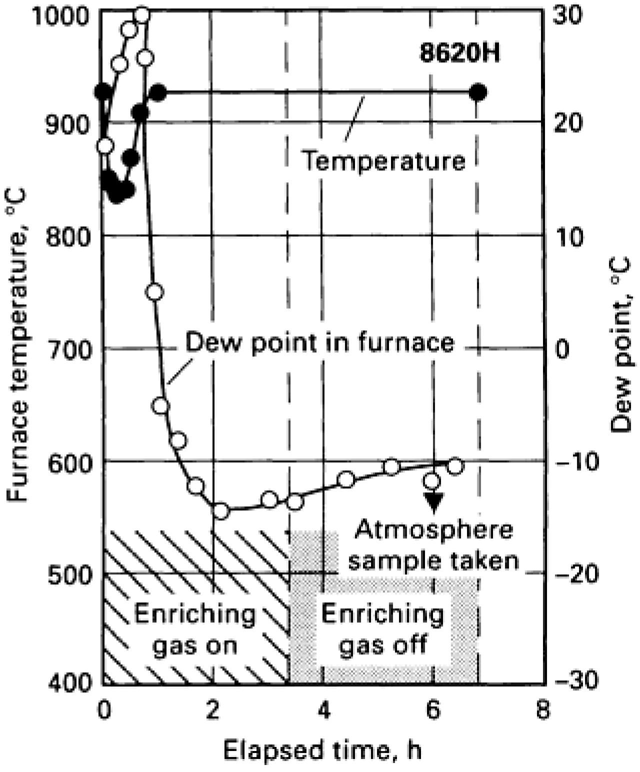
The test bar should be made of the same grade of steel as that of the workpieces. It should be accurately machined on centers to true cylindrical shape. The diameter should be such that the test bar section is representative of the critical region of the workpieces to be evaluated. The length of the test bar need only be sufficient to allow enough turnings for a carbon analysis and a check analysis.

The test bar is loaded into the furnace with the work load and is subjected to exactly the same cycle. If the work is slowly cooled from the furnace, the bars are:

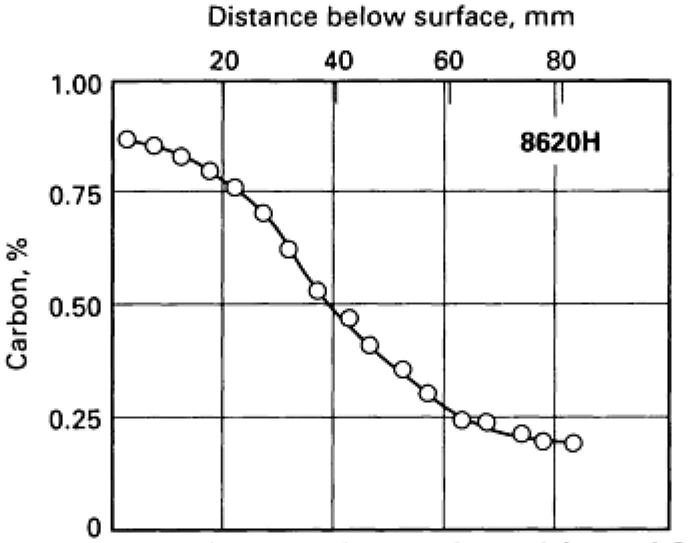
- Slowly cooled with the load
- Scrubbed with soap and water and rinsed with clean water
- Rinsed with benzene or ethyl alcohol to displace the water, and dried to prevent rust formation
- Lightly blasted with shot or grit
- Straightened to a 0.03 mm (0.001 in.) total indicator runout
- Scrubbed with soap and water and rinsed with clean water
- Rinsed with benzene or ethyl alcohol
- Machined

If the work is quenched at the end of the cycle and if the test bars are of a steel such as 1117 or 8620, the same sequence of operations can be followed except that the bars should be tempered at 600 °C (1100 °F), preferably in nitrogen, between the third and fourth steps of the procedure above.

Figure 1(a) shows the furnace temperature and atmosphere conditions employed in carburizing ring gears made of 8620H steel. Figure 1(b) indicates the resultant carbon gradient, as revealed by the analysis of consecutive cuts on the test bars that were carburized with the gears. The test bars were prepared from 28.5 mm ($1\frac{1}{8}$ in.) diam 8620H cold-drawn bar stock. The bar stock was cut to 250 mm (10 in.) lengths, which were centered and accurately machined to a nominal diameter of 25 mm (1 in.).



(a)



(b)

Fig. 1 (a) Furnace temperature and atmosphere conditions for carburizing and (b) resulting carbon gradient in 8620H steel. Conditions: Load: ring gears, 230 kg (510 lb) net, 390 kg (860 lb) gross. Furnace: electric, metallic-retort pit furnace. Carrier gas: endothermic gas at 2.8 m^3/h (100 ft^3/h) throughout the cycle, including 5 h and 59 min at temperature. Enriching gas: addition of 0.34 m^3/h (12 ft^3/h) of natural gas started when load was placed in furnace; flow of natural gas stopped after $2\frac{1}{2}$ h at temperature, or after 42% of at-temperature cycle. Generator dew point: -6 to -4 °C (22 to 25 °F) throughout the cycle. Heating-chamber pressure: 5.1 to 7.9 mm (0.20 to 0.31 in.) of water column. Carburizing temperature: 925 °C (1700 °F). Cooling method: Slowly cooled from 925 °C (1700 °F) in cooling pit. Atmosphere analysis near end of cycle: 20.8% CO, 0.4% CO_2, 34.0% H_2, 0% O_2, 0.8% CH_4

The consecutive-cuts method of evaluating the control of case carbon content provides an accurate means of determining the variations in case carbon composition that occur when different heat-treating cycles are used. In most instances, the details of these variations would be difficult to determine by any other conventional method of evaluating case carbon content.

The analysis of consecutive cuts provides an accurate method of determining the cycles to be used for carburizing, for continued checks on current cycles, and for determining whether simpler process-control methods are adequate. Variations in factors such as cycle time, gas flows, net and gross weights, loading method, and furnace condition can be evaluated. Because it provides information about the case on the finished workpiece, this method is useful for a final evaluation of all conventional types of control, such as atmosphere analysis, temperature cycle analysis, or the addition of enriching gas.

There are certain disadvantages of the consecutive-cuts method of evaluating carbon control. It is a slow analytical procedure. Information cannot be obtained until the particular workpieces represented have been processed; thus if results are not satisfactory, corrections cannot be made. Also, accuracy is required in machining and in analytical equipment and techniques.

Analysis of Shim Stock

Thin-gage shim stock can be used effectively to determine the carbon potential of an atmosphere. The success of this method is due to rapid through carburizing of the thin test strip, which eliminates carbon diffusion as a variable in the atmosphere evaluation. The accuracy of this test is adequate for application to the carbon control of commercial carburizing, carbon restoration, and carbonitriding.

In practice, a strip of annealed 1010 steel 32 by 75 by 0.1 to 0.15 mm ($1\frac{1}{4}$ by 3 by 0.004 to 0.006 in.) is weighed before and after 1 h of exposure to the furnace atmosphere. The gain in weight, as determined on an analytical balance, is used to calculate the carbon potential of the atmosphere. Thus:

$$\textit{Carbon}\ \text{potencial} = \left(\frac{\text{Gain in weight x 100}}{\text{Final weight}}\right) + \ \%\text{original carbon}$$

Total test time varies from $\frac{1}{2}$ to $1\frac{1}{2}$ h.

Figure 2 shows the carbon potential rod used in the shim stock test. Procedures for the exposure of shim stock to the furnace atmosphere are:

1. 1. Assembly of rod and test strip
2. 2. Attachment of rod to furnace wall in preparation for insertion of test strip into furnace atmosphere
3. 3. Insertion of test strip into furnace in unobstructed stream of furnace atmosphere above the work load. Test strip is exposed for 1 h
4. 4. Removal of test strip from furnace atmosphere. The same position indicated in step (b) is used for cooling the strip after it has been withdrawn from the furnace. Rod should be supported for a few minutes after withdrawal to avoid severe bending. Test strip is cooled for 15 min

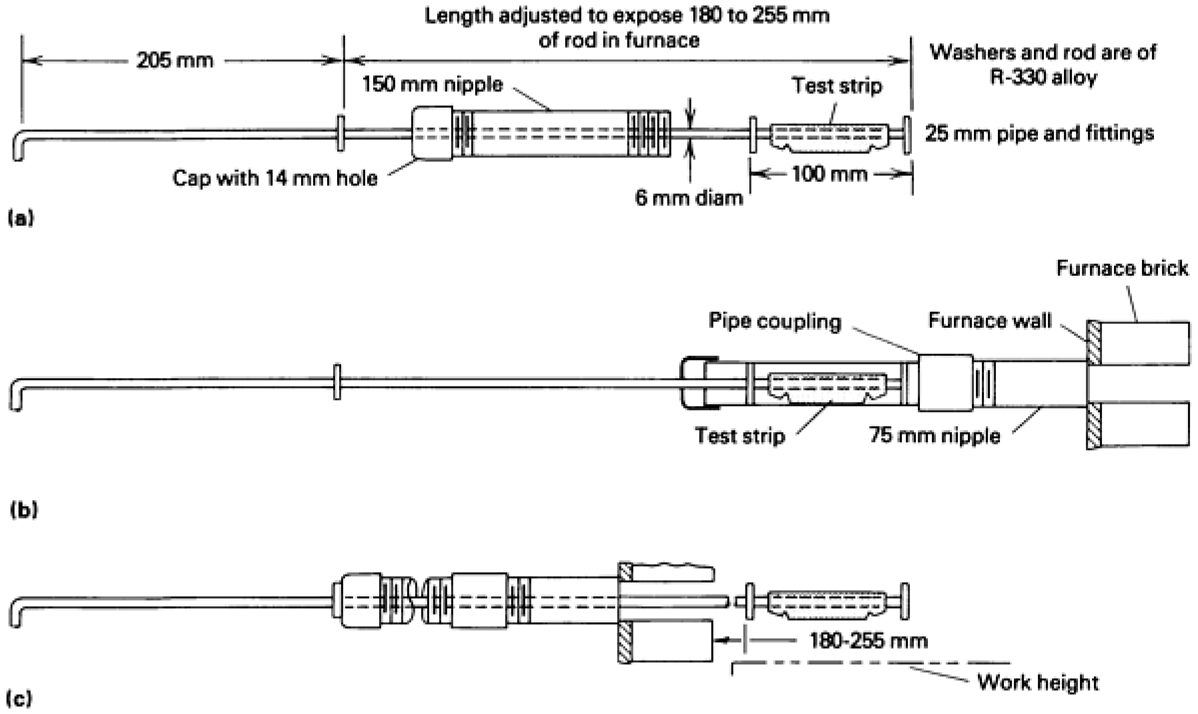


Fig. 2 Arrangements for exposing shim stock to furnace atmosphere for evaluation of carbon potential. (a) Assembly of test strip for determination of carbon potential. (b) Assembly of test strip on rod attached to furnace wall in preparation for insertion into furnace (same position used for cooling of test strip). (c) Test strip inserted into furnace above work in unobstructed stream of furnace atmosphere. (See text.)

Precautions to be taken in shim stock analysis are:

- For furnace operating temperatures of 815 °C (1500 °F) or lower, the exposure time should be increased to $1\frac{1}{2}$ h to ensure through carburizing of the testpiece
- To prevent oxidation of the test strip during cooling, the strip should be transferred from the furnace into the pipe nipple at a time when all furnace doors are closed
- The test strip should not be rolled or wrapped tightly around the carbon potential rod. This permits only partial exposure of the test strip, causing low results, and complicates removal of the strip for reweighing. Proper anchoring of the strip on the rod is accomplished by simply crimping the corners of the strip over the rod, leaving the center area open to the atmosphere
- In continuous furnaces, the carbon potential indicated by the test strip represents only the zone or area tested, not the entire furnace atmosphere
- The test strip should always be exposed to an unobstructed flow of furnace atmosphere. This is easily accomplished by placing the strip above the work load (Fig. 2c)
- A properly exposed and cooled strip containing 1.30% C or less should be clean and bright
- Slight oxide discoloration is caused by improper technique. The carbon content determined on such a strip would be slightly high because of the increase in weight due to the iron oxide
- A properly exposed and cooled strip containing about 1.40% C or more will have a dull, matte finish. Depending on actual carbon content, the steel surface may be coated with loose, dry carbon. This is a normal appearance caused by an atmosphere of high carbon potential. The surface carbon deposit should be wiped off before the shim stock is reweighed

The shim stock method permits a quick evaluation of atmosphere performance; unnecessary delays, such as the time required for completion of a carburizing cycle, are avoided. Generally, this test is supplemented by an analysis of test bars

carburized with the work for the entire furnace cycle. The correlation of strip carbon and surface carbon on parts is then established in order to arrive at a definite set of operating conditions.

The shim stock method determines the maximum carbon available in the atmosphere for batch or continuous furnaces. Generally, the atmosphere carbon is higher than the surface carbon of parts made of most SAE steels. Exceptions are steels that contain high percentages of one or more carbide-forming elements, such as 3310, 52100, and 9310. Parts made of these or equivalent steels form surface carbides and consequently have higher surface carbon than does shim stock.

This test is also applicable to carbonitriding atmospheres. Although the gain in weight is produced by both carbon and nitrogen, for all practical purposes it can be treated as though it were due to carbon only, permitting the same calculations as those used for carburizing atmospheres.

Shim stock exposed to furnace atmosphere may also be analyzed for carbon by combustion carbon analysis. This method eliminates the necessity for weighing the sample of shim stock before and after exposure.

Analysis of Rolled Wire

Rolled wire may also be used for measuring carbon potential. Wire is flattened into strip and is then used for determining carbon potential in much the same manner as shim stock is used, except that there are small differences in the design of the fixture on which the rolled wire is placed.

Spectrographic Analysis

Carbon content can be accurately determined by spectrographic analysis. This method makes use of a vacuum spectrometer, which permits the measurement of spectral lines in the ultraviolet region where air would ordinarily absorb much of the emitted radiation.

Spectrographic analysis is normally performed on flat test specimens that can be taper ground, step ground, or reground incrementally after each carbon determination. A very small amount of material is ground from the surface (to remove oxides). Successive cuts are made, and analyses are performed after each cut.

Special care must be taken to ensure that the depth corresponding to each carbon determination is measured accurately. Case depth determined on flat or round test specimens often differ from case depth determined directly on workpieces, because of differences in shape.

Whereas carbon determination by the combustion method provides an average carbon content for the amount of material removed by machining, spectrographic analysis determines the local carbon content of the specimen to a depth of 0.03 mm (0.001 in.) below the surface. Table 1 compares analyses performed on five samples of shim stock by the spectrographic and combustion methods.

Table 1 Carbon content of shim stock and workpiece surfaces as determined by spectrographic and combustion analyses

Sample number	Amount of carbon present, %		
	Spectrographic analysis	Combustion analysis	Workpiece surface (spectrographic analysis)
1	0.36	0.36	0.38
2	0.24	0.27	0.25

3	0.22	0.24	0.225
4	0.35	0.35	0.34
5	0.30	0.30	0.305

Note: Shim stock and workpieces were heat treated, in the same load, in a 915 mm (36 in.) continuous-belt furnace with an endothermic-based atmosphere (class, 301; dew point, -9 to -1 °C, or 15 to 30 °F).

Electromagnetic Testing

Two types of electromagnetic nondestructive tests have been used to evaluate the cases of case-hardened parts: One compares the magnetic properties of a part with those of a test standard, and the other measures coercive force, which is then converted to case depth through use of a calibration chart.

Magnetic-Comparator Testing

One electromagnetic test is performed by placing the part to be tested in an induction coil. A reference part of known electromagnetic response is placed in a second coil. Both parts are simultaneously subjected to identical electromagnetic fields, and their responses to these fields are compared by an electronic balancing circuit. Any imbalance between responses (indicated by a meter) is a function of the following properties of the test object: chemical composition, microstructure, case depth, surface flaws, residual stress, and work hardening.

Many electromagnetic instruments are capable of breaking down an electromagnetic response into inductive components, resistive components, third-harmonic amplitude, and phase differences. The user must correlate these variables with the property or properties to be evaluated.

Standards and Test Procedures. Electromagnetic (eddy current) testing can be used only as a comparison test; its accuracy and usefulness depend on the proper development of standards and test procedures. Acceptance and rejection standards are required for each part design to be evaluated. Once standards are developed and instrument settings are selected, production parts can be tested by comparison with the standards. Sufficient destructive testing must be carried out to produce the data required for the construction of a chart or graph by which meter readings can be converted to case depths with reasonable confidence. Periodic destructive testing should be carried out to reconfirm this correlation.

In a production situation involving many parts and wide differences in specified case depth, it is difficult and costly to establish standards for all parts. To eliminate this problem, a procedure has been developed in which a standard test specimen is processed with each heat. Case depth of the test specimen is determined by magnetic comparison. The standards for carburizing a testpiece are developed using the procedure described above, and these standards are correlated with actual parts by periodic destructive testing. The standard test specimen is made from a cold-finished bar of coarse-grained, silicon-killed 1018 modified steel with residual elements held to low levels. The testpiece is 11 mm ($\frac{7}{16}$ in.) square by 75 mm (3 in.) long. Testing of the standard specimen may yield results that are different from those obtained with actual parts, but once a correlation is established, the standard testpiece, rather than actual parts, may be used with reliability.

Effectiveness and Limitations. Test reliability for the determination of case depth is:

Error	mm	in.

Average error	0.10	0.004
Maximum error (3% of the time)	0.44	0.017
Minimum error (18% of the time)	0.00	0.000

The magnetic-comparator test will indicate whether a production lot is acceptable or of questionable quality. Destructive tests must then be conducted on questionable lots to determine which variables are out of specification and to assist in devising corrective measures.

Case depths of up to 5 mm (0.200 in.) may be measured. This method has been found to be more reliable for induction-hardened cases than for carburized cases. The chief variable that can adversely affect measurements is the case-to-core transition zone, which is much wider in carburized cases than in induction-hardened cases.

Coercive-Force Testing

A second type of electromagnetic instrument measures the coercive force of parts. A probe is placed on the part, and the coercive-force value is taken. The case depth is read from a calibration curve previously prepared by the destructive testing of samples with shallow and deep cases.

The equipment is easy to set up and use. Results can be correlated to the case depths of carburized or induction-hardened parts, usually of carbon steels. In some difficult applications, only a general trend of case depth can be given, but this is usually sufficient for production auditing. The test is extremely sensitive to core property variations accompanying abnormal quenching.

Coercive-force testing can be applied to cases up to about 20 mm (0.800 in.) deep. The instrument readings are not affected by minor differences in steel composition, but different calibration curves must be developed for different grades of carbon and alloy steels.

Case-Depth Variation

In commercial practice, case depth is controlled within certain tolerances, which depend on the intended service of the part, the type and condition of the carburizing furnace, the cycles employed, and the limitations of control equipment. The end use of the carburized part is the principal determinant of the acceptable range of case depth. Parts to be used in less-critical applications do not require close control of case depth, and the increased cost of ensuring close control would be unjustified.

The data shown in Fig. 3 provide a summary of the reproducibility of case depths within prescribed limits for test specimens and parts made of 8620 steel. Operating details are given in the descriptions that follow.

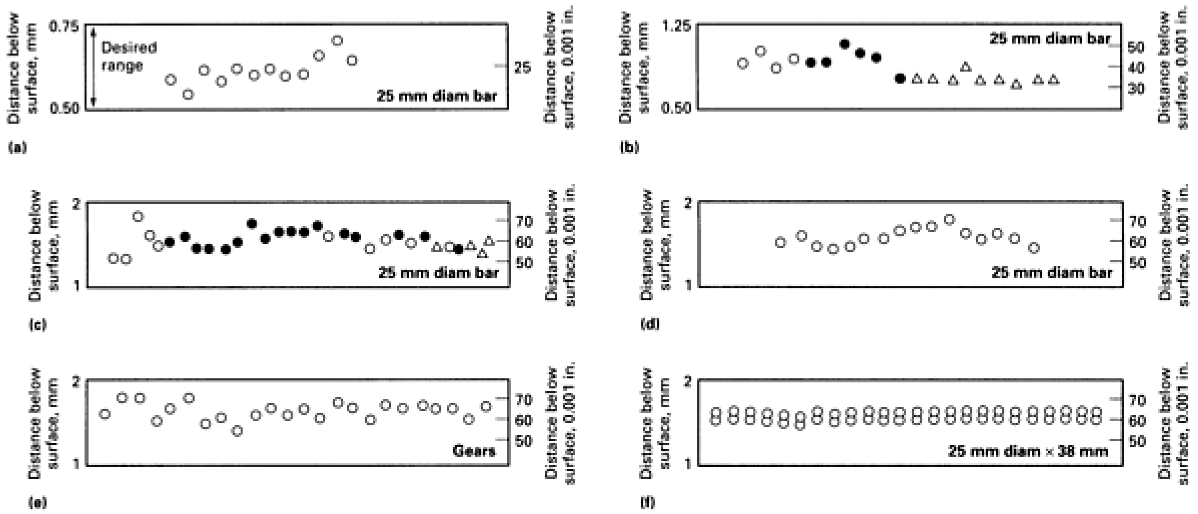

Fig. 3 Reproducibility of case depth in 8620 steel, using the criterion of depth to 0.40% C. Data points, representing individual heats, are plotted in chronological order (left to right). Data were collected in studies in two different plants. Legend for parts (b) and (c): d , furnace A; •, furnace B; V , furnace C. (See text.)

The case variation shown in Fig. 3(a) was determined from a carbon gradient curve secured by carburizing 25 mm (1 in.) rounds of 8620 steel with production parts at 925 °C (1700 °F) for $1\frac{3}{4}$ h in a horizontally loaded batch-type furnace, then reducing the temperature to 845 °C (1550 °F) before quenching in oil. A diffusion-type carburizing cycle was used. Dew point was -15 °C (5 °F) for the carburizing portions of the cycle at 925 °C (1700 °F), -12 °C (10 °F) for the diffusion portion at 925 °C, and -3 °C (27 °F) for the equalizing portion at 845 °C (1550 °F). The carburizing atmosphere was endothermic gas enriched with natural gas, without the addition of air.

After being quenched, the testpieces were tempered in lead at 650 °C (1200 °F) and then cleaned with a wire brush and liquid abrasive. The target depth to 0.40% C was 0.51 to 0.76 mm (0.020 to 0.030 in.). With 0.64 mm (0.025 in.) as the average, the distribution was:

Variation from average depth, mm (in.)	**Part distribution, %**
0.64 ± 0.03 (0.025 ± 0.001)	75
0.64 ± 0.05 (0.025 ± 0.002)	92
0.64 ± 0.08 (0.025 ± 0.003)	100

Testpieces similar to those described above were used to obtain case depth data (to 0.40% C) from three different batch-type furnaces using endothermic gas enriched with straight natural gas, without the addition of air. These data are summarized in Fig. 3(b). The loads were carburized at 925 °C (1700 °F), using a diffusion-type cycle. Dew point was

maintained at -15 °C (5 °F) for 3 h at 925 °C (1700 °F), at -12 °C (10 °F) for the diffusion portion of the cycle, and at -3 °C (27 °F) for 1 h at 845 °C (1550 °F) prior to quenching. The characteristics of the three different furnaces were:

Characteristics
Furnaces A and B
Size: 76 × 122 cm wide by 46 cm high (30 by 48 in. wide by 18 in. high)
Atmosphere control: dew cell; manual reset
Rated gross load: 68 kg (1500 lb)
Furnace C
Size: 91 by 183 cm by 61 cm high (36 by 72 in. by 24 in. high)
Atmosphere control: infrared analyzer controlling carbon dioxide; automatic reset
Rated gross load: 1588 kg (3500 lb)

The maximum variation recorded in 5 years was 0.91 to 1.19 mm; target, 1.02 mm (0.036 to 0.047 in.; target, 0.040 in.). The distribution of case depth was:

Variation from average depth, mm (in.)	**Part distribution, %**
1.016 ± 0.025 (0.040 ± 0.001)	32
1.016 ± 0.051 (0.040 ±0.002)	47
1.016 ± 0.076 (0.040 ± 0.003)	90
1.016 ± 0.102 (0.040 ± 0.004)	95

1.016 ± 0.178, -0.102 (0.040 ± 0.007, -0.004)	100

For a required case depth (to 0.40% C) of 1.40 to 1.78 mm (0.055 to 0.070 in.), the same three furnaces used to provide the data for Fig. 3(b) produced the results plotted in Fig. 3(c). The operation and means of testing were the same as those used for the shallower depths, except that the total cycle time at 925 °C (1700 °F) was 10.5 h. Total cycle time was 5 h with a dew point of -15 °C (5 °F) and 5 $\frac{1}{2}$ h with a dew point of -12 °C (10 °F). Equalizing time at 845 °C (1550 °F) was 1 h, and dew point was -3 °C (27 °F). Maximum case depth variation for 4 years was 1.422 to 1.676 mm (0.056 to 0.066 in.), with a distribution of:

Variation from average depth, mm (in.)	**Part distribution, %**
1.524 ± 0.025 (0.060 ± 0.001)	22
1.524 ± 0.051 (0.060 ± 0.002)	48
1.524 ± 0.076 (0.060 ± 0.003)	75
1.524 ± 0.102 (0.060 ± 0.004)	89
1.524 ± 0.127 (0.060 ± 0.005)	97
1.524 ± 0.152 (0.060 ± 0.006)	100

Reproducibility of Results

The data given in Fig. 4 correlate effective case depth to 50 HRC measured on the same gears in two different plants. Values were obtained by means of the hardness traverse method considered the most accurate method for measuring effective case depth. Nevertheless, several discrepancies in the results obtained at the two plants are apparent.

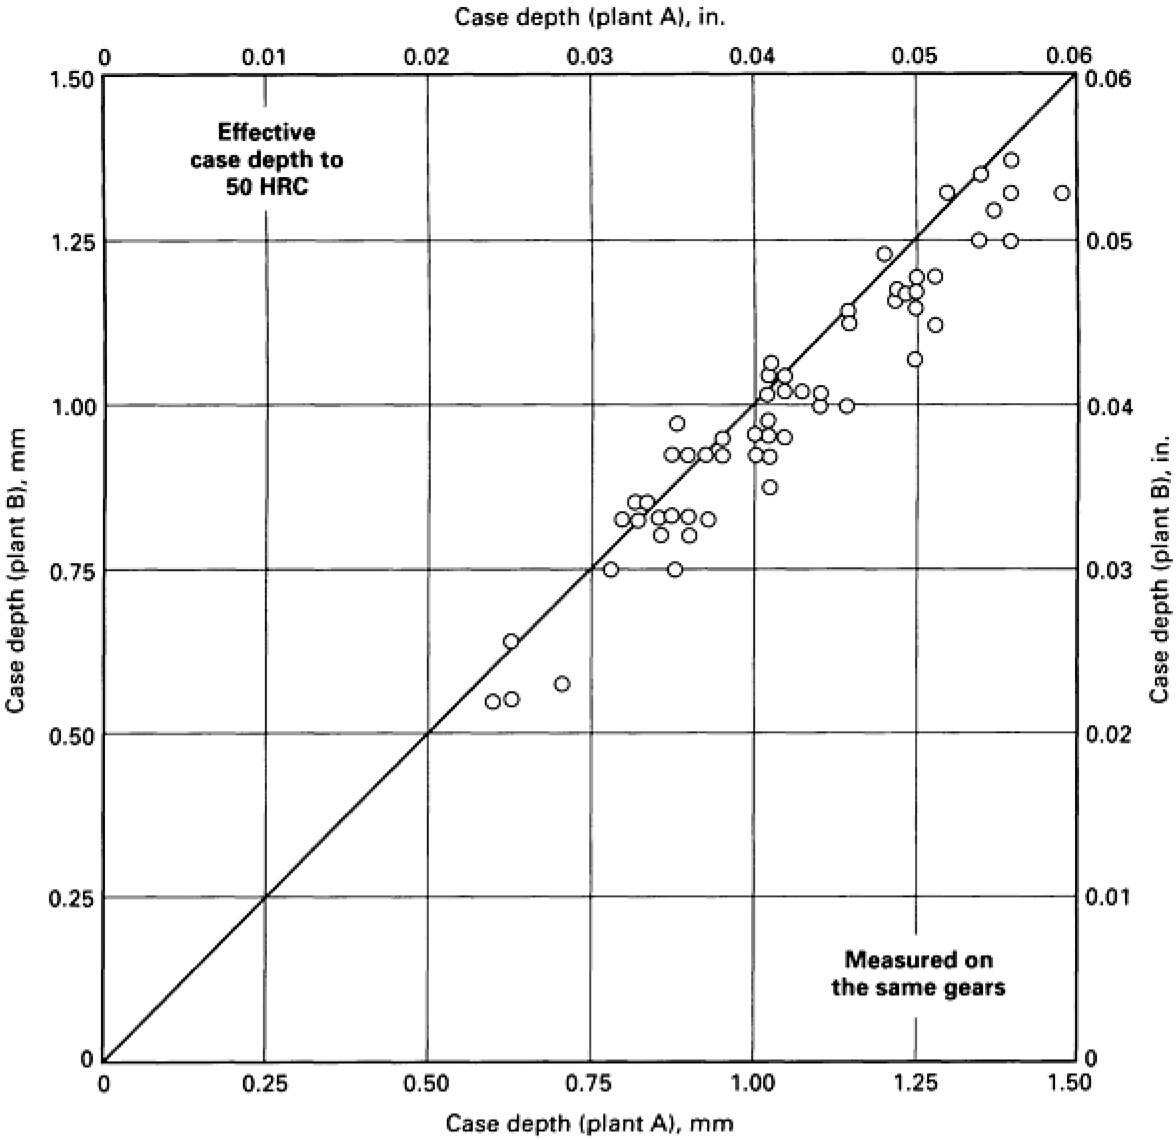

Fig. 4 Comparison of case depth measurements made on the same gears in two different plants

To compare hardness and microscopic methods of measuring case depth on the same specimens, carburized and hardened specimens of 8620 steel were prepared and submitted to five different heat-treating organizations for measurement by their laboratories. These specimens were prepared with reasonable care and were located within a short distance of one another during carburizing and hardening. All of the specimens were cut from the same bar. Each of the five laboratories that participated in the testing was asked to make all case depth measurements in accordance with identical industry standard procedures. The results are shown in Fig. 5.

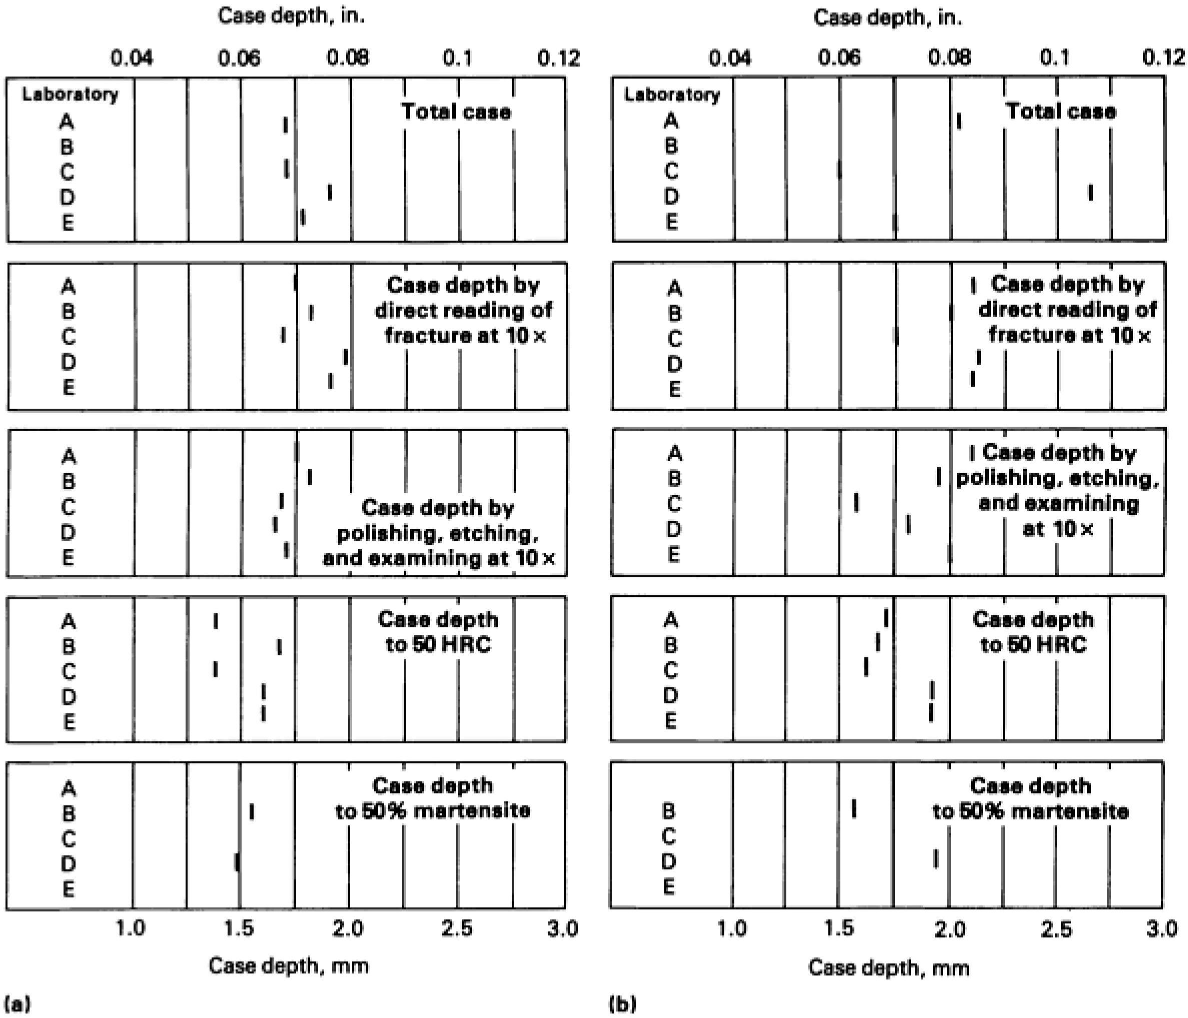

Fig. 5 Comparison of case depth measurements made on the same two samples of 8620 steel in five different laboratories. (a) Sample 1: 8620 with core hardness of 30 HRC and a surface carbon of 0.90%. (b) Sample 2: 8620 with core hardness of 40 HRC and a surface carbon of 0.90%

These measurements (all made by trained observers in qualified laboratories) diverge somewhat more widely than might be expected. They illustrate, perhaps in an exaggerated manner, the inherent lack of high precision in case depth measurements. With consultation among laboratories and a more precise definition of criteria, considerably closer agreement can be obtained, for instance, among different laboratories in the same multiple-plant organization, or between closely cooperating vendors and customers.

Carbon Concentration Gradients and Surface Carbon Content

The carbon concentration gradients of carburized parts are influenced by carburizing temperature, carburizing time, the type of cycle (various combinations of carburizing and diffusion times), the carbon potential of the furnace atmosphere, and the original composition of the steel.

The term carbon gradient not only encompasses the rate of change of carbon content with depth below the surface, but also alludes to the absolute value of carbon content in any layer other than the surface layer.

Carbon Gradients. Single-potential carburizing involves carburizing at a single temperature and constant atmosphere composition for the entire cycle. In some instances, single-potential carburizing is done to produce saturated austenite at the surface of the steel. Figure 6 shows the influence of carburizing temperature on the carbon gradient for single-potential carburizing of 1020 steel in a batch furnace. Comparable data are also given for 8620 steel carburized for $7\frac{1}{2}$ h

in an atmosphere containing 12% methane. Carburizing temperatures for both steels were 870, 900, and 925 °C (1600, 1650, and 1700 °F).

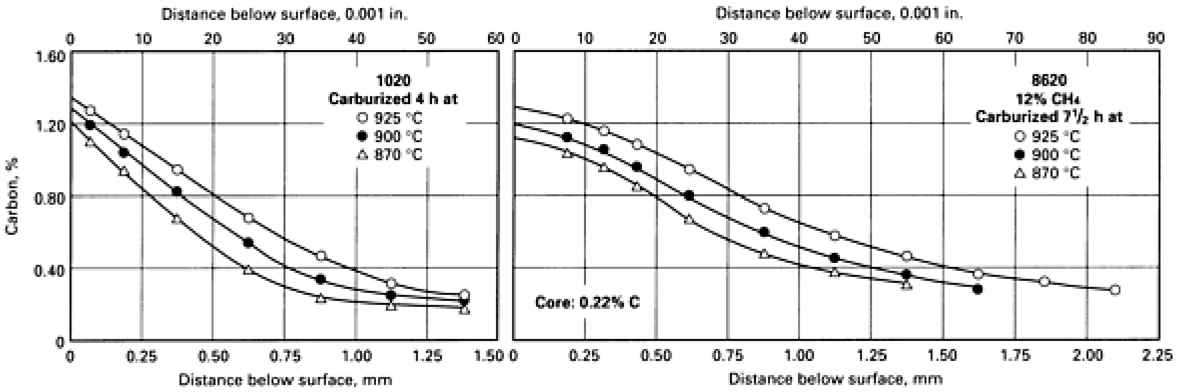

Fig. 6 Carbon gradients for 1020 and 8620 steels carburized at three temperatures. The 1020 steel was carburized in a batch furnace; the 8620 steel, in a recirculating pit furnace.

Figure 7 presents carbon gradient curves obtained in a batch furnace at a carbon potential corresponding to saturated austenite for four steels after carburizing for 4 h at 870 and 925 °C (1600 and 1700 °F). Typical influences of methane content, carbon potential, and time on the carbon gradient after single-potential carburizing of 1022 steel are shown in Fig. 8 and 9.

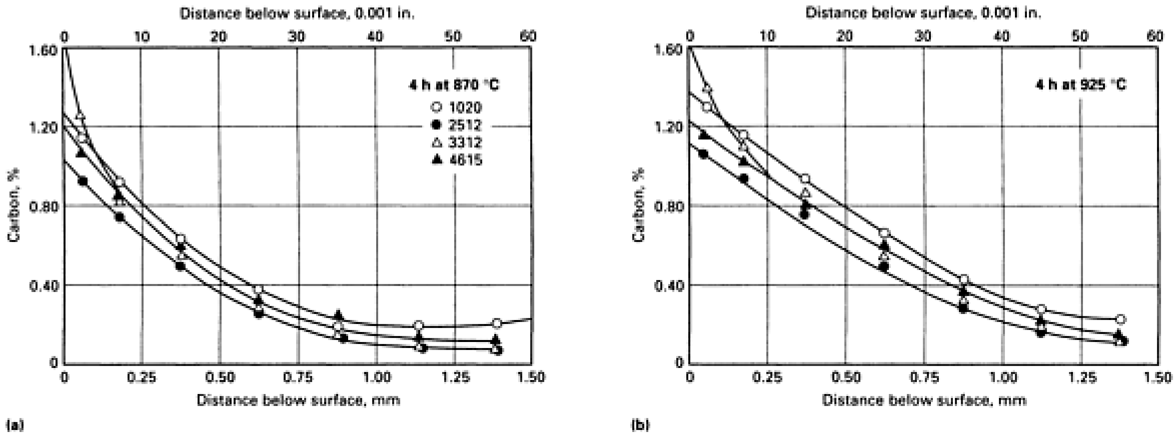

Fig. 7 Carbon gradients for four steels. (a) After carburizing for 4 h at 870 °C (1600 °F). (b) After carburizing for 4 h at 925 °C (1700 °F)

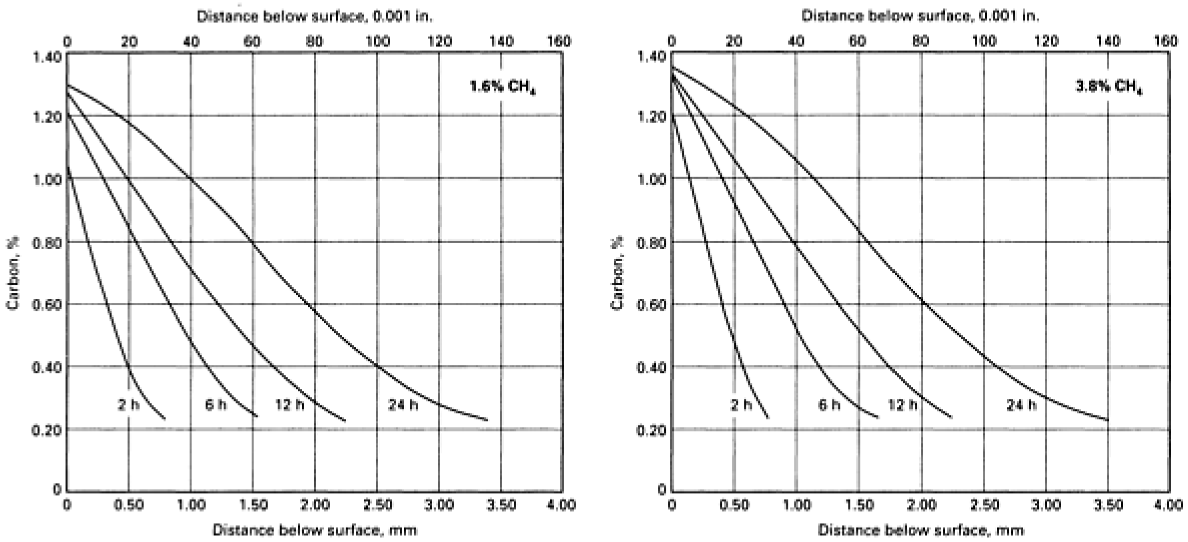

Fig. 8 Carbon gradients for carburized 1022 steel test bars carburized at 918 °C (1685 °F) in 20% CO-40% H_2 gas with 1.6 and 3.8% CH_4 added

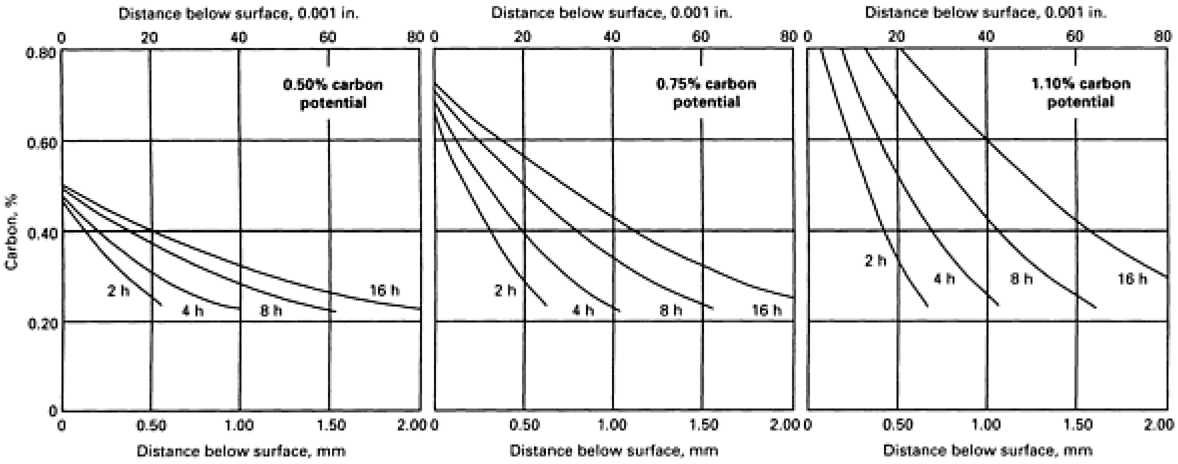

Fig. 9 Carbon gradients for carburized 1022 steel carburized at 918 °C (1685 °F) in 20% CO-40% H_2 gas containing enough H_2O to produce the carbon potentials shown

To develop optimum mechanical properties in the case, it is common practice to use carburizing cycles that consist of two or more combinations of temperature, time, and atmosphere composition (carbon potential). The main objective of using multiple-potential carburizing is to decrease the total cycle time.

The most widely used carburizing cycles are constant-temperature cycles starting with an atmosphere carbon potential that approaches the value for carbon saturation in austenite. Part way through the cycle, the flow of the enriching gas is reduced, which lowers the carbon potential of the atmosphere. During the remainder of the time at temperature, known as the diffusion cycle, the atmosphere is maintained at a carbon potential equal to the final desired surface carbon content. During the diffusion period, the surface layer is partly decarburized because it is in an environment of lower carbon activity. It must not be assumed that all of the carbon added during the carburizing cycle will be diffused inward during the diffusion cycle; most of it does diffuse inward, but some returns to the atmosphere.

Carbon gradients from multiple-potential carburizing are used for the twofold purpose of reducing the amount of retained austenite that would normally occur upon quenching, and increasing the depth of the effective case and making its

properties more uniform. The two examples that follow describe carbon gradients that are typical of those produced in continuous furnaces with zone control.

Example 1: Comparison of Carbon Gradients Produced with and without Zone Control

(Fig. 10). Two types of carburized cases were produced on 4027 steel by gas carburizing in the same continuous furnace using identical time-temperature cycles but different conditions of atmosphere control. For both cycles, total time in the furnace was 10.3 h, and the zone temperatures were 900, 925,925, and 845 °C (1650, 1700, 1700, and 1550 °F). The carbon gradients produced by the two cycles are shown in Fig. 10. One case was produced without zone control, that is, without regard to the fact that there is a high demand for carbon early in the carburizing cycle and a low demand during the final part of the cycle. A uniformly distributed mixture of carrier gas plus hydrocarbon gas was admitted continuously at various points along the length of the furnace. The ratio of carrier gas to hydrocarbon gas was high enough to ensure that only a minimum amount of soot would be deposited during the carburizing and cooling portions of the cycle. As can be seen from the curve labeled "Without zone control" in Fig. 10, the case had a high carbon content at the surface and a slightly concave curvature to the carbon gradient.

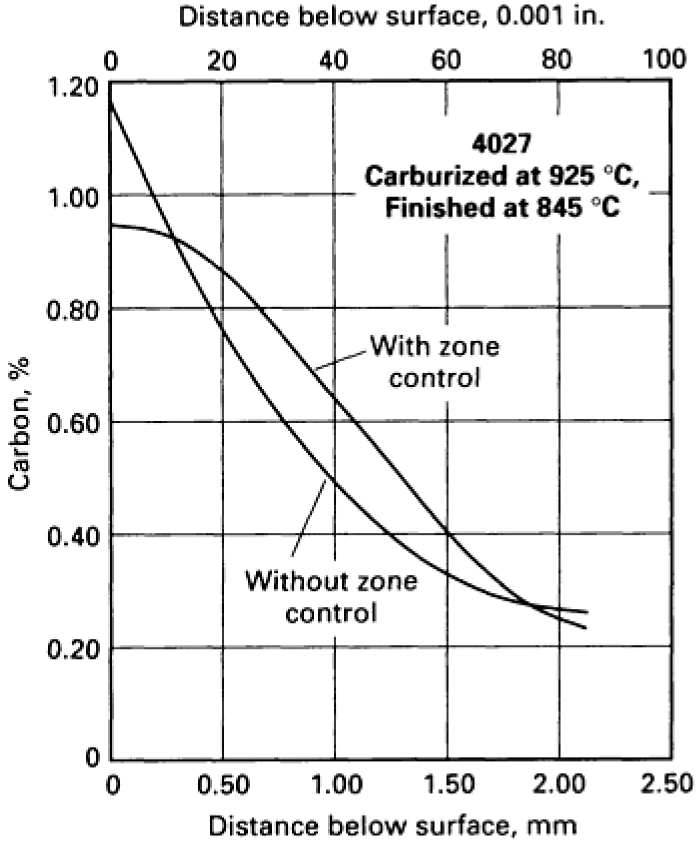

Fig. 10 Effect of zone control on carbon gradient for 4027 steel carburized in a continuous furnace (Example 1)

The other case (see curve labeled "With zone control" in Fig. 10) was produced under identical conditions, except for the distribution of the atmosphere within the furnace. Hydrocarbon gas was admitted only within the carburizing zones, with the greatest amount added in the first of these zones. The total amount of hydrocarbon gas was equal to that for the case produced without zone control. Carrier gas without enrichment was admitted to the furnace in the diffusion and cooling zones. The case had a lower surface carbon content and a greater effective depth than the case produced without zone control, and the carbon gradient curve was convex in the near-surface region of the case.

Example 2: Variation of Carbon Gradient with Processing Conditions in a Three-Zone Continuous Furnace under Manual Control

(Fig. 11). The carbon gradients shown in Fig. 11 are for 4815 steel that was carburized in a three-zone, continuous pusher furnace. Carbon potential was manually controlled. For all three cycles, the temperature in zones 1 and 2 was 920 °C (1690 °F), and the atmosphere was carrier gas enriched with methane; in zone 3, the temperature was 910 °C (1670 °F), and the atmosphere was carrier gas slightly diluted with air. The three cycles differed in the carbon potentials established in the third zone and in the time that parts were exposed in each of the three zones.

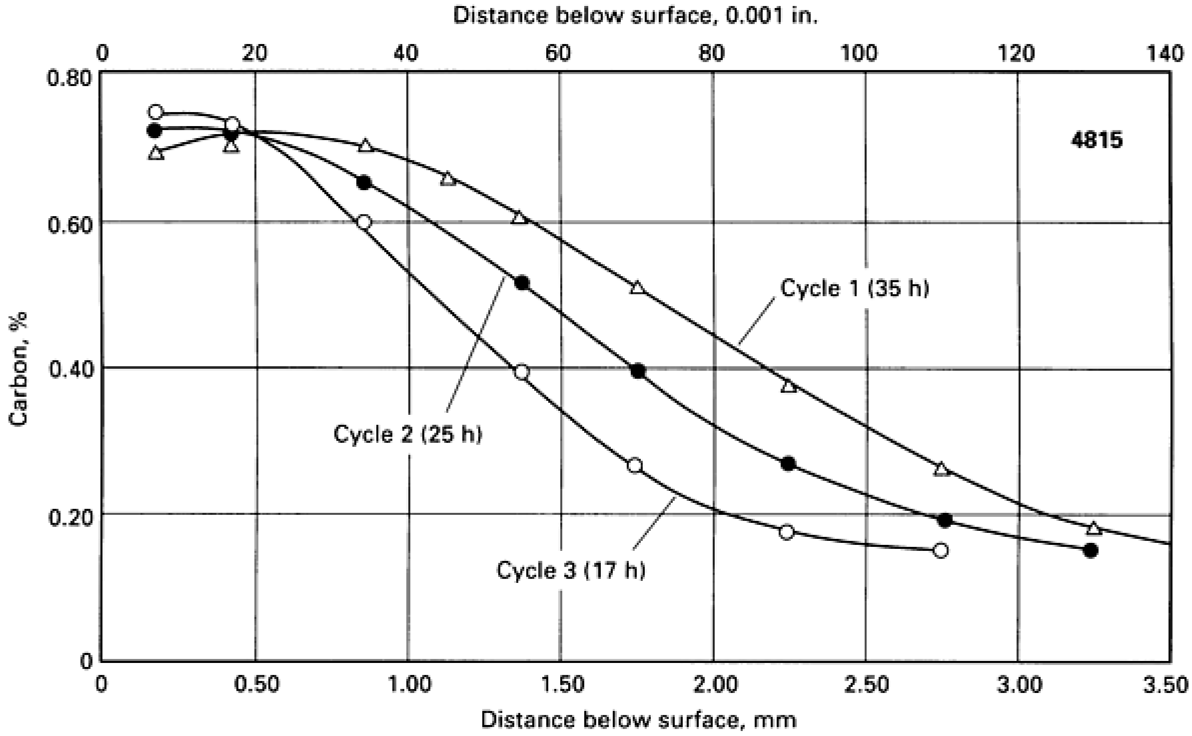

Fig. 11 Carbon gradients from three-zone, continuous pusher-type carburizing furnace with manual control of carbon potential (Example 2)

Cycle 1 was 35 h long, consisting of 8 h in zone 1 at 1.25% carbon potential, 14 h in zone 2 at 1.25% carbon potential, and 13 h in zone 3, where the carbon potential varied from 0.80% at the center of the zone to 0.55% at the discharge end. This cycle was designed to produce a total case depth of 2.8 mm (0.110 in.) at 0.25% C.

Cycle 2 was 25 h long, consisting of 6 h in zone 1 at 1.25% carbon potential, 10 h in zone 2 at 1.25% carbon potential, and 9 h in zone 3, where the carbon potential was 0.80% at the center and 0.60% at the discharge end. This cycle produced a total case depth of 2.3 mm (0.090 in.) at 0.25% C. The carbon gradient exhibited a slightly higher surface carbon content and a narrower zone of constant carbon content in the near-surface region than did the gradient resulting from cycle 1.

Cycle 3 consisted of 4 h in zone 1 and 7 h in zone 2, both at 1.25% carbon potential, plus 6 h in zone 3, where the carbon potential was 0.8% at the center and 0.75% at the discharge end, for a total carburizing-plus-diffusion time of 17 h. This cycle produced a total case depth to 0.25% C of 1.8 mm (0.070 in.). The carbon gradient showed a slightly higher surface carbon content than did either cycle 1 or 2 (Fig. 11) and a slightly shallower plateau of constant carbon content in the near-surface region of the case.

Surface Carbon Content. As indicated in Fig. 10, carbon potential control also affects surface carbon concentration. Surface carbon content has a pronounced effect on the properties of the steel and must be controlled for optimum results.

The amount of carbon in solution affects the amount of austenite that is retained after quenching, and the amount of retained austenite affects the hardness of the quenched case. The amount of austenite retained after quenching is determined by carbon potential, carburizing cycle, diffusion cycle, quenching temperature and rate, and steel composition.

Effect of Carbon Gradient on Case Properties. Carbon gradient is related to case hardness, as shown by the data in Fig. 12 for specimens of 1024 steel. The specimens were carburized for 2 $\frac{1}{4}$h at 900 °C (1650 °F) in an atmosphere containing 10% methane. They were oil quenched from 845 °C (1550 °F) and achieved a maximum surface hardness of about 62 HRC. However, a hardness of about 66 HRC was obtained at a depth of 0.25 mm (0.010 in.) below the surface, indicating the presence of some retained austenite at the surface. Retained austenite is frequently considered a normal constituent in the microstructure, corresponding to the hypereutectoid portion of the carbon gradient. Alloy steels are more likely to exhibit retained austenite than are carbon steels.

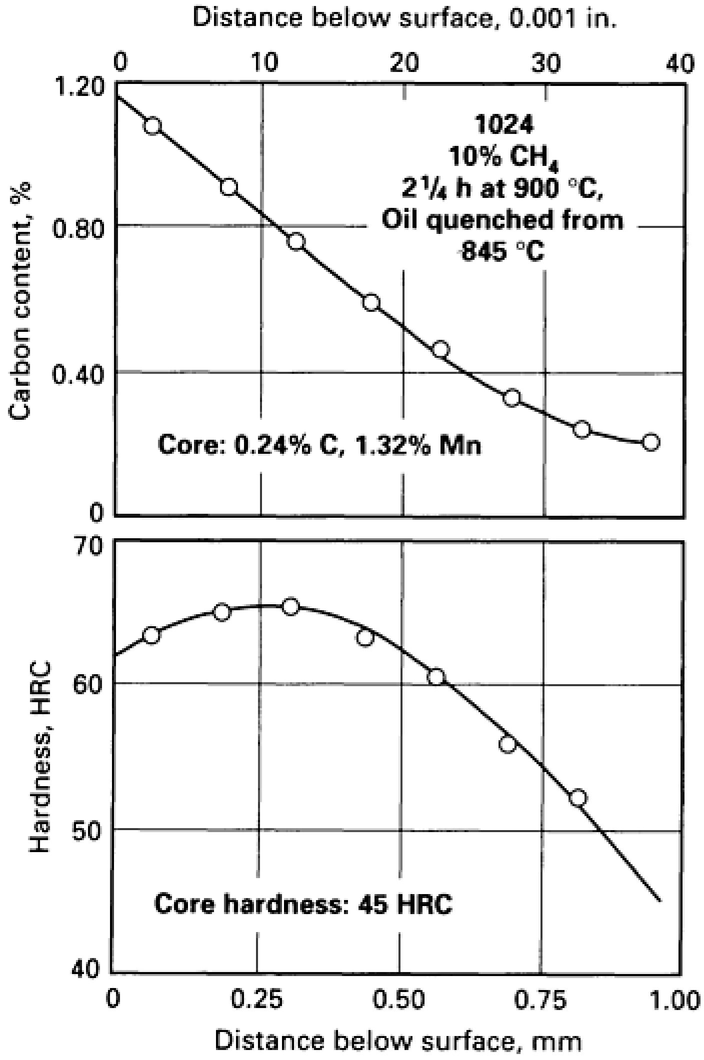

Fig. 12 Carbon and hardness gradients for 1024 steel carburized in a recirculating batch furnace under conditions that produced saturated austenite at the surface. The effect of retained austenite on surface hardness can be seen. Specimens were 25 mm (1 in.) in diameter by 150 mm (6 in.) long.

In many instances, finely dispersed retained austenite in amounts up to 30% is not detrimental to pitting-fatigue strength, whereas much lower amounts are often harmful if the austenite is not finely dispersed. However, small amounts of finely dispersed retained austenite apparently allow mating surfaces to conform at a slightly faster rate and to spread the load more evenly, thereby reducing local areas of high stress.

The effect of carbon content on pitting-fatigue strength has been the subject of controversy for many years. Undoubtedly other microstructural changes have clouded the issue. Rolling-contact fatigue tests have indicated that pitting-fatigue strength increases with increasing hardness in medium-carbon and high-carbon steels.

The effect of carbon content on resistance to wear and scuffing is too complicated to warrant a general conclusion. Excessive retained austenite permits surfaces to deform plastically under heavy loads, resulting in ripples, or "orange peel."

Low Surface Carbon. Most steels can be carburized by the carbon saturation-carbon diffusion type of cycle to produce surface carbon content well below saturation (for example, from 0.90 to 1.00% C). There is a strong preference in present carburizing practice for surface carbon concentrations of eutectoid composition or slightly higher. With the lean-alloy steels that are most often used, it is especially important to utilize the full hardenability of the steel. Maximum hardenability of the lean-alloy carburizing steels is obtained at carbon concentrations near eutectoid composition. The excess carbides formed at high carbon concentrations promote transformation to products other than martensite and may remove part of the carbide-forming elements from the austenite, thereby decreasing the effective hardenability.

Low carbon concentrations at the surface also permit direct quenching of work from the carburizing temperature, which is more economical than reheating before quenching. Direct quenching of carburized parts having high surface carbon concentrations favors the retention of austenite. Such austenite is undesirable because it lowers the indentation hardness of the case and promotes secondary hardening with the formation of untempered martensite, which may change the dimensions of the finished parts as well as embrittle them.

When surface carbon concentrations near eutectoid composition are desired, a multiple-manifold arrangement may be used by which part of the carrier gas and all of the hydrocarbon gas are introduced through ports at the front of the carburizing zone, where carbon demand is high. Only carrier gas is supplied to the other zones, and the carbon potential is adjusted to give the desired final surface carbon concentration.

Because, for a given carbon content of the core, the diffusion rate of carbon in austenite decreases with a lowering of surface carbon concentration, any "starvation" method of carburizing in which the workpiece surfaces are never carburized above the desired final value requires a longer cycle. Also, good recirculation of gases is essential. The atmosphere adjacent to the work quickly becomes depleted of carbon, and, if stagnant areas are allowed, excessively low surface carbon concentrations and shallow case depths will result on the work in these areas. This potential detriment to part quality is the chief reason why most continuous carburizing furnaces in use today are equipped with effective recirculating fans.

Variability in Surface Carbon. Statistical data relating to the control of surface carbon content are given in Fig. 13, 14, 15, and 16 for several plain carbon and low-alloy steels. These data represent practice in eight different plants and therefore involved several different types of furnaces, steel compositions, and "aim" carbon contents. Control varied from good to poor, as the graphs indicate.

Fig. 16 Variation in near-surface (0.13 to 0.25 mm, or 0.005 to 0.010 in.) carbon content for alloy steels carburized in different types of furnaces. (See text.)

The data summarized in Fig. 13 compare carbon concentrations 0.25 mm (0.010 in.) below the surface obtained in gas carburizing 25 batches in each of three similar batch furnaces. The 75 tests show a large majority of the concentrations to be within ±0.05% of the 0.90% C aim. Parts were carburized at 925 °C (1700 °F). The carbon potential was controlled through the dew point. A carrier gas with a dew point of 1.5 °C (35 °F) was enriched with natural gas to maintain a dew point of -5.5 °C (22 °F) in the furnace.

The data presented in Fig. 14(a) compare surface carbon content in rock bit cutters carburized in two pit furnaces to a desired carbon content of 0.75%. Furnaces were operated simultaneously, using the same carrier gas generator. Each furnace was about 1 m (3.3 ft) in diameter by 2 m (6.6 ft) deep and contained a load of about 1360 kg (3000 lb). A carburize-diffuse cycle was used. An automatic dew point controller was employed on the carrier gas generator but not on the furnace.

The results plotted in Fig. 14(b) show surface carbon contents (carbon content of the first 0.075 mm, or 0.003 in., cut) for 19 specimens of 4820 steel carburized along with loads of production parts in a two-row, pusher-type continuous furnace. The desired carbon content was 0.75 to 0.80%, with a specification of 0.70 to 0.90% carbon. All results were within specification, and most were within desired limits. Specimens were carburized at 925 °C (1700 °F) using a diffusion cycle, quenched from 815 °C (1500 °F) in oil at 60 °C (140 °F), tempered in lead at 620 °C (1150 °F) for 5 min, and cleaned with a wire brush, and liquid abrasive. The atmosphere at the charge end of the furnace was automatically controlled at a dew point of -15 °C (5 °F) and at the discharge end was controlled at a dew point of 3 °C (37 °F). Endothermic gas enriched with straight natural gas was used as the carburizing medium; air was added at the discharge end.

The data presented in Fig. 14(c) for 4320 steel bar specimens were obtained under the same carburizing and test conditions used for Fig. 14(b) for lengths of 4820 steel bar, except that the dew point was -1 °C (30 °F) at the discharge end and the specimens were tempered at 650 °C (1200 °F). The desired surface carbon content was 0.85 ±0.05%.

The results of 50 tests that represent variations in surface carbon content for continuous carburizing of 4027 steel are given in Fig. 14(d). These results were obtained over a period of 3 to 4 years. An automatic dew point controller was used.

The data given in Fig. 14(e) for 8620 steel bar specimens were obtained under the same carburizing and test conditions used for carburizing 4320 steel (Fig. 14c). The desired surface carbon content was 0.90 ±0.05%.

The data shown in Fig. 14(f) were based on the surface carbon content (the first 0.075 mm, or 0.003 in., depth of cut) of 25 mm (1 in.) rounds. The rounds were carburized with production parts in a horizontal batch furnace, quenched in oil from 845 °C (1550 °F), tempered in lead at 650 °C (1200 °F), and cleaned with a wire brush and liquid abrasive. The desired carbon content was 0.90 ± 0.05%. The carburizing medium was endothermic gas enriched with natural gas. No air was added. A dew point of -15 °C (5 °F) was used throughout the 925 °C (1700 °F) carburizing cycle, -12 °C (10 °F) for the diffusion cycle (also at 925 °C, or 1700 °F), and -3 °C (27 °F) for the 845 °C (1550 °F) cycle that preceded quenching.

The data in Fig. 15(a) represent carbon content at 0.18 mm (0.007 in.) below the surface. Actual surface carbon ranged from 0.85 to 1.03%. The steel was carburized in a batch-type furnace using a hot-wire analyzer for automatic atmosphere control. Actual case depth to 50 HRC was 1.10 to 1.32 mm (0.043 to 0.052 in.); required case depth was 1.15 to 1.25 mm (0.045 to 0.050 in.); total case depth ranged from 1.93 to 2.05 mm (0.076 to 0.081 in.).

The data summarized in Fig. 15(b) also represent carbon content at 0.18 mm below the surface. Actual surface carbon ranged from 0.84 to 1.19%. The steel was carburized in a batch-type furnace with manual atmosphere control. Actual case depth to 50 HRC was 0.38 to 0.58 mm (0.015 to 0.023 in.); required case depth was 0.38 to 0.64 mm (0.015 to 0.025 in.); total case depth ranged from 0.64 to 0.80 mm (0.025 to 0.031 in.).

Carburizing and test conditions for the data shown in Fig. 15(c) were the same as those for the data in Fig. 15(b). In this instance, surface carbon ranged from 0.89 to 1.48%, and case depth to 50 HRC was 0.64 to 0.94 mm (0.025 to 0.037 in.).

Specified case depth was 0.75 to 0.90 mm (0.030 to 0.035 in.); total depth ranged from 0.86 to 1.35 mm (0.034 to 0.053 in.). The same batch-type furnace was used to obtain the data for Fig. 15(a), 15(b), and 15(c).

The data shown in Fig. 15(d) represent surface carbon contents of 27 samples taken at 8-h intervals. Parts were carburized in trays in a continuous pusher furnace with dew point control of the atmosphere. Desired surface carbon was 1.0%.

The carbon concentration data for 8620 and 3310 steels that are shown in Fig. 16(a) and 16(b) were obtained on round-bar test specimens placed at several locations throughout each charge of production parts of the same steel composition. Specimens were carburized in a vertical pit furnace having a single circulating fan. The atmosphere was endothermic gas enriched with methane. The 8620 steel was carburized at 955 °C (1750 °F), without automatic atmosphere control, using a diffusion cycle in which only endothermic gas was introduced during the last third of the carburizing cycle. The 3310 steel was carburized at 925 °C (1700 °F), with automatic atmosphere control but no diffusion cycle.

Round bars were used to obtain the data shown for 8620 and 4620 steels in Fig. 16(c) and 16(d). Both steels were carburized at 955 °C (1750 °F) in a rotary retort furnace under an atmosphere of endothermic gas plus methane. A diffusion cycle, in which the methane was shut off for the last third of the carburizing cycle, was used for the 8620 steel. The 4620 steel was carburized without a diffusion cycle, and the carbon content ranged predominantly below the desired 1.0%. Results for the 8620 steel were largely above the desired carbon content.

The data in Fig. 16(e) and 16(f) for 8620 and 3310 steels were obtained from round test specimens distributed throughout loads in continuous pusher furnaces. The atmospheres were endothermic gas enriched with methane. The 8620 specimens were carburized at 925 °C (1700 °F) in a furnace with three fans, without automatic atmosphere control or a diffusion cycle. The 3310 specimens were carburized at 925 °C in a furnace equipped with two fans, with automatic atmosphere control but no diffusion cycle.

Surface carbon content may vary significantly as a function of location in the furnace. Figure 17 indicates a variation in surface carbon on 4620 steel bearing races from the tip to the bottom of the pit furnace used. The furnace was about 0.75 m (30 in.) in diameter by 0.90 m (36 in.) deep. An open load of races was carburized for 7 h in a natural gas atmosphere, and this step was followed by a $3\frac{1}{2}$-h diffusion cycle. Desired surface carbon was 1.00%. Each bar on the chart represents 14 heats of steel. It is apparent that in this instance surface carbon content was consistently higher in specimens carburized in the bottom portion of the furnace, possibly indicating a slightly higher operating temperature there.

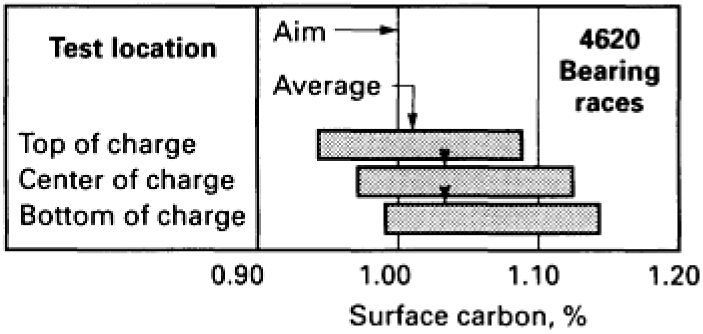

Fig. 17 Variation in surface carbon content with position in a pit furnace for 4620 steel bearing races

A horizontal batch furnace--operated as described for Fig. 3(b) and 3(c) except that, for a dew point of -12 °C (10 °F), diffusion time was 6 h--produced the distribution of case depth shown in Fig. 3(d) and tabulated as:

Variation from average depth,	Part distribution,

mm (in.)	%
1.5 ± 0.03 (0.061 ± 0.001)	31
1.5 ± 0.05 (0.061 ± 0.002)	50
1.5 ± 0.08 (0.061 ± 0.003)	63
1.5 ± 0.10 (0.061 ± 0.004)	81
1.5 ± 0.13 (0.061 ± 0.005)	100

In this instance, the target depth (to 0.040% C) was 1.4 to 1.8 mm (0.055 to 0.070 in.). Testpieces like those described for Fig. 3(a) were used to obtain the data.

A case depth of 1.4 to 1.8 mm (0.055 to 0.070 in.) (to 0.040% C) was specified for gears that were carburized at 925 °C (1700 °F) in a continuous furnace. The variation in case depth is likely to be greater in a continuous furnace than in a batch furnace, as indicated by results of 24 tests summarized in Fig. 3(e). These data were obtained from actual gears, one tested per week for 24 weeks.

Batch-type carburizing in the same plant that case hardened the gears produced case depths within an extremely close range, as indicated in Fig. 3(f). Case depths were determined by carburizing testpieces 25 mm (1 in.) in diameter by 38 mm (1 $\frac{1}{2}$ in.) in length along with 175 to 205 kg (390 to 450 lb) charges of gears, using dew point control. The testpieces were cut in half, polished, etched in nital, and then examined microscopically.

As indicated in the preceding discussion, the routine carburization of parts to a case depth variability not exceeding ±0.2 mm (±0.008 in.) is quite reasonable. This degree of maximum variation can be expected over long periods of time, provided that there is adequate process control, supplemented with frequent destructive examination (several times a week) of either actual parts or production control specimens from each furnace or integrated production line.

Carbon Restoration

Hot-worked steel products usually become more or less decarburized during heating for hot rolling, forging, extruding, and spinning. The depth of decarburization depends on the hot-working temperature, time at temperature, furnace atmosphere, reduction in area from bloom to finished size, and type of steel.

Decarburization may be corrected by carbon restoration, that is, by carburizing enough to restore the carbon content to value equal to the original or intended content. This is particularly important when the formed product must be quenched and tempered to develop high resistance to wear or fatigue. For instance, cold-heading stock intended for use in antifriction bearings or fasteners must be virtually free from decarburization. The micrographs in Fig. 18 show the restoration of carbon, in two stages, to decarburize 1035 steel heading stock.

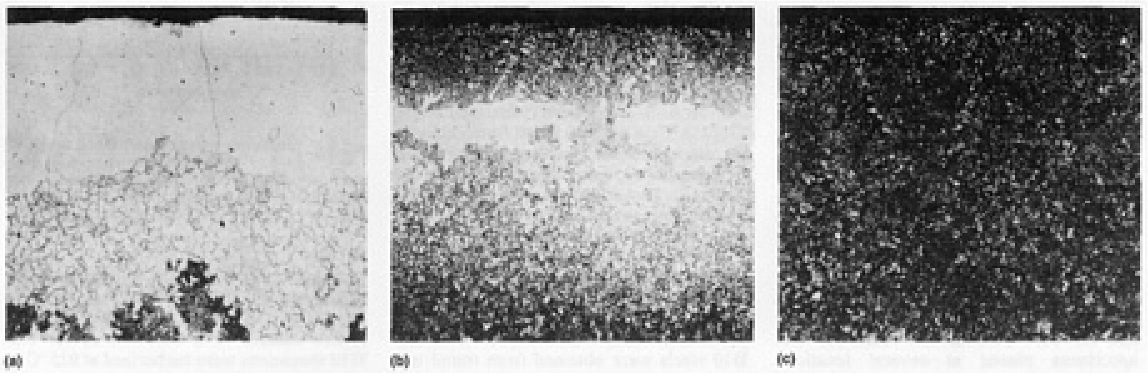

Fig. 18 Restoration of carbon in 1035 steel bar stock. (a) As-received steel with a carbon-free depth of 0.25 to 0.30 mm (0.010 to 0.012 in.); maximum affected depth, 0.38 to 0.64 mm (0.015 to 0.025 in.). (b) Same steel after carbon restoration at 850 °C (1560 °F) for 1 h followed by water quenching. (c) Same steel after carbon restoration at 850 °C (1560 °F) for 2 $\frac{1}{2}$ h followed by water quenching. All bar stock was 21.8 to 21.9 mm (0.859 to 0.862 in.) in diameter. All micrographs 100×

Four types of atmospheres are generally used for carbon restoration:

- Nitrogen-dissociated methanol
- Nitrogen enriched with hydrocarbon (usually, methane or propane)
- Dry, purified exothermic gas
- Endothermic gas

Of the four types, endothermic composition atmospheres are the best understood, the easiest to handle, and by far the most widely used in commercial practice. Nitrogen-methanol atmospheres can be considered direct replacements for generated endothermic gas because these two types of atmospheres have essentially the same composition.

When decarburization is shallow, surface carbon content can be corrected during the annealing or heat-treating cycle. For controlled carbon restoration, the annealing temperature must be above the control temperature for the steel being processed. If decarburization is deep, it may be necessary to use a higher temperature to obtain the necessary diffusion of carbon into the steel within practical time limits.

The process of restoring carbon can be applied to steels of low, medium, or high carbon content. Table 2 shows the treatment conditions used to restore carbon to four plain carbon steels of different carbon contents. The effectiveness of the treatment is also indicated. For control, both low-carbon and high-carbon shims were treated with these steels, and results for these shims are given as well. It can be seen that the low-carbon shims picked up carbon, whereas the high-carbon shims, with the exception of those treated along with the 1095 steel, lost carbon, indicating that equilibrium was established or closely approached.

Table 2 Effectiveness and conditions of carbon restoration for four plain carbon steels

(b) Represents four duplicate tests.

(c) Represents five duplicate tests.

(d) Treated for control.

(e) Analysis of atmosphere in furnace

Successful carbon restoration depends on (in order of importance):

- Composition of the furnace atmosphere
- Composition of the steel
- Processing temperature
- Surface condition of the material undergoing carbon restoration
- Type of furnace
- Furnace zone separation
- Atmosphere tightness of the furnace
- Distribution of the load
- Flow rate and degree of circulation of the furnace atmosphere

It is frequently expedient to control the dew point of an endothermic atmosphere by adding small amounts of air or methane to the furnace rather than adjusting the atmosphere generator. The addition of a small quantity of air increases the dew point, whereas the addition of methane decreases it. The addition of nitrogen to endothermic gas lowers CO_2, O_2, or dew point concentrations by *dilution.* This is seldom done, however, because the carburizing components of the endothermic gas (CO and H_2) are also diluted, resulting in a loss of carbon attainment rate and atmosphere control. If the CO content of an endothermic gas deviates widely from the normal 20% (±2%), adverse effects may be expected on carbon potential control where traditionally applied techniques are used (that is, C versus dew point, CO_2 content, and O_2 potential).

It is difficult to control the carbon potential of atmospheres so that reproducible carbon contents are developed in the surface of the part undergoing carbon restoration. A surface carbon level slightly below that of the base material is usually much less harmful than overcarburization, especially in fatigue applications. Consequently, if fatigue life is important to the serviceability of the part, it is best not to risk excessive carbon restoration.

The cost of restoring carbon to parts prior to final machining operations depends on such factors as the cost of the steel, the cost of carbon restoration, and the amount of final machining required. In general, if little or no machining is required for finishing a part, there may be an economic gain in restoring carbon. Conversely, if a part requires machining all over, which would remove most or all of the carbon-depleted area, carbon restoration may be unnecessary.

Quality Control

It is considered axiomatic that, to be effective and consistent, quality control for any facility must be properly conceived, formally documented, and rigorously followed. However, a single plan is not universally applicable; policies and procedures that work in one plant may be ineffective in another plant. The same is true of quality control for a carburizing facility.

Sampling Plans. Among commercial firms doing good-quality carburizing on a routine basis, the consensus is that only when samples are taken continually for destructive evaluation is it possible to ensure close control of case properties. The term samples may mean production parts, pieces of production parts, or specially designed test samples. Destructive examination usually means, as a minimum, etching a cross section and directly measuring case depth. In many instances the measurement of hardness gradient or examination of microstructure, or both, are also specified.

In one plant, where 44*xx* and 86*xx* steel gears of various sizes are carburized to a single set of requirements in tray-type, four-zone, continuous pusher furnaces, one gear is selected at random daily from each furnace line, after the direct-quench step. Quality is determined by taking microhardness measurements on a cross section through one of the teeth. Effective case depth to 50 HRC at the pitch line is reported, and the hardness profile is compared with that of previously produced gears. As an ongoing check, each part is tested with a mill bastard file immediately after quenching in oil to ensure that a file-hard case has been achieved.

In another plant, where a wide variety of gears is processed to various specifications and where both batch and continuous pusher furnaces are used, one sample part from each production lot is cut for destructive examination. Microstructure is observed, and effective case depth to 50 HRC is determined from a plot of microhardness (Knoop) versus depth. The operation of the furnaces is such that the type and size of gear are inconsequential. To evaluate furnace conditions, carbon gradients are measured for each furnace about every two to five working days. A standard carbon gradient bar is run along with production parts, the bar is step machined, and the carbon content of chips is determined spectrographically. For each plot of carbon gradient, the shape of the curve, case depth to 0.40% carbon, and surface carbon level are evaluated in relation to past performance.

In two other plants, part quality is evaluated by fracturing or cutting small standard test bars, etching the fractured or cut surfaces, and reading case depths with a Brinell glass. One of these plants uses test bars 11 mm square by 75 mm long (about $\frac{7}{16}$ in. square by 3 in. long) made of coarse-grained, cold-drawn, silicon-killed 1022 steel. In selecting test bar material, special narrow limits on composition, grain size, and hardenability are imposed so that normal heat-to-heat variations in response to heat treatment are minimized. In batch furnaces, at least one test bar is processed with each batch. (Sometimes, more than one is used, for example, in the tip, middle, and bottom trays of a load being carburized in a pit furnace.) In continuous furnaces, a test bar is placed in about every third tray in each row. In both plants, satisfactory case depths on carburized or carbonitrided test bars justify the release of parts into the normal production stream. If case depths on test bars are barely acceptable or are unsatisfactory, a sample part from the production lot is destructively examined and the decision to accept or reject the parts is based on the evaluation of this part.

Disposition of Rejected Parts. Experience and problem analyses have proved that nonconforming (rejected) parts must be handled by proper, strictly enforced procedures. Nonconforming parts must be identified so that they can be further investigated and then are reworked or discarded. It is extremely important that questionable parts be removed from the production area and placed in a quarantine area. Scrapped parts must be visibly mutilated to warn plant personnel against returning them to the process stream. Repairs should be made only with the knowledge of all departments concerned. Repaired components must be separated from the normal process stream until fully tested and proved to be of adequate quality.

The rejection of parts usually results from the failure of the furnace, generator, gas supply, or power. Fortunately, nonconforming components can often be reprocessed. Good preventive maintenance greatly minimizes such problems; an efficient shop produces only a small amount of scrap.

Defects and Distortion in Heat-Treated Parts

Anil Kumar Sinha, Bohn Piston Division

Introduction

MOST OF THE PROBLEMS in heat-treated parts are attributed to faulty heat-treatment practices (such as overheating and burning, and nonuniform heating and quenching), deficiency in the grade of steels used, part defect, improper grinding, and/or poor part design. This article discusses overheating and burning, residual stresses, quench cracking, and distortion in some detail and offers some suggestions to combat them.

Most of these conditions result in a characteristic appearance of the treated parts that can be easily recognized by simple inspection. Some of these factors do not produce any distinguishing features in the semifinished or finished part. In particular, some of the visual evidence does not recognize the presence of overheating and burning and the development of residual stresses leading to distortion, quench cracking, and eventual failure of the heat-treated parts; metallurgical laboratory examination is needed to establish these problems that contribute significantly to the service performance of the part. Tool designers must also be aware of the problems and difficulties in manufacture, heat treatment, and use.

Overheating and Burning of Low-Alloy Steels

When low-alloy steels are preheated to high temperature (usually >1200 °C, or 2200 °F), prior to hot mechanical working (such as forging) for a long period, a deterioration in the room-temperature mechanical properties (particularly tensile ductility and impact strength or toughness) can be obtained after the steel has been given a final heat treatment (comprising reaustenitizing, quenching, and tempering) (Ref 1, 2, 3). Linked with the impaired mechanical properties is the appearance of intergranular matte facets on the normal ductile fracture surface of an impact specimen. This phenomenon is known as overheating and has been a matter of concern, especially in the case of steel forgings. Overheating has also been noticed in steel castings (due to variation in pouring temperature and effectiveness of the proprietary grain inoculants applied to the mold surface), in heavily ground parts, and in affected zones of welds (Ref 4). The usual practice is to reject the overheated products as being unsuitable for service.

It has now been established that overheating is essentially a reversible process caused by the solution of MnS particles in austenite during heating or reheating at high temperatures; the amount increases with temperature, and its subsequent reprecipitation during cooling occurs at intermediate rates as very fine (~0.5 μm) arrays of α-MnS particles on the austenite grain boundaries. On subsequent heat treatment the intergranular network of sulfides may provide a preferential, lower-energy fracture path in contrast to a normal transgranular fracture path. As a result, when impact loaded, a ductile intergranular fracture develops due to decohesion of the MnS/matrix interface and progress of microvoid coalescence. Figures 1 (a) and (b) show the usual appearance of the fracture surface at different magnifications (Ref 1).

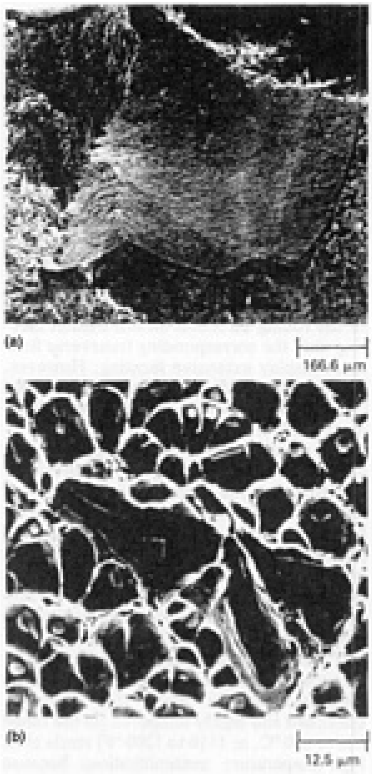

Fig. 1 Fracture surface of an impact loaded specimen. (a) Appearance of intergranular fracture of 4.25Ni-Cr-Mo steel containing 0.34% Mn and 0.008% S, in fully heat-treated condition but after cooling from 1400 °C (2550 °F) at 10 °C/min (20 °F/min). (b) Same specimen as in (a) but at higher magnification, showing ductile dimples nucleated by MnS particles precipitated at austenite grain boundaries. Courtesy of The Institute of Metals

When the low-alloy steel is preheated prior to hot working at too high a temperature (normally >1400 °C, or 2550 °F), local melting occurs at the austenite grain boundaries as a result of the segregation of phosphorus, sulfur, and carbon (Ref 5). During cooling, initially dendritic sulfides (probably type II-MnS) form within the phosphorus-rich austenite grain boundary, which then transforms to ferrite. This results in excessively weak boundaries. Subsequent heat treatment provides a very poor impact strength and almost completely intergranular fracture surface after impact failure. This phenomenon is termed burning. Burning thus occurs at a higher temperature than overheating. If this occurs during forging, the forging will often break during cooling or subsequent heat treatment (Ref 4).

Detection of Overheating

There are two basic methods for the determination of the occurrence of overheating, namely, fracture testing and metallography (or etch testing). Overheating may also be detected by a decrease in mechanical properties. But such changes are not very marked unless overheating temperature is high or overheating is too prolonged or severe; in some instances the mechanical properties do not change, even after the observation of extensive faceting. Usually the two methods mentioned above should be used in conjunction with some measure of toughness by impact or other testing in order to get a clear understanding of the degree and severity of overheating (Ref 2).

Fracture Testing. The direction of fracture testing is important in steels manufactured by conventional methods. It has been observed by some workers (Ref 6) that the longitudinal fracture test specimens parallel to the rolling direction do not exhibit faceting until the corresponding transverse fractures display extensive faceting. However, the testing direction in electroslag-refined (ESR) steels has been found to be insignificant (Ref 7).

The scanning electron microscope is considered to be the best and most convenient tool to detect the facets on the overheated fracture surfaces. These facets are characterized by small, well-defined, ductile dimples; each dimple is usually nucleated, presumably by fine arrays of inclusion particles: α-MnS particles (Fig. 1) in Mn-bearing steels (Ref 8, 9) or chromium sulfides in Mn-free steels (Ref 10, 11).

It is now well recognized that the fracture test specimen should always be tested in the toughest possible state (for example, quenched and highly tempered [in the range 600 to 650 °C, or 1110 to 1200 °F] steels after high-temperature austenitization) because this condition is most prone to overheating effects. Baker and Johnson (Ref 5) have suggested that an increased proportion of facets in the fracture specimens with increasing tempering temperature is attributed to the corresponding increase of the plastic zone size. In this case a slight amount of weakening will be sufficient to impart faceting because the grain boundary strength becomes lower (Ref 2). It should be noted that the existence of facets in the fractured specimens is not always associated with a lowering of impact strength (Ref 12).

Metallography (or Etch Testing). The most widely used etchant technique uses Austin's reagent (aqueous solution of 10% nitric and 10% sulfuric acids), ammonium persulfate, molten zinc chloride, saturated solution of picric acid at 60 °C (140 °F), and an electrolytic etch based on saturated aqueous ammonium nitrate. Table 1 shows the etching characteristics of overheated and burned steels (Ref 13). The etchant procedure with Austin's etchant is as follows: The sectioned specimen is etched for 30 s in the etchant, removed, washed off, and repeated three times. If the steel has been overheated, the original austenite grain boundaries will be preferentially attacked, and a black network of etch pits will be observed under the microscope (Ref 14). According to Preece and Nutting (Ref 13), the best results are obtained when ammonium nitrate etch is applied on the sectioned steel specimen in the fully heat-treated condition where this etchant preferentially attacks the matrix (original austenite grains), leaving the grain boundary unaffected (which appears as a white network). Bodimeade (Ref 15) concluded that all these etchants did not cope with mildly overheated low-sulfur steels. Table 2 is a summary of the results of potentiostatic etching techniques carried out by McLeod (Ref 12) using nitric-sulfuric, saturated aqueous picric acid (at 60 °C, or 140 °F), and ammonium nitrate etchants. He considered that when the suitable etching conditions were established, the potentiostatic etching method rendered more reliable and reproducible results as compared with the conventional etching techniques. However, the same problem with mildly overheated low-sulfur steels still persisted. Hence, the use of etch tests for low-sulfur low-alloy steels is not recommended for the detection of mild overheating.

Table 1 Etching characteristics of overheated and burned steels

Reagent	Method	Action on overheated steel	Action on burned steel
2.5% nitric acid in ethyl alcohol	Swab surface for 30 s	May produce grain contrast, but not indicative of overheating	White boundaries outlining preexisting austenite grains
Saturated aqueous solution of ammonium nitrate	Electrolytic, specimen anode, current density 1.0 A cm^{-2} (6.5 A $in.^{-2}$)	White boundaries outlining preexisting grains	Black boundaries outlining preexisting austenite grains
Aqueous 10% nitric acid + 10% sulfuric acid	Etch for 30 s, swab surface; repeat three times, then repolish lightly	Black boundaries outlining preexisting austenite grains	White boundaries outlining preexisting austenite grains
85% orthophosphoric acid (Fine's reagent)	Electrolytic, specimen anode, current density 0.15 A cm^{-2} (1.0 A $in.^{-2}$), etching time 15 min	Does not differentiate between overheated and nonoverheated steel	Attacks inclusions at grain boundaries
Oberhoffer's reagent	Swab surface for 30 s	Does not differentiate between overheated and nonoverheated steel	Shows phosphorus segregation at grain boundaries

Source: Ref 13

Table 2 Summary of potentiostatic etching experiments

Solution	Anodic loop voltage, mV	Observed effect	Best etching conditions		Comments
			Voltage,	Observed effect	

			mV		
Saturated aqueous ammonium nitrate	-400	Slight general etching	2200 (for 2 min)	Classic white boundaries on a dark background	Operates best in the transpassive region at >+1500 mV; time at any potential is important
					Underetching: random array of black pits
					Overetching: uniform black surface film
Aqueous 10% nitric acid + 10% sulfuric acid	200	Vigorous dissolution of specimen; formation of flaky black film	None	. . .	Most aggressive etchant of the three examined
	-250	Milder attack; large black pits in mildly etched matrix	About -250 (for 30 s)	Discontinuous array of grain-boundary pits and some random pits within grains	Polish lightly after etching to eliminate matrix etching effects
Saturated aqueous picric acid at 60 °C (140 °F)	100	No real, positive indication of overheating	None	. . .	Anodic loop very weak, necessitating long etching times because current density is very low; Teepol additions gave no improvement

Detection and Effects of Burning

Burning is not commonly encountered. The two etchants (namely, nitric-sulfuric acid and ammonium nitrate solution) used for overheating can be successfully employed for detecting burning. When applied to burned steels, these etchants react in a manner opposite to that of overheated steels. Preece and Nutting (Ref 13) found ammonium nitrate solution to be the ideal reagent to detect this phenomenon. Other reagents are Stead's and Oberhoffer's reagents, which may also be used to check the burning effect. However, these etchants are unable to differentiate between overheated and nonoverheated steels.

Factors Affecting Overheating

The occurrence and severity of overheating depend principally on important factors, notably steel composition, temperature, cooling rate, and method of manufacture.

Composition. Sulfur is the constituent that greatly influences overheating. For steels with less than 0.002 wt% sulfur, overheating does not occur; this is because of the very low volume fraction of sulfides formed. However, the commercial production of such very-low-sulfur steels (for example, ESR steels) is expensive. Above this level of sulfur, the overheating onset temperature rises with the increasing amount of sulfur. It has now been explained that steels with low sulfur content (0.01 to 0.02%) are more prone to this defect than those with high sulfur content (>0.3%) because the transgranular strength is high, and therefore a small amount of grain-boundary sulfide precipitation is enough to induce intergranular failure (Ref 16). The phosphorus content has been regarded with the most concern in connection with burning. At constant phosphorus level, there is an increase in the overheating temperature with the increase of sulfur content, whereas the burning onset temperature decreases. Burning temperature is reduced with the increase in phosphorus content. At low sulfur contents, a wide gap between overheating and burning temperatures exists. For example, in the case of vacuum remelted steels, the temperature gap between the onset of overheating and burning is

~300 to 400 °C (~570 to 750 °F) and there is a remote possibility of burning occurring within the forging range, unless the overheating is severe (Ref 2). However, at high sulfur content the gap becomes narrow.

Temperature. To avoid overheating, care must be exercised in choosing a correct heating temperature so that uneven heating, flame impingement, and so forth, do not occur (Ref 3).

Cooling Rates. The cooling rate through the overheating range affects the size and dispersion of intergranular α-MnS particles. The intermediate cooling rate generally employed, 10 to 200 °C/min (20 to 360 °F/min), gives rise to maximum faceting as well as to the greatest loss in impact strength. However, slow and rapid cooling rates will suppress overheating. At very slow cooling rates, the sulfide particles become large, small in number, and more widely dispersed, and they have no more deleterious effects than the other inclusions already present. At rapid rates, the sulfide inclusions are too fine to produce any damaging effect (Ref 17).

Methods of Manufacture. Electroslag-remelted steels are less susceptible than vacuum-remelted steels, presumably due to the difference in oxygen level. Similarly, nickel steels are more prone to overheating. Vacuum-remelted steels have a lower overheating temperature than some comparable air-melted steels.

Prevention of Overheating and Burning

For preventing overheating of steels, a properly selected temperature should lie between a temperature low enough for the metal to be safe and high enough to be sufficiently plastic. The better the temperature control, the better the compromise.

Severe overheating can be reduced to mild overheating by soaking the steel at 1200 °C (2200 °F); with care, it may be removed completely. Hot working through the overheating range to a low finish temperature is also reported to remove the effects of overheating.

The alloying additions with a greater sulfide-forming tendency, such as calcium, zirconium, cerium (~0.3% of the melt), or mixed rare earth metals (in the form of misch metal containing 52% Ce, 25% La, and 12% Nd), have been shown to increase significantly both the overheating temperature and mechanical properties of the steel (for example, ductility and toughness). Provided that a high Ce/S ratio (>2) existed, a complete change in sulfide morphology occurred in low-alloy steels where the elongated MnS inclusion occurring in the untreated steel was totally replaced by small globular type-I rare earth sulfides and oxysulfides of high thermal stability even after austenitizing at 1400 °C (2550 °F) (Ref 2). This treatment does not show intergranular faceting. Burning can also be avoided in the same way by treating with calcium, zirconium, cerium, or mixed rare earth addition to form refractory, less-soluble sulfides.

Control of Cooling Rates. Control of cooling rates is not a practical method for large forgings because extremely slow cooling is prohibitively time consuming and causes excessive scaling and decarburization, and rapid quenching from high temperatures produces cracking and distortion of the parts (Ref 2).

Reclamation of Overheated Steel

Severely overheated steels can often be completely restored by any of the following heat treatments:

- Repeated normalizing (as many as six) starting at temperatures 50 to 100 °C (90 to 180 °F) higher than usual, followed by a standard normalizing treatment (Ref 2)
- Repeated oil-hardening and tempering treatments after prolonged soaking at 950 to 1150 °C (1740 to 2100 °F) in carburizing atmosphere. Rehardening more than three times is not advisable
- Soaking at 900 to 1150 °C (1650 to 2100 °F) for several hours. This causes growth of MnS particles by the Ostwald ripening process and results in an excessive scale formation and a loss of dimensional accuracy of the forgings

Defects and Distortion in Heat-Treated Parts

Anil Kumar Sinha, Bohn Piston Division

Residual Stresses

Heat treatment often causes stress- and strain-related problems such as residual stress, quench cracks, and deformation and/or distortion. The residual stress may be defined as the self-equilibrating internal or locked-in stress remaining within a body with no applied (external) force, external constraint, or temperature gradient (Ref 18, 19). There are two types of residual stresses:

- *Macro- or long-range residual stress* is a first-order stress that represents an average of body stresses over all the phases in polyphase materials. Macroresidual stresses act over large regions as compared to the grain size of the material. Traditionally, engineers consider only this type of residual stress when designing mechanical parts
- *Microresidual stress, also termed tesselated stress or short-range stress* is a second-order or texture stress, which is associated with lattice defects (such as vacancies, dislocations, and pile-up of dislocations) and fine precipitates (for example, martensite) (Ref 20, 21, 22). Microresidual is the average stress across one grain or part of the grain of the material. This information is indispensable in studying the essential behavior of material deformation

These two types of residual stresses may also be classified further as a tensile or compressive stress located near the surface or in the body of a material. This section focuses on the effects, development, control, and measurement of long-range residual stresses.

Effects of Residual Stress

The major effects of residual stress include dimensional changes and resistance to crack initiation. Dimensional changes occur when the residual stress (or a portion of it) in a body is eliminated. In terms of crack initiation, residual stresses can be either beneficial or detrimental, depending on whether the stress is tensile or compressive.

Compressive Residual Stress. Because residual stresses are algebraically summed with applied stresses, residual compressive stresses in the surface layers are generally helpful because the built-in compressive stresses can reduce the effects of imposed tensile stresses that may produce cracking or failure. Compressive stresses therefore contribute to the improvement of fatigue strength and resistance to stress-corrosion cracking in a part and an increase in the bending strength of brittle ceramics and glass (Ref 22).

Figure 2 shows that the endurance limit fatigue strength of selected steels increases with the surface residual compressive stress developed by specific heat treatment and surface processing. It is also apparent that, in the presence of high compressive stress, a poor microstructure in steel samples has a small influence on good endurance limit fatigue strength (Ref 23, 24, 25). These fatigue improvements are of great significance in components, particularly where stress raisers, such as notches, keyways, oil holes, and so forth, are highly desirable in the design of components (for example, crank-shafts, half-shafts, and so on) (Ref 26). Many fabrication methods have been developed to exploit this phenomenon. Prestressed parts (including shrink-fits, prestressed concrete, interference fits, bolted parts, coined holes, wire-wound concrete pipe), mechanical surface working processes (such as shot peening, surface roiling, lapping, and so on) of hardened ferrous and nonferrous alloys, and surface hardening treatments are widely used to produce residual compressive stresses at the component surface.

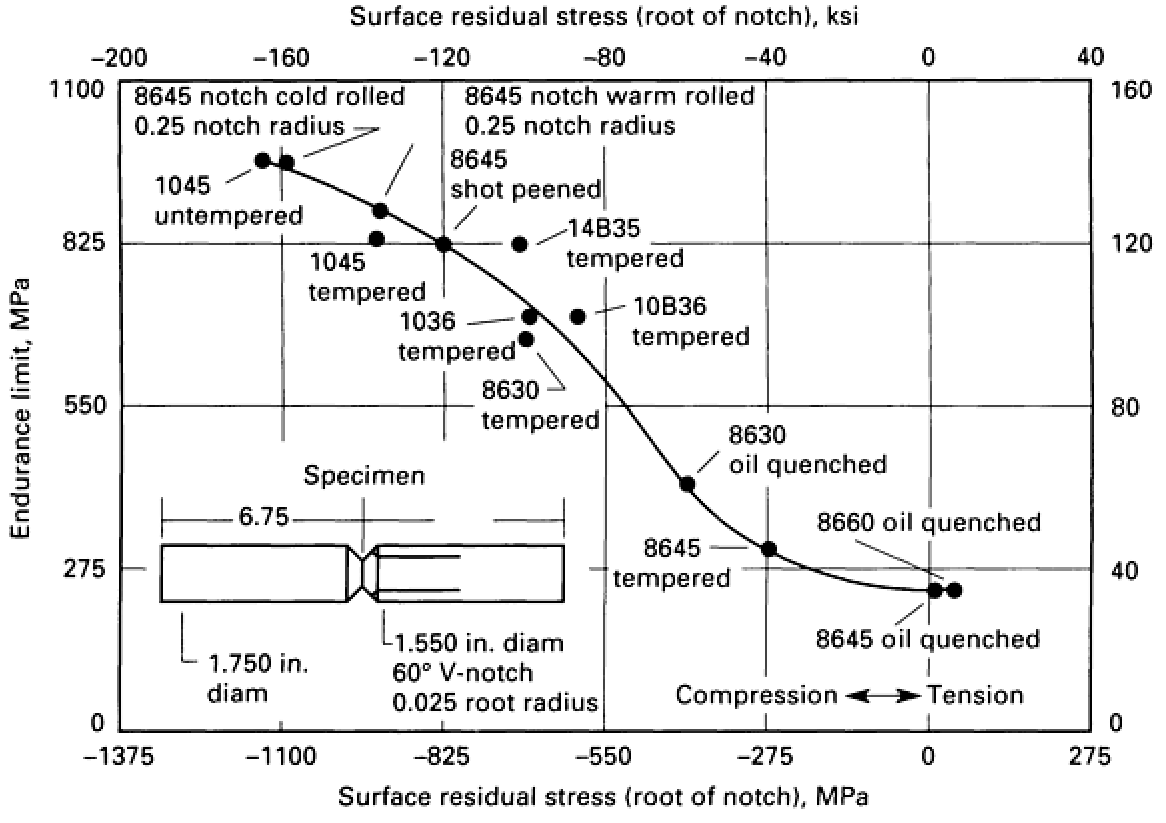

Fig. 2 Effect of surface residual stress on the endurance limit of selected steel. All samples were water quenched except as shown, and all specimen dimensions are given in inches. Source: Ref 23, 24

Residual tensile stresses at the surface of a part are usually undesirable because they can effectively increase the stress levels; may cause unpredicted stress-corrosion cracking (due to the combined effect of stress and environment), fatigue failure, quench cracking, and grinding checks at low external stresses; and tend to reduce fatigue life and strength of a part. In this case the extent of residual stresses may be closer or even larger than the strength of the material.

Residual tensile stresses in the interior of a component also may be damaging because of the existence and consequence of defects that serve as stress raisers in the interior part. The uncommon phenomenon of delayed cracking, in the absence of adverse environments and large applied stresses, has now been attributed to the action of residual stresses on minute defects in the material (Ref 26). For example, a 17.5 cm (6.9 in.) diam × 125 cm (49.2 in.) long steel shaft exploded into several pieces while lying free of any applied loads, on a laboratory floor. Under normal loading, it would have required a

tensile strength larger than 150 MPa (22 ksi) to rupture the shaft. Hence, the understanding of residual stress formation is very important, and this must be given due consideration in the manufacture and performance analysis of processed parts (Ref 26).

Development of Residual Stress in Processed Parts

Variations in stresses, temperature, and chemical species within the body during processing cause the production of macroresidual stresses. Various manufacturing processes such as forming, machining, heat treatment, shot peening, casting, welding, flame cutting, and plating render their characteristic residual stress pattern to processed parts. Table 3 lists a summary of compressive and tensile residual stresses at the surface of parts fabricated by common manufacturing processes.

Table 3 Summary of compressive and tensile residual stresses at the surface of the parts created by the common manufacturing processes

Compression at the surface
Surface working: shot peening, surface rolling, lapping, and so on
Rod or wire drawing with shallow penetration[(a)]
Rolling with shallow penetration[(a)]
Swaging with shallow penetration[(a)]
Tube sinking of the inner surface
Coining around holes
Plastic bending of the stretched side
Grinding under gentle conditions
Hammer peening
Quenching without phase transformation
Direct-hardening steel (not through-hardened)
Case-hardening steel
Induction and flame hardening
Prestressing

Ion exchange
Tension at the surface
Rod or wire drawing with deep penetration
Rolling with deep penetration
Swaging with deep penetration
Tube sinking of the outer surface
Plastic bending of the shortened side
Grinding: normal practice and abusive conditions
Direct-hardening steel (through-hardened)[(b)]
Decarburization of steel surface
Weldment (last portion to reach room temperature)
Machining: turning, milling
Built-up surface of shaft
Electrical discharge machining
Flame cutting

Source: Ref 22

(a) Shallow penetration refers to $\lesssim$1% reduction in area or thickness; deep penetration refers to $\gtrsim$1%.

(b) Depends on the efficiency of quenching medium.

In heat-treated parts, residual stresses may be classified as those caused by a thermal gradient alone, and a thermal gradient in combination with a structural change (phase transformation). When a steel part is quenched from the austenitizing temperature to room temperature, a residual stress pattern is established due to a combination of thermal gradient and local transformation-induced volume expansion.

Thermal contraction develops nonuniform thermal (or quenching) stress due to different rates of cooling experienced by the surface and interior of the steel part. Transformational volume expansion induces transformation stress arising from

the transformation of austenitc into martensite or other transformation products (Ref 27). Table 4 lists the changes in volume during the transformation of austenite into different structural constituents (Ref 28).

Table 4 Changes in volume during the transformation of austenite into different phases

Transformation	Change in volume, %, as a function of carbon content (% C)
Spheroidized pearlite $\rightarrow$ austenite	-4.64 + 2.21 × (% C)
Austenitc $\rightarrow$ martensite	4.64 - 0.53 × (% C)
Spheroidized pearlite $\rightarrow$ martensite	1.68 × (% C)
Austenite $\rightarrow$ lower bainite	4.64 - 1.43 × (% C)
Spheroidized pearlite $\rightarrow$ lower bainite	0.78 × (% C)
Austenite $\rightarrow$ upper bainite	4.64 - 2.21 × (% C)
Spheroidized pearlite $\rightarrow$ upper bainite	0

Thermal Contraction. The relation between the thermal stress (σ_{th} during cooling and the corresponding temperature gradient in the component is given by:

$$\sigma_{th} = E \cdot \Delta T \cdot \alpha \quad \textbf{(Eq 1)}$$

where E is the modulus of elasticity, and α is the thermal coefficient of expansion of the material. It is thus apparent that thermal stresses are greatest for materials with high elastic modulus and coefficient of thermal expansion. Temperature gradient is also a function of thermal conductivity. Hence, it is quite unlikely to develop high-temperature gradients in good thermal conductors (for example, copper and aluminum), but it is much more likely in steel and titanium (Ref 29). Another term involving thermal conductivity, called thermal diffusivity (D_{th}), is sometimes used in context with temperature gradient. It is defined as $D_{th} = k/\rho c$, where k is the thermal conductivity, ρ is the density, and c is the specific heat. It is clear that low D_{th} (or k) promotes large temperature gradient or thermal contraction. It should be emphasized that large size of the part and high heating or cooling rates (severity) of quenching medium also augment temperature gradients leading to large thermal contraction.

Table 5 lists some of the relevant material properties that affect thermal and residual stresses (Ref 29).

Table 5 Relevant physical properties in the development of thermal stresses

Metal	Modulus of elasticity		Coefficient of expansion		Thermal conductivity	
	GPa	psi × 10^6	10^{-6}/K	10^{-6}/°F	W m^{-1} k^{-1}	Btu in./ft^2 · h · °F

Pure iron (ferrite)	206	30	12	7	80	555
Typical austenitic steel	200	29	18	10	15	100
Aluminum	71	10	23	13	201	1400
Copper	117	17	17	9	385	2670
Titanium	125	18	9	5	23	160

Residual Stress Pattern Due to Thermal Contraction. Residual stress is developed during quenching of a hot solid part that involves thermal volume changes without solid-state phase transformation. This situation also exists when a steel part is cooled from a tempering temperature below the A_1. Figure 3 shows the development of longitudinal thermal and residual stresses in a 100 mm (4 in.) diam steel bar on water quenching from the austenitizing temperature, 850 °C (1560 °F) (Ref 30). At the start of cooling, the surface temperature *S* falls drastically as compared to the center temperature *C* (top left sketch of Fig. 3). At time *w,* the temperature difference between the surface and core is at a maximum of about 550 °C (1020 °F), corresponding to a thermal stress of 1200 MPa (80 tons/in.^{2}) due to linear differential contraction of about 0.6%, if relaxation does not take place. Under these conditions, tensile stresses are developed in the case with a maximum value of *a* (lower diagram), corresponding to time *w* in the upper diagram, and the core will contract, producing compressive stresses with a maximum of *b.* The combined effect of tensile and compressive stresses on the surface and core, respectively, will result in residual stresses as indicated by curve *C,* where a complete neutralization of stress will occur at some lower temperature *u.* Further decrease in temperature, therefore, produces longitudinal, compressive residual stresses at the surface and the tensile stresses at the core, as shown in the lower right-hand diagram of Fig. 3. Figure 4(a) is a schematic illustration of the distribution of residual stress over the diameter of a quenched bar due solely to thermal contraction in the longitudinal, tangential, and radial directions (Ref 19).

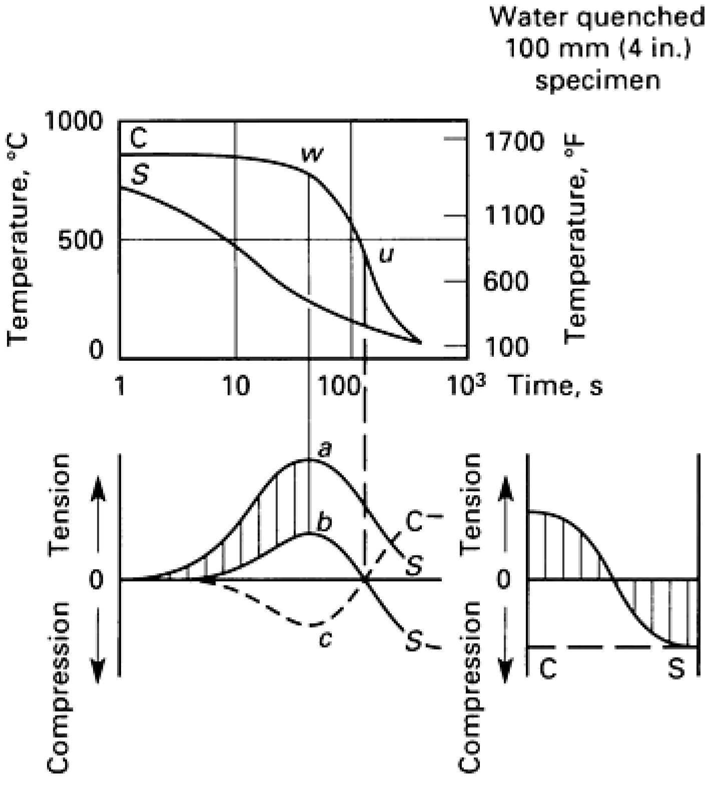

Fig. 3 Development of thermal and residual stresses in the longitudinal direction in a 100 mm (4 in.) diameter steel bar on water quenching from the austenitizing temperature, 850 °C (1560 °F). Transformation stresses are not taken into consideration. Source: Ref 30

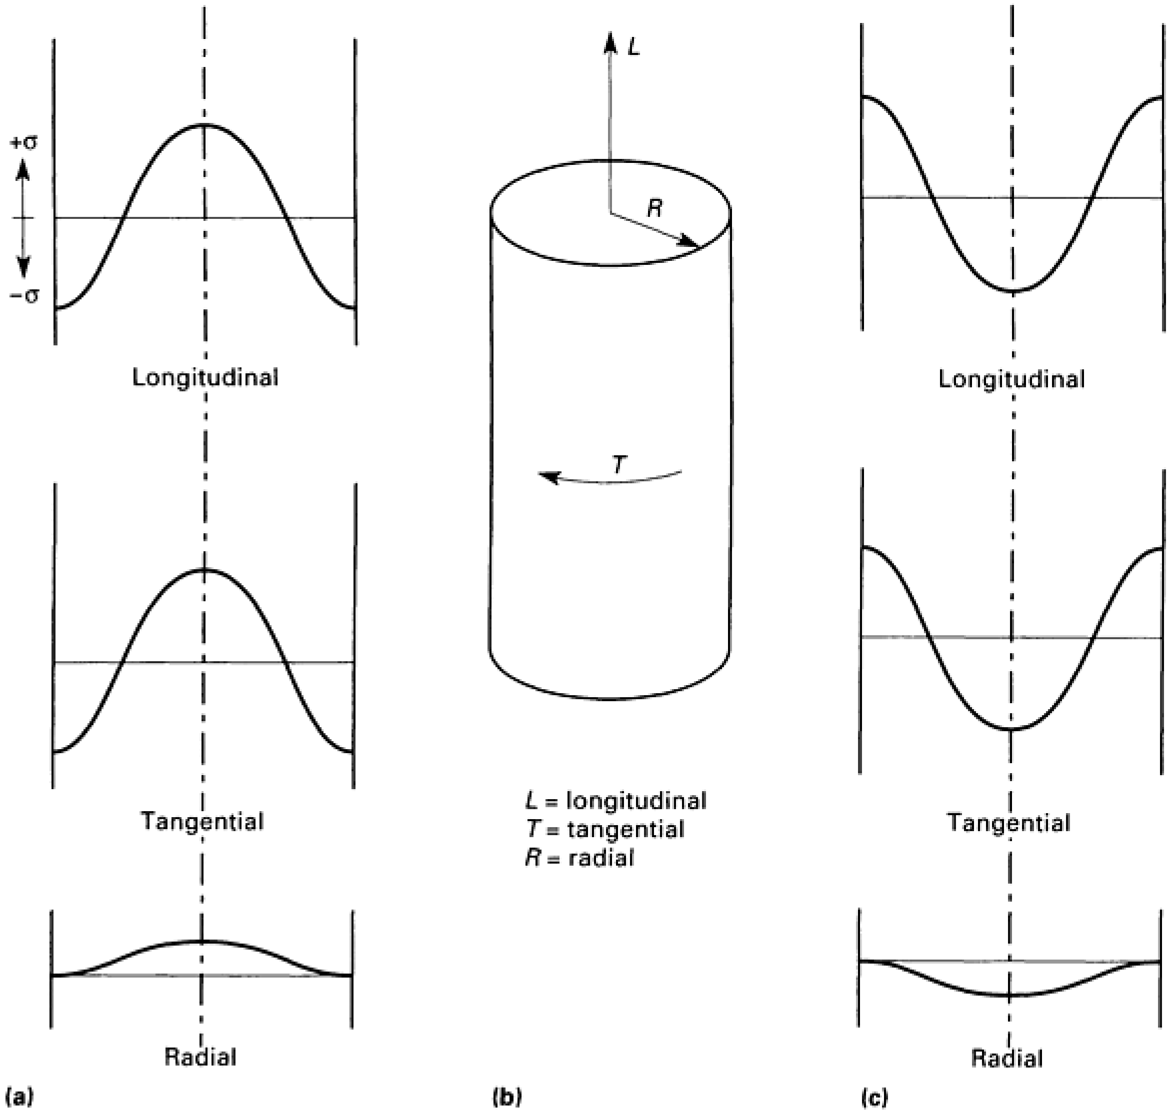

Fig. 4 Schematic illustration of the distribution of residual stress over the diameter of a quenched bar in the longitudinal, tangential, and radial directions due to (a) thermal contraction and (c) both thermal and transformational volume changes. (b) Schematic illustration of orientation of directions. Source: Ref 19

The maximum residual stress attained on quenching increases as the quenching temperature and quenching power of the coolant are increased. Tempered glass is made by utilizing quenching techniques in which glass is heated uniformly to the annealing temperature and then surface cooled rapidly by cold air blasts. This produces compressive surface stresses to counteract any tensile bending stress, if developed during loading of the glass, thereby increasing its load-carrying capacity (Ref 31).

Residual Stress Pattern Due to Thermal and Transformational Volume Changes (Ref 32). During quench hardening of a steel (or other hardenable alloy) part, hard martensite forms at the surface layers, associated with the volume expansion, whereas the remainder of the part is still hot and ductile austenite. Later, the remainder austenite transforms to martensite, but its volumetric expansion is restricted by the hardened surface layer. This restraint causes the central portion to be under compression with the outer surface under tension. Figure 4(c) illustrates the residual stress distribution over the diameter of a quenched bar showing volume expansion associated with phase transformation in the

longitudinal, tangential, and radial directions (Ref 19). At the same time during the final cooling of the interior, its contraction is hindered by the hardened surface layers. This restraint in contraction produces tensile stresses in the interior and compressive stresses at the outer surface. However, the situation as shown in Fig. 4(c) prevails, provided that the net volumetric expansion in the interior, after the surface has hardened, is larger than the remaining thermal contraction. In some particular conditions, these volumetric changes can produce sufficiently large residual stresses that can cause plastic deformation on cooling, leading to warping or distortion of the steel part. While plastic deformation appears to reduce the severity of quenching stresses, in most severe quenching the quenching stresses are so high that they do not get sufficiently released by plastic deformation. Consequently, the large residual stress remaining may reach or even exceed fracture stress of steel. This localized rupture or fracture is called quench cracking (Ref 32, 33).

It should be emphasized again that for a given grade of steel, both large size of the part and higher quenching speed contribute to the larger value of thermal contraction, as compared to the volumetric expansion, of martensite. In contrast, when the parts are thin and the quenching rate is not high, thermal contraction of the part subsequent to the hardening of the surface will be smaller than the volumetric expansion of martensite. Similarly, for a given quenching rate, the temperature gradients decrease with decreasing section thickness, and consequently the thermal component of the residual stress is also decreased (Ref 24).

Figure 5(a) shows the continuous cooling transformation diagram of DIN 22CrMo44 low-alloy steel exhibiting austenitic decomposition with the superimposed cooling curves of the surface and center in round bars of varying dimensions. If the large-diameter (100 mm, or 4 in.) bar is water quenched (that is, for slack quenching), martensitic transformation occurs at the surface, and pearlitic + bainitic transformations occur at the center, resulting in a residual stress pattern (top of Fig. 5) similar to that due solely to thermal stress (Fig. 4a). During the rapid quenching of the medium-size (30 mm, or 1.2 in.) bar diameter, the start of bainite transformation at the center coincides approximately with the transformation of martensite on the surface. This results in compressive stresses at both the surface and center, with tensile stresses in the intermediate region (middle of Fig. 5). When the smaller-diameter (10 mm, or 0.4 in.) bar is drastically quenched (for example, in brine), the entire bar transforms to martensite. This is associated with very little temperature variation between the surface and the center of the part. In this situation, tensile residual stress is developed at the surface and compressive stress at the center of the bar (bottom, Fig. 5) (Ref 34, 35).

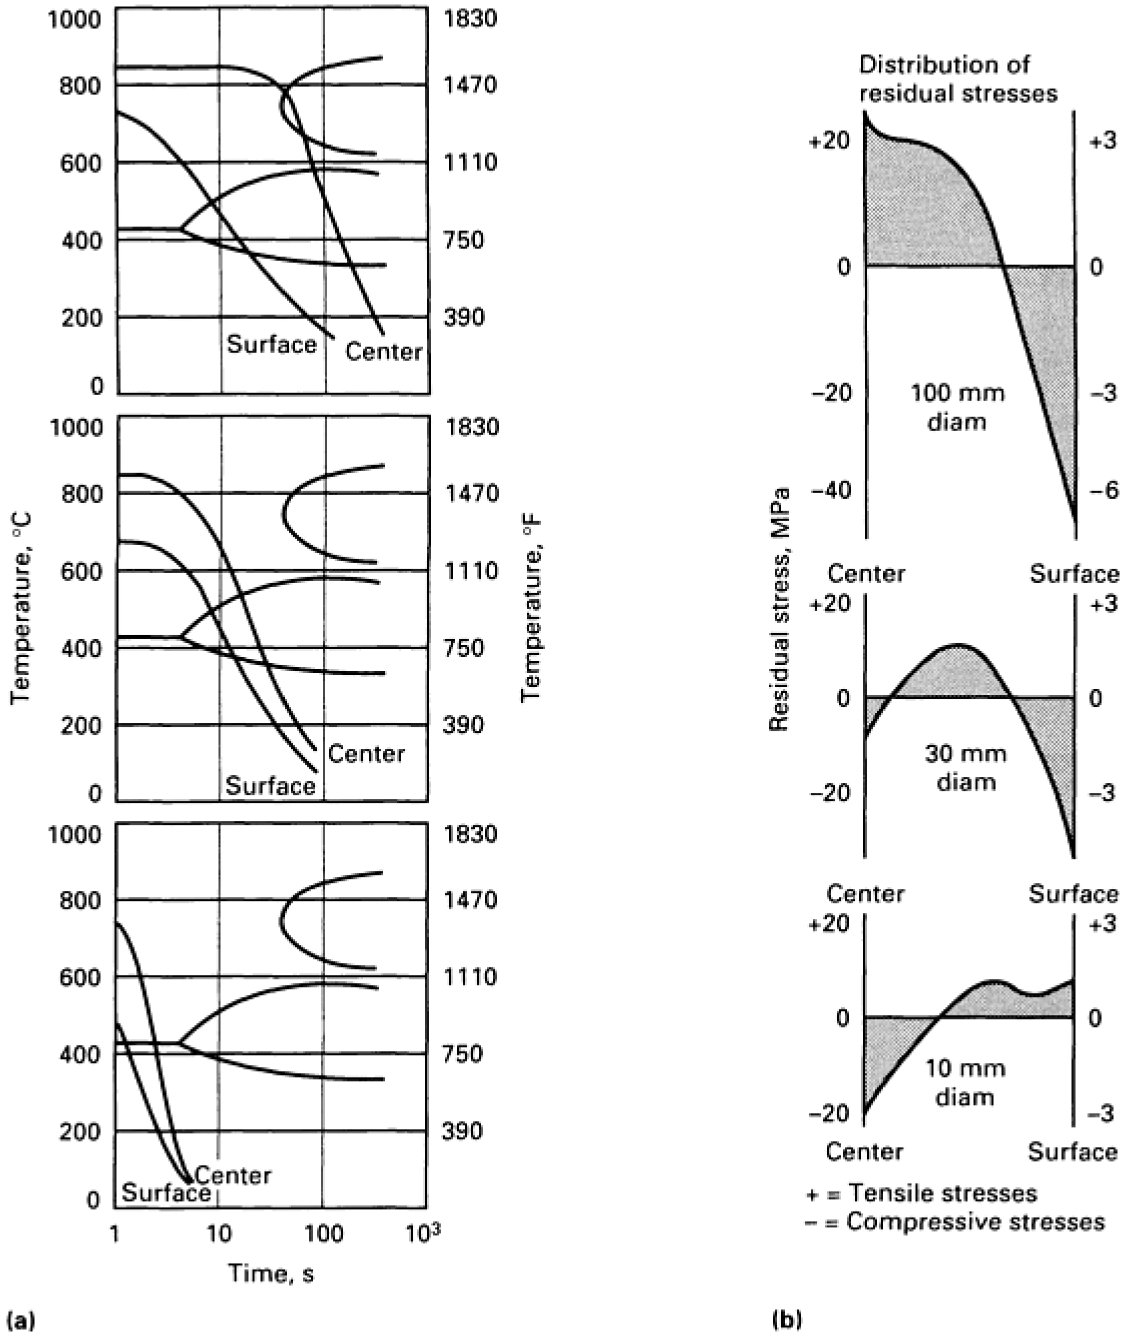

Fig. 5 (a) Continuous cooling transformation diagrams of DIN 22CrMo44 steel showing austenitic decomposition with the superimposed cooling curves of the surface and center during water quenching of round bars of varying dimensions. (b) The corresponding residual stress pattern developed because of thermal and transformational volume changes. Source: Ref 34, 35

Although the shallower hardening steels exhibit higher surface compressive stresses, deep hardening steels may develop moderately high surface compressive stresses with severe water quenching. When these deep hardening steels are through-hardened in a less efficient quenchant, they may exhibit surface tensile stresses (Ref 24, 31). Rose has pointed out the importance of transformations of core and surface before and after the stress reversal. According to him the tensile surface residual stress occurs when the core transforms after, and the surface transforms before, the stress reversal (Fig. 4c and bottom of Fig. 5), whereas compressive surface residual stress takes place when the core transforms before, and the surface transforms after, the stress reversal (top of Fig. 5). His analysis is capable of explaining complex stress patterns for various combinations of part sizes, quenching rate, and steel hardenability (Ref 21). However, the residual stress pattern in the hardened steels can be modified either with different transformation characteristics or during the tempering and finish-machining (after hardening) operations.

Residual Stress Pattern after Surface Hardening. In general, thermochemical and thermal surface-hardening treatments produce beneficial compressive residual stresses at the surface.

Carburized and Quenched Steels. When low-carbon steels are carburized and quenched, first the core transforms at high temperature (600 to 700 °C, or 1100 to 1300 °F) to ferrite and pearlite with the attendant relaxation of any transformation stresses. Later, the high-carbon case transforms to martensite at much lower temperature (less than 300 °C, or 570 °F), accompanied by volume expansion and under conditions of no (or minimum) stress relaxation. As a result, residual compressive stress is developed in the case with a maximum at the surface.

Large differences in carbon level between the case and the core determine the sequence of phase transformation on cooling after carburizing and the resultant development of compressive residual stress in the case. Likewise, compressive residual stress in the case increases as the core carbon content decreases. Increasing case depth reduces the contribution from the low-carbon core in the development of compressive stress in the case, thereby adversely affecting the fatigue properties (Ref 36).

In actual practice, a maximum compressive stress develops at some distance away from the surface (Fig. 6 and 7). This effect occurs because of the presence of retained austenite, the extent of which depends on steel composition, carbon content of the case, quenching temperature, and severity of quench. According to Koistinen (Ref 38) and Salonen (Ref 39) the peak compressive stress takes place at 50 to 60% of the total case depth corresponding to about 0.5 to 0.6% carbon level, which produces a low retained austenite content and martensite hardness around the maximum. Another factor that might influence this compressive residual stress profile is that the martensite formed in the lower-carbon regions of the case is of the lath type, which also affects the retained austenite content (Ref 20). The reversal sign of residual stress takes place at or near the case/core interface. Later, when Koistinen's theory was applied to the measured data, it appeared that the position of maximum compressive stress depends on severity of quenching, total case depth, steel hardenability, and so forth (Ref 21, 40). Figure 7 shows the details of generation of axial stress distribution of a carburized gear (made from deeper hardening steel) during quenching. In the early stages, the contour lines of equal stress were largely unaffected by the surface profile. Later a zone of high compressive stress distribution occurred in the central portion of the teeth, which remained until the end of the quench (Ref 37).

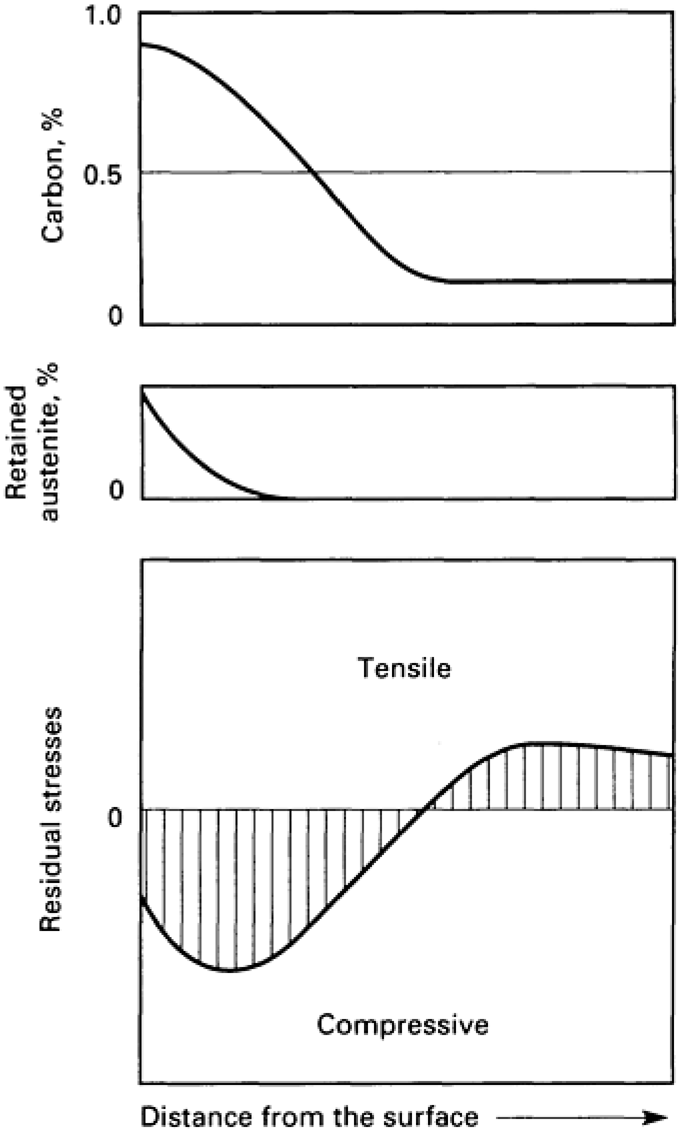

Fig. 6 Relationship between carbon content, retained austenite, and residual stress pattern. It shows the development of peak compressive stress some distance away from the surface. Source: Ref 20

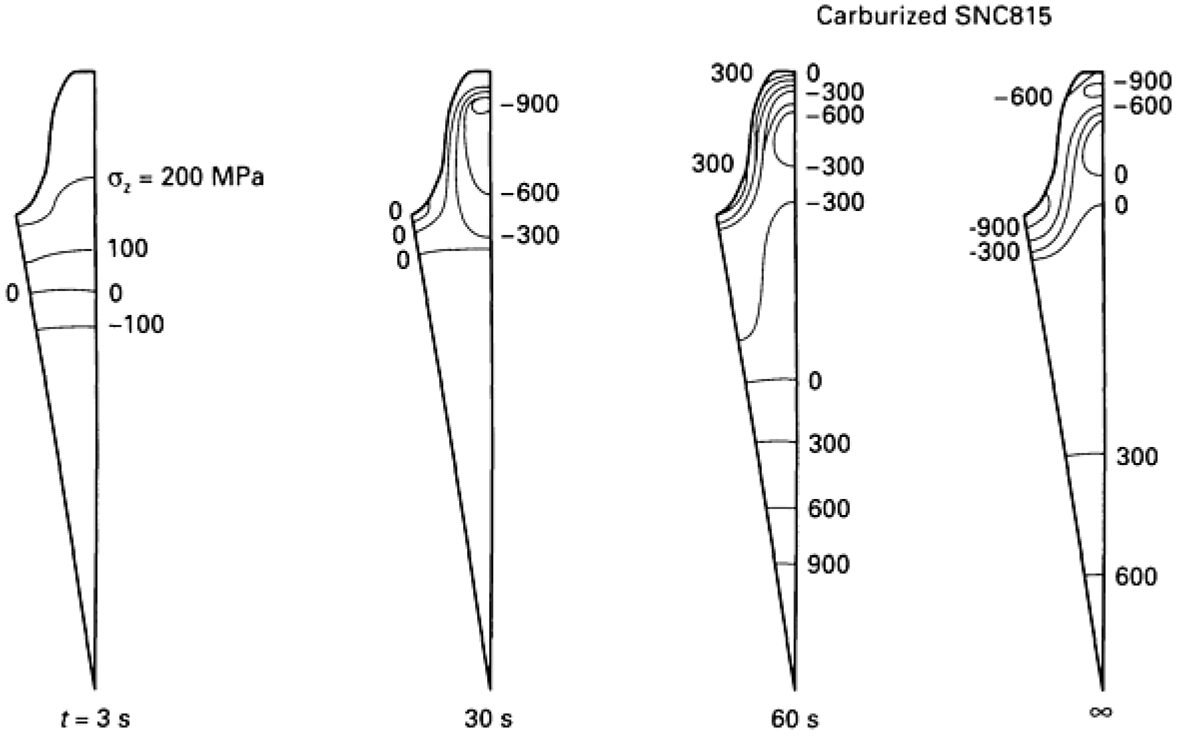

Fig. 7 Axial stress distribution (given in MPa) in carburized gear during quenching process. Source: Ref 37

In nitriding, like carburizing, a compressive residual stress is set up in the surface layers. High-temperature nitriding produces a little relaxation of stresses, whereas low-temperature nitriding imparts a maximum residual stress. In nitrocarburizing, improvement in residual surface compressive stress and fatigue strength depends on the hardness and depth of diffusion zone. These properties, in turn, decrease with increasing carbon and alloy content (that is, increased hardenability). During quenching, after nitrocarburizing, a (macro-) compressive residual stress is produced in the compound layer and gamma prime phase (Ref 41). When nitrocarburized parts are rapidly quenched, the above properties are further enhanced (Ref 42).

In borided steel processed at 900 °C (1650 °F), a high compressive residual stress is developed at the surface layers (Fig. 8), which consists of FeB and Fe_2B phases (Ref 43); this is attributed to the lower thermal expansion coefficient and the larger specific volume in a borided layer compared to that in a ferrite matrix (Ref 18, 43).

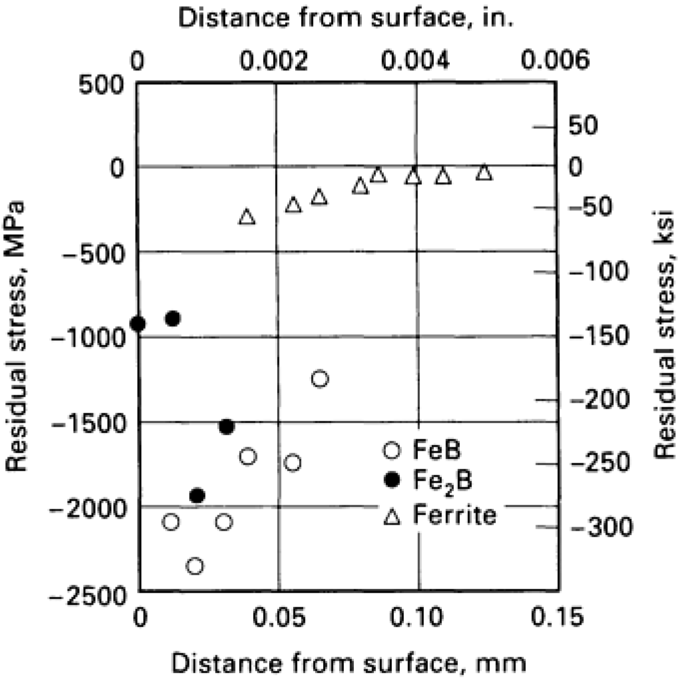

Fig. 8 Residual stress distribution of FeB and Fe_2B layers in borided steel processed at 900 °C (1650 °F). Source: Ref 18, 43

In an induction-hardened steel part, a compressive surface residual stress is produced when wear-resistant hard martensite (with slightly lower density) is formed on the surface of a section concurrently with volume expansion while nonhardened core remains essentially unchanged (Fig. 9) (Ref 44, 45). The magnitude of the compressive stress, which is affected by both thermal contraction and martensite formation, may be a considerable fraction of the yield strength, which permits the application of significantly higher stresses than could normally be possible in fatigue loading. As in the carburizing practice, the surface compressive residual stresses are usually found to increase, with depth below the surface (Ref 45) (Fig. 9, Ref 44). A fairly sharp transition to a tensile state takes place near the hardness drop-off between the case and unhardened surrounding material. With an increase in distance from the steep transition, the tensile condition gradually fades away toward zero stress (Ref 44). In induction hardening, an increase in hardenability changes the depth at which transition from compressive to tensile stress occurs. The increase in the rate of heating produces an increase in the maximum compressive and tensile residual stresses without affecting the mode of stress distribution (Ref 46).

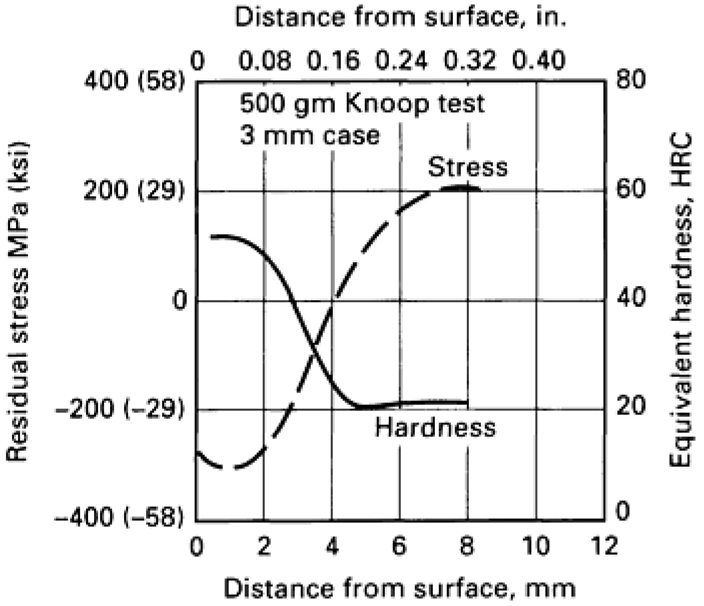

Fig. 9 A typical hardness and residual stress profile in induction-hardened (to 3 mm, or 0.12 in., case depth) and tempered (at 260 °C, or 500 °F) 1045 steel. Source: Ref 44

Residual Stress in Other Processing Steps. As welding progresses, the temperature distribution in the weldment becomes nonuniform and varying as a result of localized heating of the weldment by the welding heat source. During the welding cycle, comprising heating and cooling, complex strains develop in the weld metal and adjacent areas. As a result, appreciable residual stresses remain after the completion of welding. Since the weld metal and heat-affected zone contract on cooling (Fig. 10a), they are restrained by the cool adjacent part. This produces tensile residual stress in the weldment region and compressive residual stress in the surrounding base metal region (Fig. 10b).

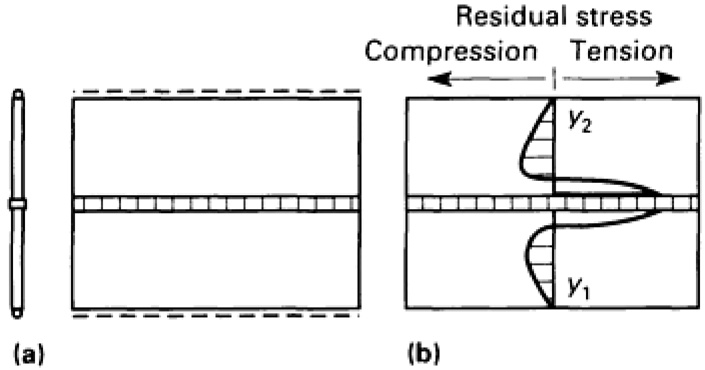

Fig. 10 (a) The transverse shrinkage occurring in butt weldments. (b) Longitudinal residual stress patterns in the weldment and surrounding regions. This also shows longitudinal shrinkage in a butt weld. Source: Ref 47

In general, a steep residual stress gradient is developed because of the steep tendency of the thermal gradient. This may, in turn, lead to hot cracking (between columnar grains) or severe center line cracking in the weld area (Ref 48). Catastrophic failures of welded bridges and all-welded ships are mostly attributed to the existence of large and dangerous tensile residual stress in them (Ref 49).

The grinding step in manufacturing is important, since it is always utilized to produce the finished surface. It has been shown that gentle surface grinding, using a soft sharp wheel and slow downfeed, produces compressive residual stress at the surface, whereas conventional (normal practice) and abrasive grinding result in surface tensile stresses of very high

magnitude (Fig. 11) (Ref 22, 50). However, the gentle grinding method is expensive from the viewpoint of operating time and wear of the wheel.

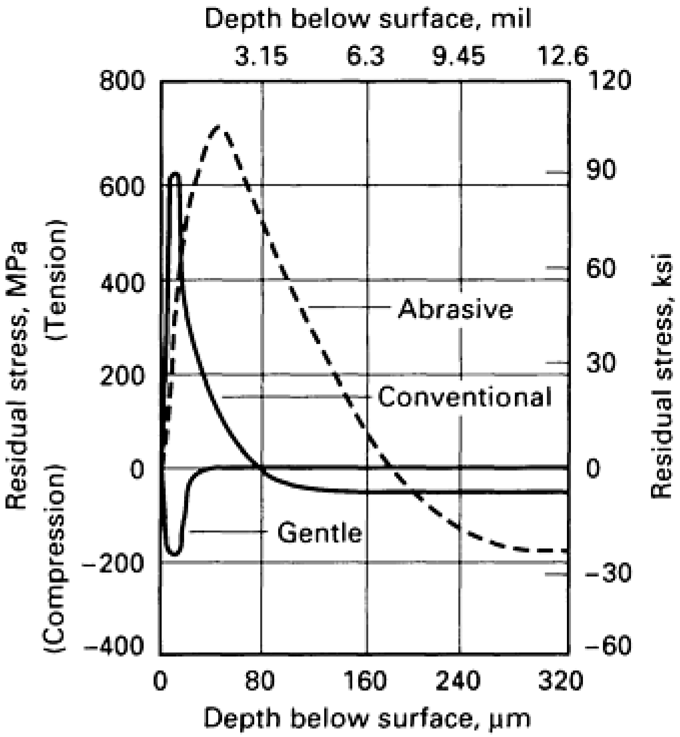

Fig. 11 Residual stress distribution after gentle, conventional, and abrasive grinding of hardened 4340 steel. Source: Ref 22

As a result of temperature gradient during cooling, castings develop compressive stresses at the surface and tensile stresses in the interior (Ref 22). However, transient temperature gradient and phase transformation occurring during the early stages of solidification and cooling of continuous steel castings in the mold may give rise to the development of harmful residual stresses leading to the formation of cracks (Ref 51).

Chemical processes such as electroplating, scale formation, and corrosion of metals can produce residual stresses due to coherency strains arising from the matching tendency of crystal structures of the outer surface product with the crystal structure of the adjacent layer (Ref 22). Residual stresses are also introduced when heat-treated parts are subjected to successive heating and cooling cycles during service conditions.

Residual Stress in the Heat-Treated Nonferrous Alloys. In nonferrous alloys, notably age-hardenable aluminum alloys, copper-beryllium alloys, certain nickel-base superalloys, and so on, a significant amount of thermal stress is generated during quenching prior to precipitation hardening. The quenching process in this condition does not invariably involve a phase change; rather, this is confined to the postquenching aging treatment. In other nonferrous alloys such as uranium and titanium alloys, the final structural condition is not obtained by a slow cool.

When high-strength titanium alloy is quenched from a solution annealing temperature of 850 to 1000 °C (1560 to 1830 °F), it develops large residual stress caused by poor thermal conductivity of titanium leading to high-temperature gradient. This problem can, however, be avoided by stress-relief annealing at 650 to 700 °C (1200 to 1290 °F), which produces a slight reduction in mechanical properties. When a high-strength aluminum age-hardening alloy is rapidly quenched from the solution temperature, high thermal and residual stresses are induced due to high coefficient of expansion of aluminum. Uphill quenching from liquid nitrogen temperature (-196 °C, or -320 °F) in a steam blast alleviates this problem. This induces stresses opposite in sign to those developed on water quenching from the solutionizing and cancels out their effect. This is followed by aging of the alloy in the conventional manner (Ref 29).

Fast polyalkylene glycol (PAG) quenching of solution-treated aluminum alloys tends to reduce residual stress levels because of its more uniform heat extraction rate (thermal shock is smaller, and thereby machining is less likely to produce

further distortion), thereby helping solve major and long-standing distortion problems among aluminum workpieces (Ref 52).

Control of Residual Stresses in Heat-Treated Parts

Table 6 lists some typical values of maximum residual stresses developed in the surface-hardened steels that have been reported in the literature (Ref 29). It is worth noting that there is a marked influence of tempering on the residual stress level. Tempering must be accomplished at about 150 °C (300 °F) to maintain 50 to 60% retention of the residual stress level obtained after quenching because a higher tempering temperature greatly reduces surface compressive stresses. However, a higher stress-relief temperature (~600 °C, or 1110 °F) is used for mechanically deformed components (for example, hot-rolled bars) or components with tensile surface residual stresses. Alternatively, serious residual tensile stresses may be avoided effectively by gentle grinding of the surface.

Table 6 A compiled summary of the maximum residual stresses in surface heat-treated steels

Steel	Heat treatment	Residual stress (longitudinal)	
		MPa	ksi
832M13 (type)	Carburized at 970 °C (1780 °F) to 1 mm (0.04 in.) case with 0.8% surface carbon		
	Direct-quenched	280	40.5
	Direct-quenched, -80 °C (-110 °F) subzero treatment	340	49.0
	Direct-quenched, -90 °C (-130 °F) subzero treatment, tempered	200	29.0
805A20	Carburized and quenched	240-340[a]	35.0-49.0
805A20	Carburized to 1.1-1.5 mm (0.043-0.06 in.) case at 920 °C (1690 °F), direct oil quench, no temper	190-230	27.5-33.5
805A17		400	58
805A17	Carburized to 1.1-1.5 mm (0.043-0.06 in.) case at 920 °C (1690 °F), direct oil quench, tempered 150 °C (300 °F)	150-200	22-29
897M39	Nitrided to case depth of about 0.5 mm (0.02 in.)	400-600	58.0-87.0
905M39		800-1000	116.0-145.0
Cold-rolled steel	Induction hardened, untempered	1000	145.0
	Induction hardened, tempered 200 °C (390 °F)	650	94.0

	Induction hardened, tempered 300 °C (570 °F)	350	51
	Induction hardened, tempered 400 °C (750 °F)	170	24.5

Measurement of Residual Stresses

There are two methods of measuring residual stresses: the destructive method, also called the dissection method, and the nondestructive methods comprising mainly x-ray diffraction, neutron diffraction, ultrasonic, and magnetic methods.

Destructive (or Dissection) Method. This method is old but reasonably accurate, practically nondestructive, uses well-established methods, and can be employed in confined situations at site (Ref 53). However, it is tedious, time consuming, and expensive (Ref 54). The other drawbacks are the destructive, or at best semidestructive nature of the method, and its ability to measure only the macroresidual stresses. The hole-drilling method is used extensively for measuring residual stresses, which depends on the dissection approach. It consists of the mounting of strain gages or a three-element strain-gage rosette on the surface and measurement of strains. Then a rigidly guided milling cutter is used to drill a small, straight, circular, perpendicular, and flat-bottomed hole not exceeding 3.2 mm (0.125 in.) at the center of the rosette and into the surface of the component being analyzed. Strain redistribution occurring at the surface in the surrounding area of the hole (resulting from the residual stress relief) is then measured with the previously installed strain gages. The residual stress is calculated at a large number of points in a surface from the strain measurements using the well-established method (Ref 22, 28). To minimize the introduction of spurious strains by the grinding operation, the rate of metal removal should be less than 3.125×10^{-4} m/s (1.23×10^{-2} in./s), and readings are recorded after 15 min of the end of the grinding process to ensure that any heat generated has been dissipated (Ref 55).

Nondestructive Methods. The main difficulty with the nondestructive methods is that measurements of crystallographic lattice parameters, ultrasonic velocities, or magnetization changes are made that are indirectly related to the residual stress. The above quantities are usually dependent on the stress and material parameters (such as metallurgical textures), which are difficult to quantify (Ref 54, 56).

The x-ray diffraction method is the well-established technique for measuring both macro- and microresidual stress nondestructively. In most instances, the x-ray diffraction method has been employed to provide quantitative values for residual stress profiles in surface or fully hardened components (Ref 57). This technique depends on the determination of lattice strains and the stress-induced differences in the lattice spacing. Macroresidual strain is measured from the shift of diffraction lines in the peak position using the so-called nonlinear $\text{Sin}^2 C$ method from which residual stress is calculated (Ref 57). For the measurement of microstrain the Voigt single-line method is applied (Ref 58). Precision in lattice strain measurement of the order of 0.2% is possible.

Portable x-ray diffraction equipment is now commercially available in various forms that allow stress measurement to be made very quickly (ranging from 4 to 30 s). The main drawbacks are that it cannot be applied to noncrystalline materials such as plastics, and it is only capable of measuring residual stresses of materials very close to the surface under examination. That is, the measurement is purely surface related (a depth of 0.01 mm, or 0.4 mil, is commonly quoted) (Ref 59).

Neutron radiography or diffraction, used for polycrystalline materials, has a much deeper penetration than x-rays, but has major safety problems and the disadvantage of being nonportable.

Ultrasonic method for evaluating residual stress involves ultrasonic stress birefringence or sonoelasticity; this depends upon the linear variation of the velocities of sound in a body (that is, ultrasonic waves) with the stress. This method has the potential for greater capability, versatility, and usefulness in the future (Ref 53, 56). However, this has the disadvantage, in common with the magnetic methods, that it requires transducers shaped to match the surface being inspected (Ref 60).

The magnetic method is based on the stress dependence of the Barkhausen noise amplitude. Each time an alternating magnetic field induced in a ferromagnetic material is reversed, it generates a burst of Barkhausen noise. The peak amplitude of the burst, as determined with an inductive coil near the surface of the component material, varies with the surface stress level. Since Barkhausen noise depends on composition, texture, and work hardening, it is necessary in each application to use calibrated standard (reference) samples with the same processing history and composition as the component being analyzed. This method is used to measure residual stresses well below the yield strength of the ferromagnetic materials. This method is rapid, and the measurements are made with the commercially available portable equipment. However, this method is limited to only ferromagnetic materials (Ref 56).

Thermal evaluation for residual stress analysis (TERSA) is a new nondestructive method that is in an experimental stage. It has the advantage that it is completely independent, remote, and noncontacting. It consists of merely directing a controlled amount of energy from a laser energy source into the volume of the material being inspected and then making a precise determination of changes in the resulting temperature rise by infrared radiometry. However, the working instrument will also require some form of display to enable visual examination to be made of any high-stressed regions (Ref 60).

Quench Cracking

Anything that produces excessive quenching stress is the basic cause of cracking. Quench cracking is mostly intergranular, and its formation may be related to some of the same factors that cause intergranular fracture in overheated and burned steels. The main reasons for cracking in heat treatment are: part design, steel grades, part defects, heat-treating practice, and tempering practice (Ref 61).

Part Design. Features such as sharp corners, the number, location, and size of holes, deep keyways, splines, and abrupt changes in section thickness within a part (that is, badly unbalanced section) enhance the crack formation because while the one (thin) area is cooling quickly in the quenchant, the other (thick) area immediately adjacent to it is cooling very slowly. One solution to this problem is to change the material so that a less drastic quenchant (for example, oil) can be employed. An alternate solution is to prequench, that is, to cool it prior to the rest of the part. This will produce an interior of the hole or keyway that is residually stressed in compression, which is always desirable for better fatigue properties (Ref 61). The third solution is a design change, and the fourth is to use a milder quenchant.

Steel Grades. Sometimes this can be checked by means of a spark test, whereas at other times a chemical analysis must be made. In general, the carbon content of steel should not exceed the required level; otherwise, the risk of cracking will increase. The suggested average carbon contents for water, brine, and caustic quenching are given below:

Method	Shape	Carbon, %
Induction hardening	Complex	0.33
	Simple	0.50
Furnace hardening	Complex	0.30
	Simple	0.35
	Very simple, such as bar	0.40

A decrease in carbon content from 0.72 to 0.61% has been shown to slightly increase the thermal crack resistance of rimquenched railroad wheels (Ref 62).

Because of segregation of carbon and alloying elements, some steels are more prone than others to quench cracking. Among these steels, 4140H, 4145H, 4150H, and 1345H appear to be the worst. A good option is to replace the 4100 series with the 8600 series. An additional disadvantage with the use of 1345H steel is the manganese floating effect, which leads to very high manganese content in the steel rolled from the last ingot in the same heat. Similarly, dirty steels (that is, steels with more than 0.05% S, for example, AISI 1141 and 1144) are more susceptible to cracking than the low-sulfur grades. The reasons for this are that they are more segregated in alloying elements, the surface of this hot-rolled high-sulfur steel has a greater tendency to form seams, which act as stress raisers during quenching, and they are usually coarse grained (for better machinability), which increases brittleness and therefore promotes cracking. If these high-sulfur grades are replaced by calcium-treated steels or cold-finished leaded steels, this problem can be obviated (Ref 61).

Part Defects. Surface defect or weakness in the material may also cause cracking, for example, deep surface seams or nonmetallic stringers in both hot-rolled and cold-finished bars. Other defects are inclusions, stamp marks, and so forth. For large-seam depths, it is advisable to use turned bars or even magnetic particle inspection. The forging defects in small forgings, such as seams, laps, flash line, or shearing crack, as well as in heavy forgings, such as hydrogen flakes and internal ruptures, aggravate cracking. Similarly, some casting defects, for example, in water-cooled castings, promote cracking (Ref 50).

Heat-Treating Practice. Higher austenitizing temperatures increase the tendency toward quench cracking. Similarly, steels with coarser grain size are more prone to cracks than fine-grain steels because the latter possess more grain-boundary area to stop the movements of cracks, and grain boundaries help to absorb and redistribute residual stresses. An outstanding contributor to severe cracking is improper heat-treating practice, for example, nonuniform heating and nonuniform cooling of the component involved in the heat-treatment cycle. It is a good heat-treating practice to anneal alloy steels prior to the hardening treatment (or any other high-temperature treatment, for example, forging, welding, and so forth) because this produces grain-refined microstructure and relieves stresses (Ref 63).

Water-Hardening Steel. The water-hardening steels are most susceptible to cracks if they are not handled properly. Soft spots are most likely to occur in the water-hardening steels, especially where the tool is grabbed with tongs for quenching. Normally the cleaned surface shows adequate hardening and the scaled surface insufficient hardening, which can be examined with a file. Soft spots may occur from the use of fresh water, or water contaminated with oil or soap. Most large tools emerging from hardening operations contain some soft spots. However, accidental soft spots in the wrong place should be investigated, and steps must be taken to eliminate them.

Figure 12 shows the typical appearance of a thumbnail check as soft spot on chipping chisels, which occurs on the bit near the cutting edge. The cracks enclosing the soft spots should be avoided by switching to brine quench (Ref 64).

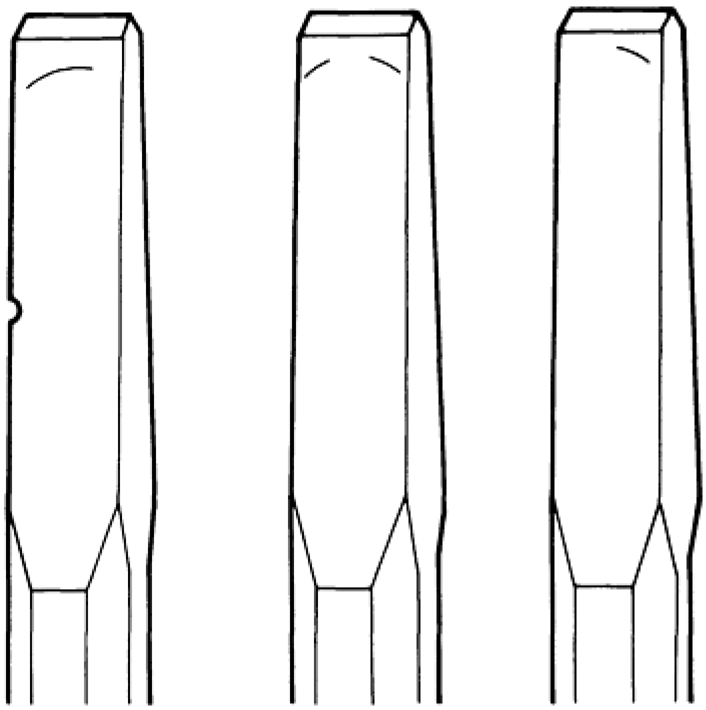

Fig. 12 Typical appearance of thumbnail check as soft spot on chipping chisel. Source Ref 64

Air-Hardening Steel. Similarly, when air hardening steels are improperly handled, they are likely to crack. For example, avoidance of tempering treatment or use of oil quenching in air-hardening steel can lead to cracking. However, the common practice in the treatment of air-hardening steels is initially to quench in oil until "black" (about 540 °C, or 1000 °F), followed by air cooling to 65 °C (150 °F) prior to tempering. As compared to air cooling right from the quenching temperature, this practice is totally safe and minimizes the formation of scale.

Polymer quenchants have found well-established use in the quenching of solution-treated aluminum alloys, hardening of plain carbon steels with less than 0.6% C, spring steels, boron steels, hardenable stainless steels, and all carburizing and alloy steels with section thickness greater than about 50 mm (2 in.), through-hardening and carburizing steel parts, and induction and flame-hardening treatments because of their numerous beneficial effects, including elimination of soft spots, distortion, and cracking problems associated with trace water contamination in quenching oils (Ref 65).

Agitation is an important parameter in polymer quenching applications both to ensure a uniform polymer film around the quench part and to provide a uniform heat extraction from the hot part to the adjacent area of quenchant by preventing a buildup of heat in the quench region.

Salt bath cooling of induction-hardened complex-shaped cast iron parts reduces danger of cracking, which is usually experienced when air cooling followed by hot-water quenching is used (Ref 66).

Decarburized Steel. Decarburization usually arises from insufficient protection as a result of plant failure (for example, defective furnace or container seals, defective valves), poor process control (for example, insufficient atmosphere-monitoring equipment, poor supervision), or the existence of decarburizing agents in the furnace atmosphere (for example, CO_2, water vapor, and H_2 in the Endogas (Ref 61, 67).

A partially decarburized surface on the part occurring during tool hardening also contributes to cracking because martensite transformation is completed therein well before the formation of martensite in the core. Decarburized surface on the tools has reduced hardness, which will lead to premature wear and scuffing. Partial decarburization must be avoided, especially on all deep-hardening steels, either by providing some type of protective atmosphere during the heating operation, stock removal by grinding, or carbon restoration process. In addition to protective atmosphere, salt baths, inert packs, or vacuum furnaces may be used to obtain the desired surface chemistry on the tools or dies. The fact

that the better and more consistent performance of the tools is observed after regrinding reveals the existence of partial decarburization remaining.

Carburized Alloy Steel. Two types of peculiar cracking phenomena prevail in the carburized and hardened case of the carburized alloy steels: microcracking and tip cracking. Microcracking of quenched steels are small cracks appearing across or alongside martensite plate (Fig. 13) (Ref 67) and the prior austenite grain boundaries (Ref 68). They form mostly on those quenched steel parts that contain chromium and/or molybdenum as the major alloying elements with or without nickel content and where the hardening is done by direct quenching.

Fig. 13 Microcracking in a Ni-Cr steel. Source: Ref 67

Microcracks are observed mostly in coarse-grained structures, such as large martensite plates. This is presumably because of more impingements of the larger plates of martensite by other large plates. Another cause of microcracking is the increased carbon content of martensite (that is, increased hardenability), which is a function of austenitizing temperature and/or time (Ref 67). This finding was established for 8620H steel, which has a higher austenitizing temperature prior to quenching where there is a greater tendency to microcrack (Ref 69). This problem can be avoided by selecting a steel with less hardenability (that is, with less austenitizing temperature). Another solution is to change the heat-treating cycle to carburizing, slow cooling to black temperature, reheating to, for example, 815 or 845 °C (1500 or 1550 °F), and quenching (Ref 61). Microcracking in case-hardened surfaces may be aggravated by the existence of hydrogen, which tends to absorb during carburizing. However, this hydrogen-enhanced microcracking can be eliminated by tempering the carburized parts at 150 °C (300 °F) immediately after quenching. Tempering exhibits an additional beneficial effect in that it has the ability to heal the microcracks due to the volume changes and associated plastic flow that develop during the first stage of tempering (Ref 70). No adverse report on the influence of microcracks on the mechanical properties has been noted; however, the controlling factors should be varied so as to keep the incidence of microcracks to a minimum (Ref 67).

Tip cracking refers to the cracking that appears in the teeth of carburized and quenched gears and runs partly or fully to the ends of the teeth in a direction parallel to the axis of the part. Many heat treaters have solved this problem to a great extent by decreasing the carbon content and case depth to the minimum acceptable design level or by copper plating the outer diameter of the gear blank prior to hobbing (Ref 66).

Nitrided Steels. The nitrided cases are very brittle. Consequently, cracking may occur in service prior to realizing any improved wear and galling resistance. This can be avoided by a proper tool design, for example, incorporating all section changes with a minimum radius of 3 mm (0.125 in.).

Tempering Practice. The longer the time the steel is kept at a temperature between room temperature and 100 °C (212 °F) after the complete transformation of martensite in the core, the more likely the occurrence of quench cracking. This arises from the volumetric expansion caused by isothermal transformation of retained austenite into martensite.

There are two tempering practices that lead to cracking problems: tempering too soon after quenching, that is, before the steel parts have transformed to martensite in hardening, and skin tempering, usually observed in heavy sections (≥50 mm, or 2 in., thick in plates and >75 mm, or 3 in., in diameter in round bars).

It is the normal practice to temper immediately after the quenching operations. In this case, some restraint must be exercised, especially for large sections (>75 mm, or 3 in.) in deep-hardening alloy steels. The reason is that the core has not yet completed its transformation to martensite with the expansion, whereas the surface and/or projections, such as flanges, begin to temper with shrinkage. This simultaneous volume change produces radial cracks. This problem can become severe if rapid heating practice (for example, induction, flame, lead, or molten salt bath) is used for tempering. Therefore, very large and very intricate tool steel parts should be removed from the quenching medium, and tempering should be started while they are slightly warm to hold comfortably in the bare hands (~60 °C, or 140 °F).

Skin tempering occurs in heavy section parts when the final hardness is >360 HB. This is due to insufficient tempering time and is usually determined when the surface hardness falls by 5 or more HRC points from the core hardness. This cracking often occurs several hours after the component has cooled from the tempering temperature and often runs through the entire cross section. This problem can be removed by retempering for 3 h at the original tempering temperature, which is associated with a change in hardness of 2 HRC points maximum (Ref 61).

Distortion in Heat Treatment

Distortion can be defined as an irreversible and usually unpredictable dimensional change in the component during processing from heat treatment and from temperature variations and loading in service. The term dimensional change is used to denote changes in both size and shape (Ref 71). The heat-treatment distortion is therefore a term often used by engineers to describe an uncontrolled movement that has occurred in a component as a result of heat-treatment operation (Ref 72). Although it is recognized as one of the most difficult and troublesome problems confronting the heat treater and the heat-treatment industries on a daily basis, it is only in the simplest thermal heat-treatment methods that the mechanism of distortion is understood. Changes in size and shape of tool-steel parts may be either reversible or irreversible. Reversible changes, which are produced by applying stress in the elastic range or by temperature variation, neither induce stresses above the elastic limit nor cause changes in the metallurgical structure. In this situation, the initial dimensional values can be restored to their original state of stress or temperature.

Irreversible changes in size and shape of tool-steel parts are those that are caused by stresses in excess of the elastic limit or by changes in the metallurgical structure (for example, phase changes). These dimensional changes sometimes can be

corrected by mechanical processing to remove extra and unwanted material or to redistribute residual stresses or by heat treatment (annealing, tempering, or cold treatment).

When heat-treated parts suffer from distortion beyond the permissible limits, it may lead to scrapping of the article, rendering it useless for the service for which it was intended, or it may require necessary correction. Allowable distortion limits vary to a large extent, depending on service applications; in cases where very little distortion can be tolerated, specially desired tool steels are used. These steels possess metallurgical characteristics that minimize distortion.

Types of Distortion

Distortion is a general term that involves all irreversible dimensional change produced during heat-treatment operations. This can be classified into two categories: size distortion, which is the net change in specific volume between the parent and transformation product produced by phase transformation without a change in geometrical form, and shape distortion or warpage, which is a change in geometrical form or shape and is revealed by changes of curvature or curving, bending, twisting, and/or nonsymmetrical dimensional change without any volume change (Ref 72, 73). Usually both types of distortion occur during a heat-treatment cycle.

Dimensional Changes Caused by Changes in Metallurgical Structure during Heat Treatment. Various dimensional changes produced by a change in metallurgical structure during the heat-treatment cycle of tool steels are described below (Ref 74).

Heating (Austenitizing). When annealed steel is heated from room temperature, thermal expansion occurs continuously up to Ac_1, where the steel contracts as it transforms from body-centered cubic (bcc) ferrite to face-centered cubic (fcc) austenite. The extent of decrease in volumetric contraction is related to the increased carbon content in the steel composition (Table 4). Further heating expands the newly formed austenite.

Hardening. When austenite is cooled quickly, martensite forms; at intermediate cooling rates, bainite forms; and at slow cooling rates, pearlite precipitates. In all these transformation sequences, the magnitude of expansion increases with the decrease in carbon content in the austenite (Table 4). The volume increase is maximum when austenite transforms to martensite, intermediate with lower bainite, and is least with upper bainite and pearlite (Table 4). The volume increases associated with the transformation of austenite to martensite in 1 and 1.5% carbon steels are 4.1 and 3.84%, respectively; the volume increases involved in the transformation of austenite to pearlite in the same steels are 2.4 and 1.33% , respectively. Such volume increases are less in alloy steels and least in 2C-12Cr and A10 tool steels. It should be noted that plastic deformation (or strain) occurs during such transformations at stresses that are lower than the yield stress for the phases present (Ref 75). The occurrence of this plastic deformation, called the transformation plasticity effect, influences the development of stresses during the hardening of steel parts (Ref 76). During quenching from the austenite range, the steel contracts until the M_s temperature is reached, then expands during martensitic transformation; finally, thermal contraction occurs on further cooling to room temperature. As the hardening temperature increases, a greater amount of carbide goes into solution; consequently, both the grain size and the amount of retained austenite are increased. This also increases the hardenability of steel.

More trouble with distortion comes from the quenching or hardening operation than during heating for hardening, in which the faster the cooling rate (that is, the more severe the quenching), the greater the danger of distortion. When the milder quenchants are used, the extent of distortion is lessened. The severity of quenching thus influences the distortion of components.

The dependence of volume increase, particularly in tools of different dimensions, on grain size (or hardenability) is another important factor. Variations in volume during quenching of a fine-grained shallow-hardening steel in all but small sections is less than a coarse-grained deep-hardening steel of the same composition.

Tempering. Them is a certain correlation between the tempering temperature and volume change. Tempering reduces the volume of martensite but not adequately enough to equalize completely the prior volume increase as a result of martensitic transformation unless the components are completely softened. In low-alloy and plain (medium- and high-) carbon steels, during the first and third stages of tempering, a decrease in volume occurs that is associated with the decomposition of: high-carbon martensite into low-carbon martensite plus ϵ-carbide in the former stage, and aggregate of low-carbon martensite and ε-carbide into ferrite plus cementite in the latter stage. In the second stage, however, an increase in volume takes place (due to the decomposition of retained austenite into bainite) that tends to compensate for the early volume reduction. As the tempering temperature is increased further toward the A_1, more pronounced volume

reduction occurs. In some highly alloyed tool-steel compositions, the volume changes during martensite formation are less striking because of the large proportion of retained austenite and the resistance to tempering of alloy-rich martensite. These hardened steels show sharp increases both in hardness and volume between 500 and 600 °C (930 and 1110 °F) owing to the precipitation of very finely dispersed alloy carbides from the retained austenite. This produces a depleted matrix in alloy content, raising the M_s temperature of retained austenite. During cooling down from the tempering temperature, further transformation of retained austenite into martensite will occur with an additional increase in volume.

Size Distortion. Table 7 shows the typical volume percentages of microconstituents present in four different tool steels after their standard hardening treatments. Typical dimensional changes during hardening and tempering of several tool steels are given in Table 8. It is apparent here that some steels such as M3 and M41 high-speed steels show appreciable increase in size of about 0.2% after hardening and tempering between 540 and 595 °C (1000 and 1100 °F) to produce complete secondary hardening. Other types, such as A10, expand very little when hardened and tempered over the entire temperature range up to 595 °C (1100 °F). Excessive size changes in oil-hardening nonshrinkable tool steel is usually caused by lack of stress relief (when necessary), and hardening and/or tempering at the incorrect temperature. The golden rule is to learn to be suspicious of tools that are seriously off size in only one dimension. It is further noted that alloying addition in steels brings about a change in the specific volume of many microconstituents, but to a lesser extent than carbon (Ref 77). This table provides comparative data on size distortion in a variety of steels; however, this information cannot be used alone to predict shape distortion factor.

Table 7 Typical volume percentages of microconstituents existing in four different tool steels after their standard hardening treatments

Steel	Hardening treatment	As-quenched hardness, HRC	Martensite, vol%	Retained austenite, vol%	Undissolved carbides, vol%
W1	790 °C (1450 °F), 30 min; WQ	67.0	88.5	9	2.5
L3	845 °C (1550 °F), 30 min; OQ	66.5	90	7	3.0
M2	1225 °C (2235 °F), 6 min; OQ	64	71.5	20	8.5
D2	1040 °C (1900 °F), 30 min; AC	62	45	40	15

Note: WQ, water quenched; OQ, oil quenched; AC, air cooled.

Shape Distortion or Warpage. This is sometimes called straightness or angularity change. It is found particularly in nonsymmetrical components during heat treatment. From the practical viewpoints, warpage in water- or oil-hardening steels is normally of greater magnitude than is size distortion and is more of a problem because it is usually not predictable. This is caused by the sum effect of more than one of these factors:

- Rapid heating (or overheating), drastic (or careless) quenching, or nonuniform heating and cooling causes severe shape distortion. Slow heating as well as preheating of the parts prior to heating to the austenitizing temperature yields the most satisfactory result. Rapid quenching produces thermal and mechanical stresses associated with the martensitic transformation. In the case of low- and high-hardenability steels, respectively, this problem becomes severe or very small
- Residual stresses present in the component before heat treating. These arise from machining, grinding, straightening, welding, casting, spinning, forging, and rolling operations, which will also furnish a marked contribution to the shape change (Ref 78)
- Applied stress causing plastic deformation. Sagging and creep of the components occur during heat treatment as a result of improper support of components or warped hearth in the hardening furnace. Hence, large, long, and complex-shaped parts must be properly supported at critical positions to avoid sagging or preferably are hung with the long axis on the vertical
- Nonuniform agitation/quenching or non-uniform circulation of quenchant around a part results in an assortment of cooling rates that creates shape distortion (Ref 79). Uneven hardening, with the formation of soft spots, increases warpage. Similarly, an increase in case depth, particularly uneven case depths in

case-hardening steels, increases warpage on quenching (Ref 80)

- Tight (that is, thin and highly adherent) scale and decarburization, at least in certain areas. Tight scale is usually a problem encountered in forgings hardened from direct-fired gas furnaces having high-pressure burners. Quenching in areas with tight scale is extremely retarded compared to the areas where the scale comes off. This produces soft spots, and, in some cases, severe unpredicted distortion. Some heat treaters coat the components with a scale-loosening chemical prior to their entry into the furnace (Ref 79). Similarly, the areas beneath the decarburized surface do not harden as completely as the areas below the nondecarburized surface. The decarburized layer also varies in depth and produces an inconsistent softer region as compared to the region with full carbon. All these factors can cause a condition of unbalanced stresses with resultant distortion (Ref 79)
- Long parts with small cross sections ($>L = 5d$ for water quenching, $>L = 8d$ for oil quenching, and $>L = 10d$ for austempering, where L is the length of the part, and d is its diameter or thickness)
- Thin parts with larger areas ($>A = 50t$, where A is the area of the part, and t is its thickness)
- Unevenness of, or greater variation in, section

Examples of Distortion

Ring Die. Quenching of ring die through the bore produces the reduction in bore diameter as a result of formation of martensite, associated with the increased volume. In other words, metal in the bore is upset by shrinkage of the surrounding metal and is short when it cools (Ref 24). However, allover quenching causes the outside diameter to increase and the bore diameter to increase or decrease, depending upon precise dimensions of the part. When the outside diameter of the steel part is induction- or flame-hardened (with water quench), it causes the part to shrink in outer diameter (Ref 63). These are the examples of the effect of mode of quenching on distortion (Ref 81).

Thin die (with respect to wall thickness) is likely to increase in bore diameter, decrease in outside diameter, and decrease in thickness when the faces are hardened. If the die has a very small hole, insufficient quenching of the bore may enlarge the hole diameter because the body of die moves with the outside hardened portion.

Bore of Finished Gear. Similarly, the bore of a finished gear might turn oval or change to such an extent that the shaft cannot be fitted by the allowances that have been provided. Even a simple shape such as a diaphragm or orifice plate may, after heat treatment, lose its flatness in such a way that it may become unusable.

Production of Long Pins. In the case of the production of long pins (250 mm long × 6 mm diameter, or 10 × $\frac{1}{4}$ in.) made from medium-alloy steel, it was found, after conventional hardening, that when mounted between centers, the maximum swing was over 5 mm (0.20 in.). However, the camber could be reduced to within acceptable limits by martempering, intense or press quenching.

Hardening and Annealing of Long Bar. When a 1% carbon steel bar, 300 mm long (or more) × 25 mm diameter (12 in. long, or more, × 1 in. diameter), is water quenched vertically from 780 °C (1435 °F), the bar increases both in diameter and volume but decreases in length. When such bars are annealed or austenitized, they will sag badly between the widely spaced supports. Hence, they should be supported along their entire length in order to avoid distortion.

Hardening of Half-Round Files. Files are usually made from hypereutectoid steel containing 0.5% chromium. Files are heated to 760 °C (1400 °F) in an electric furnace after being surface coated with powdered wheat, charcoal, and ferrocyanide to prevent decarburization. They are then quenched vertically in a water tank. On their removal from the tank, the files appear like the proverbial dog's tail. The flat side has curved down, the camber becomes excessive, and the files can no longer be used in service. One practical solution is to give the files a reverse camber prior to quenching. The dead flat files could, however, be made possible, and the judgment with regard to the actual camber needed depends upon the length and the slenderness of the recut files (Ref 82).

Similarly, when a long slender shear knife is heat treated, it tends to curve like a dog's tail, unless special precautions are taken.

Hardening of Chisels (Ref 63). Chisels about 460 mm (18 in.) long and made from 13 mm (0.5 in.) AISI 6150 bar steel are austenitized at 900 °C (1650 °F) for 1.5 h and quenched in oil at 180 °C (360 °F) by standing in the vertical position with chisel point down in special baskets that allow stacking of two 13 mm (0.5 in.) round chisels per 650 mm^2

($1\ in.^2$) hole. Subsequently, hardened chisels are tempered between 205 and 215 °C (400 and 420 °F) for 1.5 h. These heat-treated parts show 55 to 57 HRC hardness but are warped. The reasons for this distortion are:

- The portion of the bar that touches the basket cools slowly, producing uneven contraction and thermal stress
- The martensite formation is delayed on the inner or abutting side of the bar, causing unequal expansion during transformation. This distortion can be eliminated or minimized by loading the parts in the screen-basket in such a way that stacking arrangement permits sufficient space between each part and by slightly decreasing the austenitizing temperature (Ref 62). Distortion can also be minimized by austempering the part, provided that the carbon content is on the high side of specification to produce the lower bainitic structure of 55 to 57 HRC. If higher yield stress is not warranted, only chisel ends need hardening and subsequent tempering (Ref 63)

Hardening of a Two-Pounder Shot. The hardness of a two-pounder shot was specified at 60 HRC on the nose and 35 HRC at the base. A differential hardening technique was performed on the shot made of a Ni-Cr-Mo steel. This technique consisted of quenching the shot in the ice-cold water by its immersion in a tank up to the shoulder, followed by drawing out the water from the tank at a stipulated rate until the water line reached the base of the nose. The final step involved withdrawing the shot from the tank when completely cold. The back end was then softened by heating in a lead bath after initial tempering. The first few shots hardened in this way were observed to split vertically across the nose. The failure was, however, avoided by withdrawal of the shot before attaining ice-cold temperature and its subsequent immersion in warm water (Ref 82).

Hardening of a Burnishing Wheel. In the manufacture of railway axles, the gearing surface on which the axle rests in the housing has to be given a high burnishing polish employing a circular pressure tool that is made of 1.2C-1.5Cr steel. For satisfactory results, the hardness of the tool surface should be about 60 HRC. It has been found that the tool usually cracks before its withdrawal from the cold-water quenching bath. This problem may, however, be avoided by quenching the tool in water for 10 s prior to transferring it to an oil bath for finish quenching. Time quenching can be judiciously applied for many heat treatment problems of distortion or cracking. Stress-relieving treatment after the use of the tool for some time may also enhance its performance life. As indicated above, martempering is also one of the solutions for this problem (Ref 81).

Hardening of Case-Carburized Mild Steel. If oil-hardening steels are not available for making a component, mild steel parts are carburized and water quenched to obtain the desired hardness, possibly resulting in excessive distortion, which is very difficult to straighten without cracking.

Hardening of Carburized Low-Carbon Steel Rollers. The best course of quenching carburized En32 steel rollers (25 mm diam × ≥600 mm long, or 1 in. diam × ≥2 ft long), employed in textile printing, is to roll them down skids into water-quenching tanks because this produces less warpage than when quenched slowly with the bar either in vertical, horizontal, or inclined positions. These are the procedures adopted for hardening of cylinders with length considerably greater than the diameter.

Hardening of Helix Gears. The distortion of the helical gears made of IS 20MnCr1 grade steel (similar to AISI 5120) used as the third speed gear in the gear box of Tata trucks is an unavoidable natural consequence of the hardening process after carburizing. This type of distortion is linked with increased length and decreased diameter and occasionally increased helical angle (Ref 83). If the extent of distortion can be controlled, a constant correction to the helix angle can be imparted in the soft-stage manufacturing (machining) prior to heat treatment so that this correction can compensate for the distorted angle and may result in a gear with desired helix angle. Thus a constant magnitude of distortion without minimization is assured in every job of every batch of production in commercial manufacturing. However, the residual stress system and metallurgical properties such as core strength, case depth, surface hardness, proper microhardness in the surface regions, and so forth, are assured (Ref 84). Similarly, when heavy-duty tooth gear is gas carburized and quenched to harden the surface layer, the diameter and tooth span increase and tapering and bending also occur.

Nitriding of Screw. A rolling mill screw, after liquid nitriding, may also show a small decrease in length, which causes pitch errors in the screws (Ref 83).

Induction and Flame Hardening of Spur Gears. Spur gears, after induction and flame hardening, exhibit increased circular pitch, the error being maximum for the tooth groove quenched first. Similarly, in line-heating process, the thin plate undergoes convex bending and the thick plate concave bending (Ref 83).

Precautions

Inadequate support during the heat-treatment cycle, poorly designed jigs and quenching fixtures, or incorrect loading of the parts may cause distortion (Ref 73). In general, plain-carbon and low-alloy steels have such a low yield strength at the hardening temperature that the parts are capable of distorting under their own weight. Every care, therefore, must be taken to ensure that parts are carefully supported or suspended during heating; long parts are preferably heated in a vertical furnace or with the length in the vertical plane (Ref 85). They should be quenched in the vertical position with vertical agitation of the quenchants. Also, it must be remembered that many tool steels are spoiled by failure to provide enough support when they are taken out from the furnace for quenching. Thus, every precaution is taken to ensure that parts are adequately supported during entire heat treatment by employing well-designed jigs, fixtures, and so on.

Other precautions to minimize distortion include:

- Tool steels should be heated to hardening temperature slowly, or in steps, and uniformly. Hot salt baths are used to render fast, uniform heat input
- It is best to heat small sections to the lower region of the recommended hardening temperature range and to heat large sections at the higher temperature range. Overheating by employing too high a temperature or too long a heating time must be avoided
- It is a good practice to protect the surface of the component from decarburization (by packing it in cast iron chips or using a vacuum furnace, for example). If a separate preheating furnace is not available, the part can be put in a cold furnace, after which the temperature is raised to proper preheating temperature and kept at that temperature to attain uniform heating throughout, prior to proceeding to the hardening temperature (Ref 86)
- With the slower cooling rate, which is consistent with good hardening practice, a lower thermal gradient will be developed, thereby producing less distortion
- Thus rapid heating and cooling rates of irregularly shaped parts must be avoided
- Proper selection of quenchant with desirable quenching properties and adequate agitation during hardening must be provided

Methods of Preventing Distortion (Ref 82, 87)

Straightening is one method to remove or minimize distortion. Since straightening (after hardening) can largely relieve the desirable residual compressive stresses (in plain-carbon and low-alloy steels) that may cause breakage, it would be better to accomplish this before the steel cools below the M_s temperature, that is, when the steel is in the metastable austenitic state (Ref 35). This temperature is above 260 °C (500 °F) for most tool steels and is preferably about 400 °C (750 °F) for long shear knives, which are usually made of 2C-12Cr steel. Warping on parts such as shafts and spindles can be corrected by straightening during or after hardening, followed by grinding to size (Ref 84). Mostly high-alloy steels are straightened after hardening due to the higher percentage of retained austenite and their comparatively low yield stress. Straightening also can be accomplished during the tempering process (Ref 35). However, straightening of hardened parts with higher strength will cause a loss of fatigue properties and possibly initiation of cracks at the surface. Hence, straightening after the hardening treatment must be very carefully controlled and should be followed by a low-temperature tempering treatment.

The case-hardened (for example, nitrided, carburized) parts can be straightened to a very large extent as a result of their lower core hardness. Nitrided parts may be straightened at 400 °C (750 °F) (Ref 35).

Support and Restraint Fixtures. Fixtures for holding finished parts or assemblies during heat treatment may be either support or restraint type. For alloys that are subjected to very rapid cooling from the solution-treatment temperature, it is common practice to use minimum fixturing during solution treatment and to control dimensional relations by using restraining fixture during aging. Support fixtures are used when restraint type is not needed or when the part itself renders adequate self restraint. Long narrow parts are very easily fixtured by hanging vertically. Asymmetrical parts may be supported by placing on a tray of sand or a ceramic casting formed to the shape of the part (Ref 64). Restraint fixtures may require machined grooves, plugs, or clamps. Some straightening of parts can be accomplished in

aging fixtures by forcing and clamping slightly distorted parts into the fixture. The threaded fasteners for clamping should not be used because they are difficult to remove after heat treatment. It is preferable to use a slotted bar held in place by a wedge (Ref 64). The bore of a hub, the most important dimension in the hardening of thin spur gears, can be mechanically plugged to prevent the reduction of the bore and keep the out-of-roundness close to tolerance limits. When hardening large hollows, either restraining bands on the outside during tempering or articulated fillers serve the same purpose.

Quenching Fixtures. When water quenching or oil quenching is essential, distortion can be minimal by employing properly designed quenching fixtures that forcibly prevent the steel from distorting (Ref 88). Figure 14 shows a typical impingement-type quenching fixture. The requirements essential for the better design of this type of fixture are as follows (Ref 79):

- There must be an accurate positioning of the part in the fixture. Whenever possible, round bars should be rotated during quenching to level out variations in jet pressure around the part
- There should be an unhindered flow of quenchant through the sufficiently large holes (3.3 to 6.4 mm, or 0.13 to 0.25 in. in diameter). Jets as large as 12.25 mm (0.50 in.) in diameter may be employed with furnace-heated heavy sections (for example, plates). A large portion of the excess quenchant with these large jets is for the removal of scale (Ref 89)
- Spacing between the holes should be reasonably wide (for example, 4*d*, where *d* is the hole diameter)
- For oil-quenching fixtures, the facility to submerge the part is required to reduce fumes and flashing
- There must be the provision for efficient cleaning of the holes
- A facility must be available to drain out the hot quenchant for effective quenching performance with cold quenchant

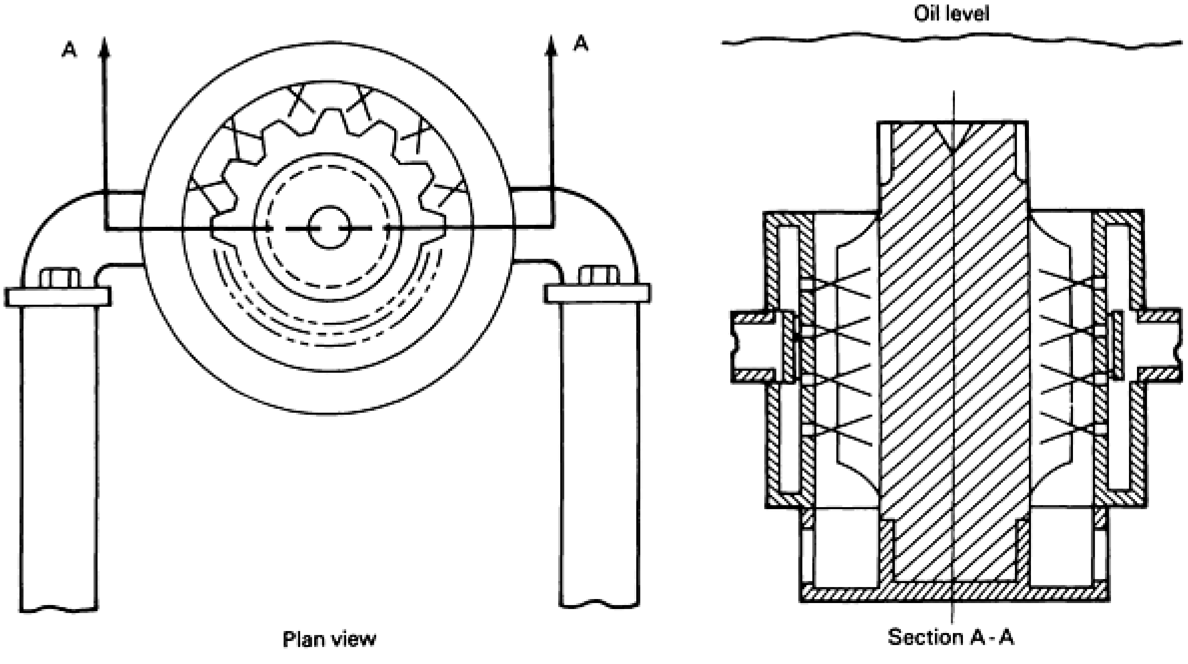

Fig. 14 A typical impingement-type quenching fixture. Source: Ref 80

Pressure quenching is the most efficient method of cooling parts from elevated temperature by using a combination of high pressure (such as 5 MPa, or 5 atm) and turbulent gas flow throughout the entire surface area of the workload (Ref 90). This is economical and fast, provides even cooling, offers a unique design and minimum distortion and improved metallurgical qualities. As a result of these beneficial effects this is suited to quench large-diameter tooling for the aluminum extrusion industry; quench larger-diameter carburized gear, larger fasteners, and precision gears to be jigged vertically; harden high-speed steel tools (such as saw blades, dies, and other parts with edge configuration) and 718 jet engine compressor blades (Ref 90). This is also employed to quench (vacuum processed) large sections of titanium alloy castings for aircraft applications (Ref 91). Figure 15 is a pressure-quench module that may be attached to vacuum-sealed quenched and continuous-vacuum furnace as a replacement for the oil-quench section.

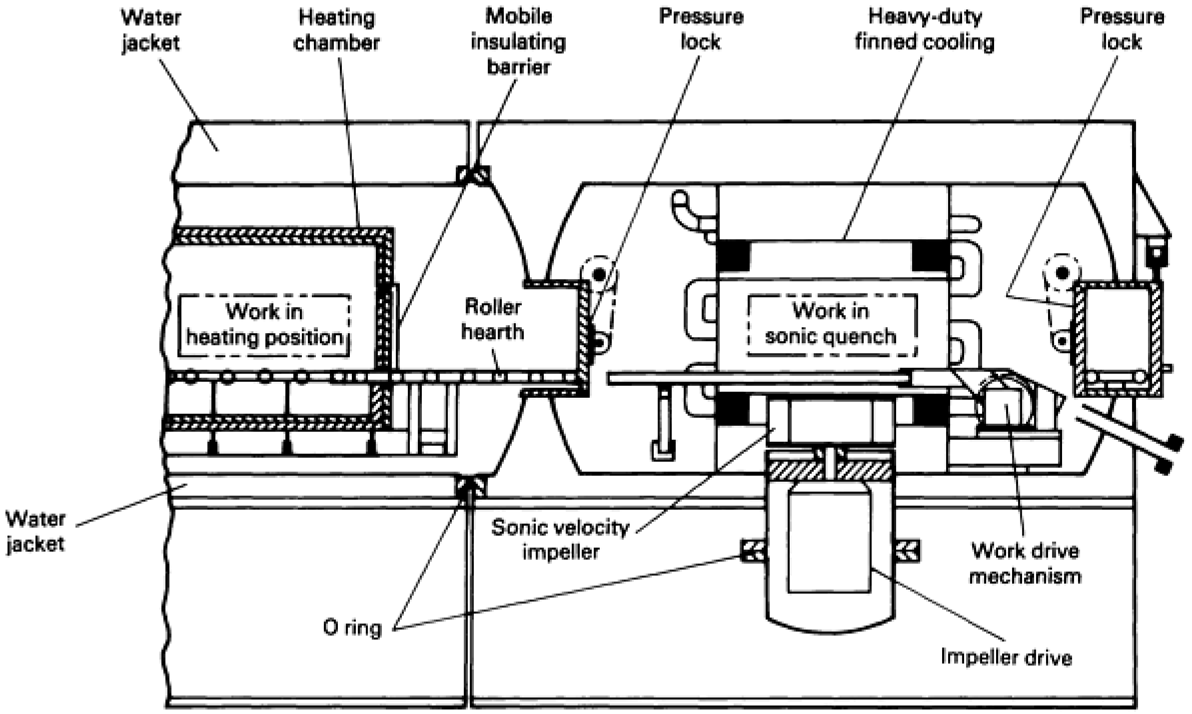

Fig. 15 Pressure-quench module for attachment into standard vacuum-sealed quenched and continuous vacuum furnaces. Source: Ref 90

Press quenching is widely employed in preventing and controlling quench distortion in components where the geometry renders them particularly prone to distortion (Ref 92). For example, flat circular diaphragms of spring steel used in the control or measurement of pressure are press quenched between two copper blocks, which cannot be accomplished by direct quenching (Ref 80).

Rolling Die Quenching. A rolling die quench machine can provide uniform water quenching with minimal distortion for large-production runs. When a heated part is placed on the rollers, the die closes and the rolls turn. This removes any distortion incurred during heating. According to manufacturers of rolling die quench machines, symmetrical parts with the following straightness can be achieved in production:

$$TIR = K\frac{l}{d} \qquad \text{(Eq 2)}$$

where *TIR* is the total indicator reading of straightness, *l* is the length (in.), *d* is the diameter (in.), and K is the constant = 10^{-4}.

For minimum yield strength requirements of 310 MPa (45 ksi), air-hardened or normalized parts with negligible distortion can be produced (Ref 79).

Stress Relieving. The presence of residual stresses in the parts caused by cold working, drawing, extrusion, forging, welding, machining, or heading operations greatly increases the tendency of distortion. However, these residual stresses can be relieved by subcritical annealing or normalizing treatment just before the final machining operation, which decreases the distortion to an appreciable extent. This is of special importance for intricate parts with closed dimensional tolerances (Ref 80). Stress reduction is necessary to avoid distortion during hardening and to avoid cracking resulting from the combination of residual stress to the thermal stress produced during heating to the hardening temperature. In the event that stress relieving is not performed after heat treatment, large distortions of the part can be removed by heavy grinding. However, the drawbacks of this operation are: possible elimination of most, if not all, of the hardened case of the carburized and hardened part; and danger of burning and crack formation on the surface layers. Hence, it is customary to stress relieve plain carbon or low-alloy steel parts at a temperature of 550 to 650 °C (1020 to 1200 °F) (for 1 to 2 h),

hot-worked and high-speed steels at 600 to 750 °C (1110 to 1380 °F), and the heavily machined or large parts at 650 °C (1200 °F) (for 4 h) prior to final machining and heat-treatment operations. Subresonant stress relieving may also be employed to neutralize thermally induced stress without changing the mechanical properties or the shape of the component. These components include: large workpieces, premachined or finish-machined structural or tubular, nonferrous, hardened, nonsymmetrical or varying section thickness, stationary, or assembled. However, this does not work on copper-rich alloys and the edges of burned plates (Ref 93).

Control of Distortion

In order to remove or minimize distortion, the modern trend is to shift from water-quenching practice to milder quenching, for example, oil quenching, polymer quenching, martempering, austempering, or even air-hardening practice. Milder quenchants produce slower and more uniform cooling of the parts, which drastically reduces the potential distortion. Other strategies of controlling distortion for age-hardening aluminum, beryllium, and other alloys include: alloy and temper selection, fixturing, age-hardening temperatures, proper machining, and stamping operations (Ref 94). The fewer the number of reheats applied to components in case-hardening steels following carburizing, the smaller is the distortion on the finished part. When top priority is given to minimum distortion, it is desirable to make the parts from oil-hardening steels with a controlled grain size and to harden them by martempering direct from carburizing. Presently polyalkylene glycol-base quenchants, such as UCON quenchants HT and HT-NN, are variously used for direct quenching from the forging treatment, continuous cast quenching, and usual hardening of forged and cast steels and cast iron. In this case boiling does not take place at the component surface but rather at the external surface of the deposited polymer film. More uniform cooling occurs, and thermal stresses are released. Because of the lower boiling point and high thermal conductivity, UCON quenchants act through the martensite zone more rapidly than oil (Ref 95).

Distortion during ferritic nitrocarburizing is minimal because of low treatment temperature and the absence of subsequent phase transformations (Ref 66). There are many methods of reducing distortion in induction-hardened components; these methods are usually found by experience with variables such as the hardening temperature and the type and temperature of quenching medium employed. Methods of reducing distortion in induction-hardened parts include: the hardening of small spindles held vertically in jigs; the plug-quenching of gears to prevent the bores from closing in; the flattening of cams by clamping them together during tempering; and the selective hardening of complex shapes (Ref 96).

As a replacement of medium- or slow-quenching oils, UCON quenchants E and E-NN can be readily used in induction- and flame-hardening operations, both in spray and immersion types, for high-carbon and most alloy steels and traditional hardening of cast iron and cast or forged steels of complex geometry with better distortion-reduction properties. Agitation of quenchant should be carried out by motor-driven stirrers to move the medium with respect to the part being quenched or by pumps that force the medium through the appropriate orifice. Alternatively, the parts are moved through the medium, and for some applications, spray quenchant is recommended. Water additives are sometimes employed in salt baths to increase heat extraction (Ref 64).

Ultrasonic quenching is also effective in controlling distortion, which involves the introduction of ultrasonic energy (waves with a frequency of 25 kHz) in the quenching bath. This breaks down the vapor film that surrounds the part in the initial stages of water or oil quenching (Ref 86).

Distortion after Heat Treatment

Straightening. When every possible case has been employed to minimize distortion, it may still be essential to straighten after heat treatment, which has already been discussed.

Grinding after Heat Treatment. In the case of carburized or nitrided parts, the metallurgist and designer, together with the production engineer, must collaborate regarding the amount to be removed by grinding after heat treatment. This grinding allowance must be taken into account when determining the initial dimensions and also when specification for the case depth is to be applied.

Distortion may also occur after heat treatment, with time, owing to the completion of any unfinished transformation or the effect of increased temperature during grinding. For example, fully hardened components such as blade shears may be damaged by characteristic crazing pattern because of heavy and careless grinding. Local overheating results in the transformation of undecomposed austenite, and the accompanying changes in volume produce sufficient stresses to cause cracking and developing of a crazing pattern.

Dimensional Stability. To achieve dimensional stabilization or stability (that is, retention of their exact size and shape) over long periods, which is a vital requirement for gages and test blocks, the amount of retained austenite in heat-treated parts must be reduced because retained austenite slowly transforms and produces distortion when the material is kept at room temperature, heated, or subjected to stress. Dimensional stabilization also reduces internal (residual) stress, which causes distortion in service.

Stabilization can be obtained by multiple tempering (with prolonged tempering times); the first tempering reduces internal stress and facilitates its transformation to martensite on cooling. The second and third retempering reduce the internal stress produced during the transformation of retained austenite.

It is the usual practice to carry out a single or repeated cold treatment after the initial tempering treatment. In cold treatment, the part is cooled below the M_f, which will cause the retained austenite to transform to martensite; the extent of transformation depends on whether the tool part is untempered or first tempered. Cold treatment is normally accomplished in a refrigerator at a temperature of -70 to -95 °C (-100 to -140 °F). Tools must be retempered immediately after return to room temperature following cold treatment in order to reduce internal stress and increase the toughness of the fresh martensite. Finally, they are ground to size. It may be pointed out that vibratory techniques are being used more frequently to achieve dimensional stability but do not offer any metallurgical benefits (Ref 80).

Distortion and Its Control in Heat-Treated Aluminum Alloys

The high levels of residual stress and distortion that are produced in the water-quenched aluminum extrusion and forgings (such as 2000, 6000, and 7000 series) and aluminum castings can be reduced 60 to 100% by using proper selection of polyalkylene glycol quenchant or polyvinyl pyrrolidone 90 concentration (for example, 25% solutions for wrought alloys, 20 to 30% UCON quenchant A for thicknesses up to 25 mm (1 in.), and 17 to 22% for larger than 25 mm (1 in.) section thicknesses in casting alloys) with sufficient agitation, lower bath temperature, proper fixture (throughout solutionizing, quenching, and age-hardening treatments), and straightening (in the as-quenched state after taking out from the fixture) procedure. The initial cost of these polymer solutions as a replacement to the conventional hot-water quenching method is easily compensated for by other advantages such as reduced scrap, reduced machining (compared to two machining operations required--one before and another after heat treatment--in the conventional water-quenching method), and increased fatigue life as a result of reduced convective heat transfer or film coefficient between the part and the quenchant, more uniform quench, precise control of quench rates, and improved heat-transfer qualities from the deposition of liquid organic polymer on the surface of the part being quenched (Ref 97, 98, 99). This method costs less, therefore saves time and allows easy shaping, bending, and twisting of the parts without establishing residual stresses. Such parts as leading edge wing skins, spars, and bulkheads are used in the aerospace industries (Ref 96).

Importance of Design

The wrong design of the tool material may result in the establishment of nonuniform heating and cooling of the components, which produces overload and/or internal stresses leading to distortion and failure during or after hardening. Correct consideration at the design stage plays an important role in lessening the distortion and danger of cracking. The basic principle of successful design is to plan shapes that will minimize the temperature gradient through the part during quenching. Fundamental rules such as maintaining a simple, uniform, regular, and symmetrical section with comparatively few shape changes, ensuring small and smooth cross-sectional size changes, and using large radii are still too frequently overlooked at the design stage. Thus, successful heat treatment demands a rational design that avoids sharp corners as well as sudden and undue changes of section.

It is often possible for tool designers to compensate for size distortion. For example, in preparing precision hobs for gear cutting, dimensional accuracy must be kept within very close tolerances. On linear longitudinal growth, it is the general practice to go out-of-round in the following high-speed steel bars as much as 0.3% in M1 type, 0.2% in M2 type, and 0.15% in T1 type during heat treatment. These data will alter slightly with changes in design of the hobs, but essentially the growth in tungsten-base high-speed steel is lower than that of the molybdenum-base high-speed steel (M1 and M2). This does not require any difficulty if the growth is compensated for and if the steel is consistent in its growth (Ref 87).

The distortion produced in the surface hardening of long shafts by the scanning method can be a great problem if the equipment is not in very good condition. Due consideration must be given so that locating centers run concentrically, in line and at the appropriate speed; the coil must be accurately aligned, and the quench must be correctly designed with sufficient number of holes of suitable size and angle. For long shafts with a relatively small diameter (for example, half-shafts, which are likely to distort), the use of hydraulically operated restraining rolls usually overcomes this (Ref 100).

The designer should bear in mind the following rules while designing a die or machine part that is to be heat treated:

- Distribution of the material should be as uniform as possible
- Provide fillets (large radii) at the base of keyways, cutter teeth, and gear teeth to avoid stress concentration; semicircular keyways, which permit the use of round-cornered keyways, are the right

choices. Ideally, drives using involute splines are preferred over keyways

- Avoid abrupt changes of section; in other words, provide smooth changes of section
- Large holes (such as drawing or cutting openings in die rings or plates) must be centrally located from the outer contour. In some cases holes are drilled through the heaviest section of the tool in order to help fairly balance the weight of the section rather than to unbalance it (Ref 64). Deep blind holes should always be avoided because they cause nonuniform quenching. If this is not possible, the hole can be ground in after hardening. Drilled hole junctions in a steel part should be avoided because they enhance very high and undesirable cooling conditions. The problem with these cross holes is to get sufficient quenchant into them. The inside surface of the holes tends to be in a state of high tensile stress, usually leading to cracking, at least with water quenching. As a minimum, the corner at the junction of the holes with outer diameter of the part should be given a generous radius to better distribute the tensile stress (Ref 90). Similarly, grooves and keyways in highly stressed areas should be avoided, or, if possible, they should be located in low-stressed areas of the part. Alternatively, fixtures should be used that make it possible for the hole or the inside of the groove to be quenched in the beginning or more rapidly than the rest of the part (Ref 24)
- Round off all the holes, corners, and outer edges
- If sharp corners are unavoidable, provide relief notches in place of sharp edges
- The insertion of identification marks on the hardened component is recommended, preferably after hardening with tools having well-rounded edges and minimum deformation (shallow penetration depth), and at positions far away from the high-stress concentration zones (reentrant angles, bends, and so on) (Ref 101)
- Large intricate dies should be made up in sections, which frequently simplifies heat treatment (Ref 64)

Statistical Process Control of Heat-Treating Operations

Jon L. Dossett, Midland Metal Treating, Inc.; Gordon M. Baker, New Age Industries, Inc.; Terrence D. Brown, Lindberg Heat Treating Company; Daniel W. McCurdy, Marathon Monitors, Inc.

Introduction

AS DEMAND FOR INCREASED QUALITY and documentation is felt by heat treaters, the subject of automatic collection and use of process information in a statistical process control/statistical quality control (SPC/SQC) format becomes increasingly critical. Data acquisition and documentation 10 years ago meant a chart recorder for temperature and a log sheet for the operator's dew-point readings. Today, it more than likely means a computer system tied into key points on the heat-treating equipment with the objective of logging important information for later review or perhaps being taken into account in real time.

Traditional versus Statistical Control

When man first heat treated a sword made from an iron carbon alloy, he learned that it was necessary to heat it until it glowed red and then plunge it into water. He further learned that the resulting product was often very brittle but could be made more usable by heating it again, this time to a much lower temperature. This small body of knowledge was enough process control to produce many useful products for many years.

Initially, it was noticed that if certain temperature ranges were used in certain circumstances, products of better quality would result and the idea of controlling temperature was born. Much later it was discovered that control of the carbon content of the material was important. Modern science was now controlling the properties of the end product.

If the tools used for process control in heat treating today are viewed against this backdrop, our current position on the evolutionary ladder can be pinpointed:

- *Step 1:* Rudimentary process knowledge from direct observation
- *Step 2:* Understanding of certain obvious influences from experimentation
- *Step 3:* Manual control of obvious influences like temperature
- *Step 4:* Automatic control of these obvious influences
- *Step 5:* Documentation of continued variation in process results, using statistical techniques to manually identify special problems
- *Step 6:* Use results of statistics and enhanced process understanding to gain control of the less obvious influences
- *Step 7:* Control the process from a theoretically complete model, taking into account all possible influences to produce a near-perfect product every time

The state of the art is currently at Step 5, the application of statistics in the search for problems. The jump to Step 6 is being made in some manufacturing disciplines using a new technique called "design of experiments." This is a complex statistical approach that may incorporate artificial learning into data regression-based computer programs. A program of this type will direct the human operator to perform experiment after experiment with a process in order to gain insight into any possible effects, direct or synergistic, that an entire list of possible process parameters might have. A process model initialized with known theory, but ultimately based on derived statistics, will emerge that can be used to indicate those parameters that will make significant contributions and should therefore be subject to automatic control.

A model such as this could be used to bake a better cake, for example. The model might direct the operator to make a cake with 1 egg the first time, 0.5 eggs the second, and 1.5 eggs the third. It would then ask for quantified results as to the measured quality of each of the experimental cakes. The model might conclude by saying that the optimum cake must be made with between 1.1 and 1.2 eggs, along with similar odd amounts of all the other applicable ingredients. It might even conclude that no salt is necessary in a cake because the statistics did not bear out importance of this item.

Basic SPC/SPQ Nomenclature

The purpose of this article is to provide a practical discussion of the application of SQC techniques to heat-treating operations and for that reason many of the applicable definitions and equations are not used but can be found by the reader in other reference materials on this subject. However, it is felt that the following minimum basic definitions and equations are necessary to be presented here for a better understanding of the text.

- *Accuracy versus precision:* Accuracy is measured by the extent to which the measured average of a group of readings, regardless of how widely the readings are dispersed, agrees with the true value of the unit being measured. Precision is the repeatability of the measurement (how much dispersion exists between readings) regardless of how close the readings are to the true value (or how accurate the readings are)
- *Gage repeatability and reproducibility study* (*GR & R*): A study conducted on measurement devices to determine the precision and accuracy of the device. Results are expressed as an R & R index
- *Process:* Any specific combination of machines, tools, methods, materials, and/or people employed to attain specific output in a product or a service. A change in any one of the constituents results in a new process
- *Process capability:* Refers to the reproducibility of a process over a long time period during which

normal changes in workers, material, and other conditions are encountered

- *Quality:* Product features which are free from deficiencies and thus meet the needs of the customer and provide product satisfaction
- *Statistical process control:* The application of statistical techniques for measuring and analyzing the variation in processes
- *Statistical quality control:* The application of statistical techniques for measuring and improving the quality of processes and products. Statistical quality control includes statistical process control, diagnostic tools, sampling plans, and other statistical techniques
- *C_p index:* Stands for capability of process, and is the ratio of the specification tolerance to six standard deviations (6σ). C_p is a measure of the dispersion of data only
- *C_{pk} index:* A measure of both dispersion and centeredness of the data as follows:

$$C_{pk} - \textit{the} \text{ lesser of: } \frac{\text{USL - mean}}{3s} \textit{ or } \frac{\textit{mean} \text{ - LSL}}{3s}$$

where USL is the upper specification limit, and LSL is the lower specification limit

Use of Statistical Control in Heat Treating. In the last few years, it has become commonplace to see heat treaters tracking the results of their most critical processing with SPC techniques. The most commonly examined parameters include hardness, case depth, and distortion, although many others are tracked as well. Unfortunately, it has also become commonplace to observe these very same heat treaters failing to use these techniques for anything more than supplying required after-the-fact documentation on treated parts. It seems that the promise of statistical process control and its roll in the revitalization of manufacturing quality in heat treatment is not being fulfilled.

It is important to understand that any SPC program is a means, not an end. Statistical process control is a tool to audit a process and help distinguish controllable variables from uncontrollable variables. It also provides a means for quantitatively measuring the level quality of a process. Statistical process control alone does nothing to improve the process. Continual improvement of the heat-treating process is the real goal and this comes from actions taken by people. Statistical process control is utilized as a tool to direct those actions.

Simply installing an SPC system on a dilapidated furnace does not improve the performance of the furnace. SPC alerts the furnace operator to the fact that, statistically, a problem does exist and requires investigators to determine which variables are causing excessive variations to occur. Statistical process control does not tell *what* is wrong, only that, statistically, excessive variation is present and this condition should be investigated to determine the assignable cause.

SPC versus SQC. It is necessary to make a distinction between statistical process control and its relative, statistical quality control. The latter is what most heat treatment shops are really using when histograms, mean/range charts, and capability indices are calculated for the variation in attained results (for example, hardness, case depth, and so on) in the processing of a given component.

Because statistical quality control is an after-the-fact tool, its best use is in the control of continuous processing where trends can be noticed and corrected before significant damage occurs. Processes such as large volume induction hardening (see the article "Induction Heat Treating of Steel" in this Volume) and continuous carburizing have been substantially improved with SQC charting techniques.

In batch processing, however, statistical quality control is of little value in preventing problems because at least one entire load of parts will be adversely affected before a problem can even be noticed. Even if the problem is caught after one load, the proposed solution cannot be tested without committing yet another load. Statistical quality control can be very helpful in batch or short run type (set-up dominated) processes by using it to analyze set-up variables. If the process is then set up to optimal set-up parameters (as determined by experimentation or evaluation of part outputs), meeting parts specifications will necessarily result.

Statistical Process Control. The idea behind true statistical process control is that the results of a process can be guaranteed if none of the relevant process parameters are allowed to stray outside of previously established control limits.

The long standing problem in applying statistical process control to heat treatment has been finding methods to quantify and measure process parameters that are of known importance (outside of the obvious ones). Many SPC programs are based upon charting controlled parameters such as temperature, atmosphere carbon potential, quenchant temperature, and so on. While this approach is certainly not incorrect, it does often lead to a situation where a deviation in an SQC chart (results) commonly cannot be attributed to any special cause deviation in a corresponding SPC chart (processing parameters), because all the things being charted are controlled variables that by design will not normally change.

Processing Methods Considerations

Repeatability is a key issue when considering how to improve a heat treatment process. The more process variables that can be controlled within specific known limits from part to part, furnace load to furnace load, and day to day, the more repeatable the process results will be.

Continuous Operations. The continuous types of heat treatment equipment (that is, rotary retort, pusher carburizers, belt furnaces, and so on) offer the most straightforward approach to applying SQC and SPC techniques to improve process performance.

Because a high volume of work pieces is involved, there is adequate opportunity to perform in-process sampling of key product characteristics. Negative outcomes can be predicted before they take their full course. Also, special causes are often more identifiable because process variables are steadier in continuous processes than in batch-type processes.

Single Part Treatments. With induction and flame heat treating, parts are typically processed one at a time. Using part evaluation techniques to predict negative results becomes difficult and impractical. Thus, the focus must shift to statistical process control and the identification, monitoring, and controlling of the process variables to ensure repeatability of the results.

Electric power, flame temperature, scan speed, coil dimension, part positioning, and quenchant temperature are some variables that need to be considered. Trending of process variables can be used to determine special causes.

Batch Operations. Batch-type furnaces usually offer the opportunity to do a significant amount of sampling and analysis within a load. However, all this does is develop a degree of confidence on the results of the entire load. The process variables must be monitored and analyzed to ensure that the process is under control and there is repeatability from load to load and from day to day. This is especially true when each load is different in terms of part geometry, material and/or specification, which is the norm in commercial heat treating.

Process Deterioration

A fact of life in any heat-treating process is that the equipment gradually succumbs to the wear and tear of constant operation, thus the process inevitably gets worse with time. The challenge is to counter this natural deterioration with corrective action before out-of-specification parts are produced.

SPC techniques can be utilized to measure furnace performance and address process deterioration in heat treating. By monitoring key process variables and/or key process outputs, preferably in on-line fashion, trends can be spotted and action taken before nonconforming product is produced.

Key process variables may mean not only controllable variables, but also uncontrollable and secondary variables.

Uncontrollable Process Variables. Examples of uncontrollable variables that are useful in the monitoring of a heat-treating process are:

- *Quench transfer time:* Although this is not a controllable variable in most furnace systems, it is often a critical parameter in terms of producing good parts. It may be beneficial to monitor and analyze transfer time in order to get an early warning of the deterioration of the transfer mechanism. One method for verification of sufficiently fast transfer time is to compare the maximum allowable transfer time for a successful process to the actual transfer time which would trigger an alarm if the maximum were exceeded. This automatic control method would then flag suspect loads or parts resulting from either a mechanical failure or equipment function deterioration

- *Temperature recovery time:* By measuring and analyzing the time it takes for a batch furnace to reach setpoint temperature (with a standard load weight or empty), trends can be picked up that would indicate a loss in furnace performance. These out of control trends as plotted on an SPC chart would then trigger an investigation to determine the cause of the condition (for example, damaged insulation, poor door seals, heating system malfunction, and so on)
- *Quench temperature rise:* Although a quench system may be controlled within a specific range (that is, 30 to 65 °C, or 90 to 150 °F), it may be important to know how the temperature cycles from quench to quench. This would give a macroanalysis of the entire quenching system and give warnings of failed, or impaired, agitation and/or quenchant cooling. Over-loading of the furnace could also be indicated

Secondary process variables are those that are caused by the deterioration of control loops. Examples are of secondary variables:

- *Fuel consumption:* By monitoring gas or electric consumption for a standardized furnace cycle and loading (could be empty), diminished performance in the heating system can be detected
- *Additive atmosphere gas:* By monitoring and trending the amount of natural gas (or propane) addition required to control a specific carbon potential setpoint, the deterioration of furnace atmosphere integrity can be detected

Process and Product Capabilities

Capability studies are conducted on all types of manufacturing processes to determine the statistical variation of a product with respect to a measured characteristic. For heat-treating processes, characteristics frequently measured are hardness and case depth. Because these metallurgical characteristics are sometimes difficult to define, specifications may initially need to be clarified with regard to the exact test scales or test methods to be used and the critical locations where these tests are to be made before a capability study is conducted. Process results for many metallurgical and heat-treating processes are dependent on material-related characteristics such as hardenability, material chemistry, and/or part geometry that also make the process test results sensitive to those variables.

After the metallurgical requirements are clearly established, a basic process capability study may be conducted. Care should be taken so that the parts tested are from the loading locations representing the extremes in process variability. A good guideline for test sample locations is to use those loading locations prescribed for temperature uniformity surveys in specification MIL-H-6875.

For continuous processes, it is important to collect the samples over a sufficiently long period of time in order to reflect process heating power fluctuations or other process abnormalities that could be time dependent.

The use of normal probability paper for data representation and plotting is highly recommended. If the data does not plot as a straight line indicating a normal distribution, a metallurgical or process-related reason for this skewness should be apparent or be determined. An example of a capability study of an atmosphere harden and temper operation for automotive seat belt parts made from SAE 4037 steel is shown in Fig. 1 and Fig. 2.

Fig. 1 Final hardness distribution analysis for a typical quench and temper operation

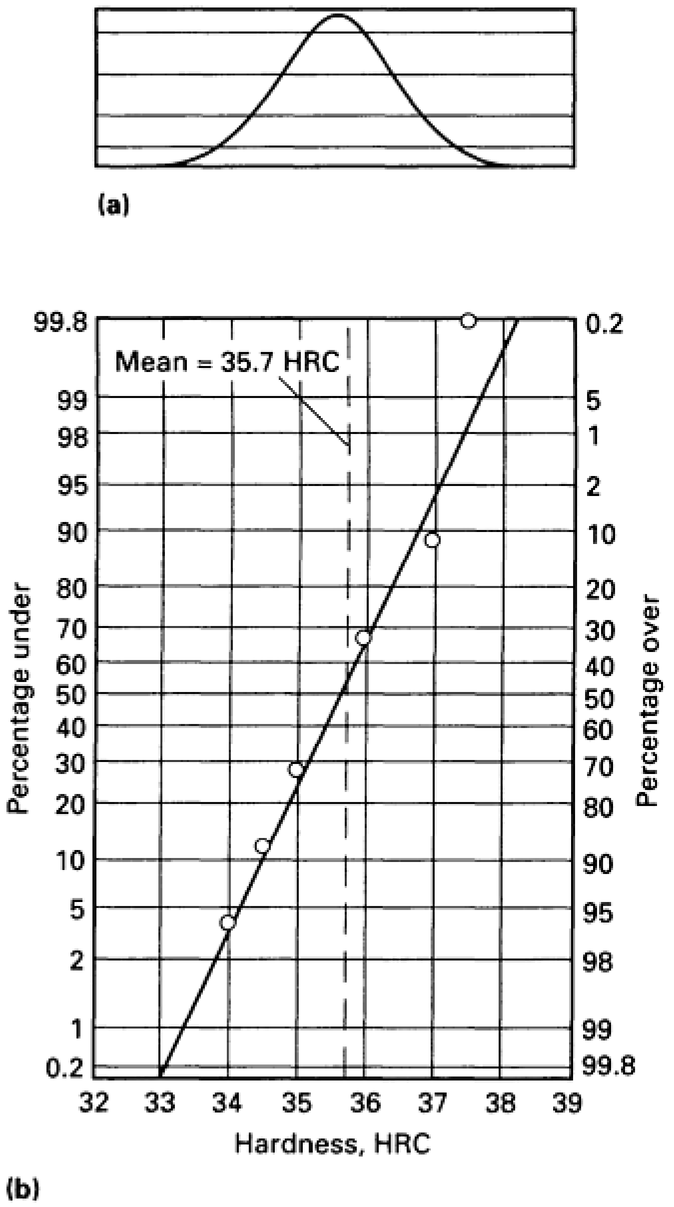

Fig. 2 Normal probability plot of data from Fig. 1. (a) Frequency distribution. (b) Distribution analysis sheet. Specification, mean = 35 HRC; range = 7 HRC. Results, mean = 35.7 HRC, 6σ = 5.5 HRC, C_p = 1.27. Action, adjust temper to adjust mean to 35 HRC

As can be seen in Fig. 3, the overall process capabilities results are the result of many contributing factors:

- *Base material contributions:* Unique material characteristics, material defects, and hardenability differences. These can vary from lot to lot and also between materials
- *Part-related contributions:* Part geometry and section size variations
- *Process-related contributions:* Temperature uniformity as affected by process control and mass effects, time control, atmosphere control, and cooling method (as determined by uniformity and average severity)
- *Evaluation method contribution:* Standards accuracy and testing method accuracy

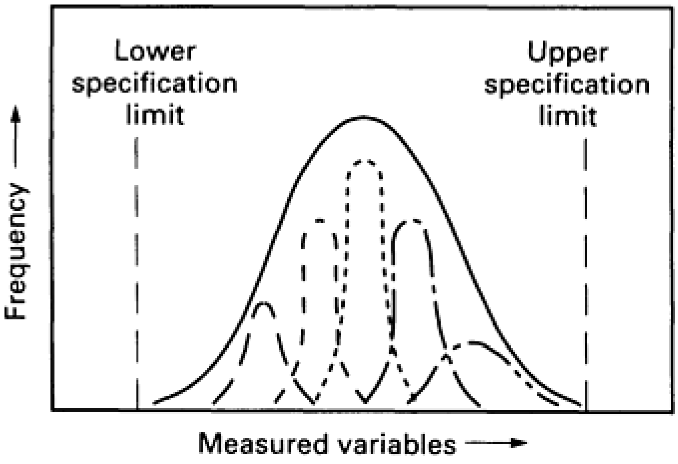

Fig. 3 Factors contributing to overall heat-treating process result variations

Thus, to successfully use the process capability study as a dynamic tool to refine and narrow process variability, the following three steps should be used in conjunction with process capability studies:

Step No. 1:

- Identify critical control variables and their relative contributions to process attribute variations (this can be done by process modeling techniques)
- Measure process inputs with corresponding process output results
- Document process control procedures

Step No. 2:

- Modify control procedures, manufacturing procedures, or equipment in order to reduce process variability

Step No. 3:

- Remeasure process capability (as in Step No. 1 above) to ascertain the effectiveness of the changes

The overall heat-treating process variability result may be characterized as being comprised of the following factors (they may be classified into four categories) and the accompanying sources of the undesirable background signals (intrinsic or extrinsic noise):

- Base material related (intrinsic noise)
- Part configuration and manufacture related (intrinsic noise)
- Process related (extrinsic noise)
- Evaluation method related (extrinsic noise)

By using properly standardized test coupons as the basis of a process capability study, we can separate out the variability due to intrinsic noise factors and arrive at the inherent process capability. However, in practice, we will still have these contributions in the process and this should be kept in mind. Additionally, a GR & R study may be performed on the evaluation method to determine the contribution of these factors to variability.

Base Material Considerations

Cast irons are probably the best example of a material where test results (that is, hardness) can be a function of the hardness testing scale used. This sensitivity of hardness value to the testing method and the hardness scale used is because the different phases present in the workpiece vary significantly in hardness. This same effect exists in other materials which are heat treated (see Fig. 4).

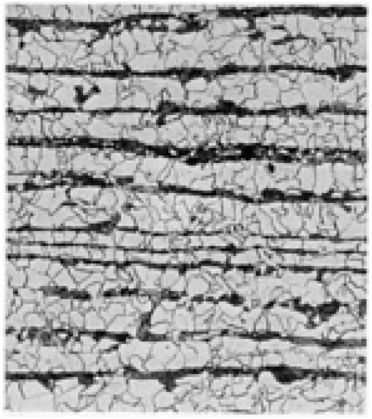

Fig. 4 Microstructure of hot-rolled AISI 1022 steel showing severe banding. Bands of pearlite (dark) and ferrite were caused by segregation of carbon and other elements during solidification and later decomposition of austenite. Etched in nital. 250×

Another type of problem that can influence testing results which are not the direct result of processing is "banding." Many steels, particularly a resulfurized one such as AISI 1100 or 1200 series, exhibit banding or microalloy segregation. The bands exist prior to heat treatment and the ferrite-rich and pearlite-rich areas run in bands across the longitudinal rolling direction of the bar stock from which parts are made.

It has been found that this condition can result in a 4 to 10 point of Rockwell C hardness variation after hardening between these bands of different chemical composition. This problem is greatest when the bands are widest and the heat treatment times are very short, such as for induction hardening processes.

Decarburization. Surface carbon reduction to a greater or lesser degree exists on most steels having more than 0.30% C. This defect results from basic steel manufacturing and if not removed in the part manufacturing process prior to heat treatment can influence the surface hardness of parts after induction, flame, or direct hardening processes that may not be capable of correcting the surface decarburization condition. However, it should be recognized that many heat-treating processes can also cause this same problem. It is thus important for one to have characterized the incoming product to be processed so that the controllable incoming material variability can be isolated and corrected independently from the product variations due to the process.

Material Variations. Before applying statistical control techniques to monitor process or product uniformity, it is important to understand how the raw material uniformity is controlled prior to heat treat processing. That is, whether or not the incoming material is identified and kept separate by heat numbers in the case of steel or by batch number in the case of cast materials.

Part-Related Contribution

Each part evaluated by statistical means after heat treat processing can have other unique features such as section size variation, geometry, and/or surface finishes which can affect the test results obtained.

Use of Test Coupons. Test coupons can be used to provide an accurate heat-treating process evaluation if one is only interested in measuring changes or variations in the process. Test coupons must be carefully designed to be an effective statistical process control tool. They must be:

- Properly selected for size, shape, and material that can be directly correlated to the material and parts configuration being processed
- Prepared in sufficient quantity (same heat of steel) and quality to eliminate or minimize the material uniformity variable from the processing variation

By using statistical quality control with test coupons in conjunction with statistical quality control on heat treated parts, product variations attributed to process only variations may be identified and controlled.

Example 1: Use of 10 000 Test Pins Measuring 64 mm (2 $\frac{1}{2}$ in.) Long by up to 17.8 mm (0.700 in.) OD Made from a Single Heat of 8620H Steel Used to Monitor the Carburizing and Hardening Operations of 5- to 8-Pitch Gears.

Test pins were used to monitor carburizing and hardening processing for 5- to 8-pitch gears made mostly from 8620H steel. This procedure is used to monitor the *process variation* in carburizing of surface hardness, effective case depth, and core hardness. The diameter chosen for the test pin is based on the gear tooth thickness and the fact that the test pin center cooling rate would be on the steeper portion of the Jominy hardenability curve. This means that monitoring the center core hardness on test pins is an indirect measurement of quench uniformity.

Purchase and Processing of Test Pins. The minimum quantity of test pins purchased was 10 000 pieces from a single heat of 8620H. The OD of these pins were ±0.13 mm (±0.005 in.) for a given lot of pins with the absolute size being 12.7 to 17.8 mm (0.500 to 0.700 in.). The length was 64 ± 1.6 mm (2 $\frac{1}{2}$ ± $\frac{1}{16}$ in.). A groove was added to the pin for attaching the pin by wire to the load.

At least one test pin is processed with each batch load or one pin is run every 4 h on each row of all continuous furnaces.

Test pins were hung in all furnace loads in a location where the processing was typical of the parts processed.

The test pins are evaluated as-quenched only. *No tempering is permitted.* Test pins evaluated for purposes of SQC control were from pure cycles with no abnormal changes in times, temperatures, or quench procedure.

Testing Procedures for Test Pins. File the surface of the pin to check for file hardness and to make a smooth surface. Check three hardness readings on Rockwell C scale and record the average. Do not use V anvils but use flat or spot anvil only.

Cut parallel section 6.4 mm ($\frac{1}{4}$ in.) thick from the center of the test pin. Set the diamond and anvil by checking at mid-radius. Check the center hardness by Rockwell well C scale and record.

Effective Case Depth. On the section cut from above, grind the surface to be checked on a 120-grit or finer paper. Test from the surface in to the point where the hardness is 85.5 HR15N (50 HRC). Measure from the surface to the center of that mark using a Brinell glass. Record the reading as effective case depth in thousandths of an inch.

The referee method for checking effective case depth is by 500-g microhardness to 50 HRC equivalent. Therefore, at least one of every ten checks and/or any check of effective case depth not within the specified limits is to be verified by the microhardness method.

The results from above are to be plotted by *cycle* and *furnace* on the form shown in Fig. 5.

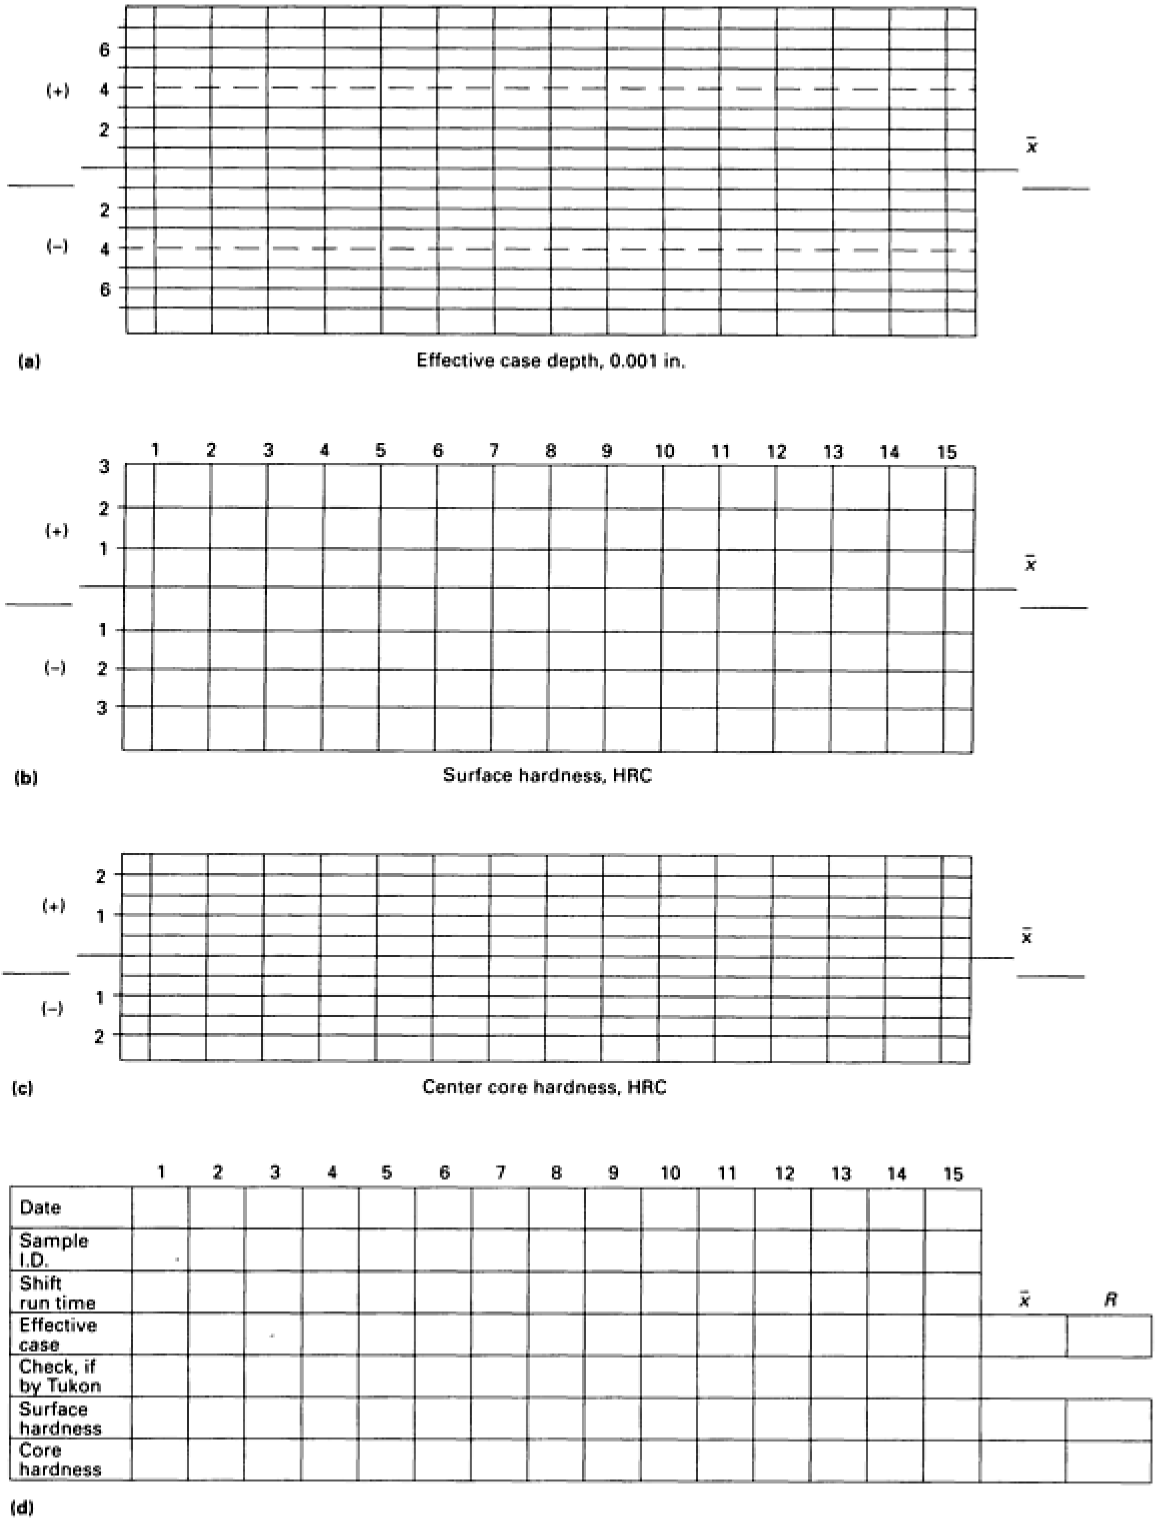

Fig. 5 Chart for plotting 8620 steel test pin variation by characteristic. (a) Effective case depth characteristic. (b) Surface hardness characteristic. (c) Center core hardness characteristic. (d) Chart to plot data from (a), (b), and (c) by cycle and furnace

This method can be started and used on a monitoring basis only for a short time until mean values with upper and lower control limits can be established.

Process-Related Contributions. This is the most important characteristic to identify and control to reduce variability of the heat treated products. Exactly how to accurately control process parameters is covered in the section "Design of

Experiments" in this article. By using standardized test pins and modeling to separate processing parameters, the individual parameter contribution to a measured characteristic such as effective case depth can be shown as detailed in Table 1.

Table 1 Contribution of selected parameters to variations in effective case depth for required 0.85 to 1.00% surface carbon level at 870 °C (1600 °F) processing temperature

Case depth		Variation in case depth for selected parameters, %[(a)]											
		Temperature variation (Δ*T*)			Time variation (Δ*t*)			Carbon variation (Δ *C*)					
								Atmosphere			Quench uniformity[(b)]		
mm	in.	11 °C (20 °F)	28 °C (50 °F)	56 °C (100 °F)	5 min	10 min	30 min	0.10%	0.15%	0.25%	0.05%	0.10%	0.20%
0.51	0.020	6	14	33	3	7	20	8	13	27	11	23	45
1.02	0.040	6	16	34	1	2	5	8	13	27	11	23	45
1.52	0.060	7	17	35	>1	1	2	8	13	27	11	23	45

(a) Total process variation = $\sqrt{A^2+B^2+C^2+D^2...+Z^2}$, where *A, B, C, D,* and *Z* are % variations attributed to Δ*T,* Δ*t,* atmosphere Δ*C,* quench uniformity Δ*C,* and additional variables, respectively

(b) Variation in case carbon level when quenched to 50 HRC.

The most significant observation from Table 1 is that quench uniformity is an equally significant factor in the carburizing process with time, temperature, and atmosphere control as variables.

Measurement Accuracy

The most important reason for calibrating with traceable test blocks and indenters and using a stable hardness standard is the U.S. industry movement toward higher levels of statistical quality control.

Testing variables must be eliminated wherever possible to permit the production part process as much range as possible. This means keeping the tester, anvil, operator, indenter, and test block error to the smallest possible percentage of the production tolerance. Test block consistency is one very important controllable variable. Some test blocks state maximum variation of 0.2 hardness units down to 40 HRC. With ten standardizing tests on a larger, thicker block that show no greater variation than 0.2 hardness units, there is the likelihood there would be few readings found above that variation. Conversely, on a thin standardizing test block with five tests where one reading out of five may show a variation of 0.4 hardness units, there is the likelihood that there would be other 0.4 or greater measurement variations. When plotting $\bar{x}$-*R* control charts (see the article "Statistical Quality Design and Control" in Volume 17 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*) where $\bar{x}$ is the sample mean and *R* is the range, this greater test block variation over time could erroneously show the hardness tester is not consistently accurate within tight limits. The variation could lead to incorrect process adjustments or put into question the process capability. The higher consistency, more stable test block would show a tighter band of tester accuracy and repeatability performance.

In order to assist in reducing the variability in hardness testing, the following items should be utilized:

- Digital hardness tester with reduced operator influence features (that is, motor drive or automatic full load application and removal)
- Very stable and consistent hardness test blocks
- Certified diamond indenters as reference standards
- Good operator training program on hardness testers
- Proper clamping devices to support odd-shaped parts and/or fixtures for additional support
- Daily checks of hardness testing equipment using standardized test blocks in the range or ranges most commonly encountered on production parts tested with the machines

SPC Process Analysis

The concept of process analysis is a relatively new way to deal with a group of old ideas. For example, what is the best temperature from which to harden a particular steel? How was this temperature determined? Is this temperature the one that takes the best advantage of the material's hardenability or is it the one that gives the lowest distortion or was it chosen for other reasons? What effect will raising or lowering this temperature have on the final variation in results?

Process analysis should follow a step-by-step characterization plan as follows:

1. Determine the process capability
2. Describe the process in operational terms
3. List, in order of importance, the output characteristics for each process element
4. Decide upon the measurement method and determine instrument variability (GR & R study)
5. Estimate the process variability
6. List all input variables (both controllable and uncontrollable) for the above output characteristics
7. Select the variables to be included in the process characterization
8. Decide the objective of the process characterization
9. Determine characterization methods and how data will be displayed
10. Construct a characterization implementation plan
11. Choose analysis method for process optimization (that is, evolutionary operations, EVOP, response surface methodology, RSM, and so on)
12. Determine effective process control plan
13. New process capability determination
14. Process documentation
15. Repeat if necessary

Design of Experiments

Before anything else can be done, the important process parameters must be identified and their effects documented. While this is often a matter of metallurgical common sense, the complex interaction of many variables can often lead to results that do not appear to make sense at all.

For example, in the hardening of steel, the variables of quenchant selection and quenchant temperature are vitally imporant. Common sense (as well as heat transfer] logic) says that the higher the quenchant temperature, the slower the quench. Unfortunately, this rule may or may not be true depending on the quenchant and the temperature range.

Many quench oils show peaks in their cooling characteristics that dictate a certain quenchant temperature is required for the fastest quench. Going either above or below this temperature will slow it back down. To complicate the matter, this performance peak may change depending upon aging of the oil and the agitation level of the oil. For all quenchants, agitation is a very significant factor in cooling performance. Thus, picking the optimum quench is not an easy task.

The category of methods developed for dealing with such complexity is known as the design of experiments. These methods must not be confused with simple linear regression interpolation from empirical data.

For example, consider the fictitious empirical data on the hardening of a high-carbon steel part in Table 2.

Table 2 Determining optimum austenitizing-tempering cycle to obtain a 55 HRC hardness in a high-carbon steel part

Austenitizing temperature		**Hardness at selected tempering temperature, HRC**		
°C	**°F**	**150 °C (300 °F)**	**260 °C (500 °F)**	**370 °C (700 °F)**
790	1450	60-62	55-57	46-50
845	1550	62-63	55-62	49-53
900	1650	61-64	57-61	50-55

It is desired that the final part be 55 HRC and no other parameter (distortion, ductility, and so on) is important. Looking at the data, it is obvious that there are going to be many combinations of austenitizing and tempering temperatures that will center the results at the desired point.

A design viewpoint on these data would help the selection of the best combination from a result variability viewpoint. It can be seen that the selection of 900 °C (1650 °F) for austenitizing along with perhaps a 315 °C (600 °F) temper will center the results at around 55 HRC, just as an austenitizing-temper combination of 790 °C (1450 °F) and 260 °C (500 °F) would. The choice of which sequence is best to reduce variability in the desired hardness might be governed by two observations:

- It would appear from the data that the higher the austenitizing temperature, the wider the range of the measured hardness results
- The effect on hardness of increases in tempering temperatures seems more dramatic from 260 to 370 °C (500 to 700 °F) than from 150 to 260 °C (300 to 500 °F)

Based on these observations, one might conclude that the 790 °C/260 °C (1450 °F/500 °F) combination is more desirable than the 900 °C/315 °C (1650 °F/600 °F) combination, as the results will likely fall into a tighter range, that is, resulting in a greater process capability around 55 HRC.

The key goals in a design of experiments exercise in heat treating are generally two-fold:

- Determine which variables (and combinations of variables) have significant, observable influence over the results based on a balance between economic and quality considerations
- Determine the optimum values for these variables in order to center the process at the desired point, reduce the variation in results due to possible or expected variation in these process parameters, and reduce the variation in results due to variation in the material

The following case history is presented to illustrate a design of experiments exercise.

Example 2: Induction Hardening of an AISI 1040 Cold-Drawn Combination Yoke and Spline Shaft Bar.

The bar had a 34.11 mm (1.343 in.) diameter and was 900.68 mm (35.460 in.) in length.

These parts were being hardened on a 6-station scanner with a 10 kHz motor generator (800 V, 375 A, 300 kW). The induction coil size was 44.45 mm (1.75 in.).

The stated objective of the design exercise was to determine the relationship between various induction hardening parameters and the resultant metallurgical properties (including distortion). The ultimate goal of the project was to optimize the process to produce a part with acceptable metallurgical properties while exhibiting minimum distortion.

Table 3 summarizes the various characteristics desired in the final part.

Table 3 Desired properties of a 34.11 mm (1.343 in.) OD cold drawn combination yoke-spline 1040 steel shaft

Characteristic	Preferred dimension	Optimum condition	
		Value	**Goal**
Effective case depth	Nominal	$\bar{x}$= 4.83 mm (0.190 in.)	40 HRC
Surface hardness	Maximum	58 HRC	1040 steel
Spline size change	Minimum	0.0000 mm (0.0000 in.)	Absolute value
Out-of-straightness (TIR)	Minimum	0.000 mm (0.000 in.)	. . .

The factors affecting the process were split into two groups:

- *Process factors:* Those factors that could be changed (for example, speed and power)
- *Noise factors:* Those factors, such as the induction station number, *that cannot be changed.* One very important variable that could not be changed during the experiment was the analysis of the individual heats of steel involved

The practical limits on the process factors and noise factors (that is, factors that could not be controlled) were determined and cataloged in Table 4 and Table 5.

Table 4 Process factors for three heats to induction harden a 34.11 mm (1.343 in.) yoke-spline 1040 steel shaft per Table 3 specifications

Process factor	Process conditions		
	Heat 1	**Heat 2**	**Heat 3**
Scan speed, s/m (spf)[a]	110 (36)	120 (40)	. . .
Power supply, %[b]	98	94	90

Quench temperature, °C (°F)	25 (80)	40 (100)	50 (120)
Quench pressure, kPa (psi)	55 (8)	70 (10)	83 (12)
Speed of rotation, rev/min	10	36	60

(a) spf, seconds per foot.

(b) At 100% set point, power output is 800 V.

Table 5 Noise factors for three heats to induction harden a 34.11 mm (1.343 in.) yoke-spline 1040 steel shaft per Table 3 specifications

Degree of hardenability	Steel making process	Heat No.	Composition, %						Chemical ideal diameter, *DI*[(a)]
			C	Mn	Ni	Cr	Mo	Si

16	120	40	90	720	25	80	83	12	36
17	120	40	90	720	40	100	55	8	60
18	120	40	90	720	50	120	70	10	10

(a) spf, seconds per foot

The experiments were run and the results (characteristics) measured and documented. The results were then analyzed mathematically using the concept of signal-to-noise ratio, or S/N.

(This concept is somewhat difficult to grasp as it relates to process control but it is helpful to consider the S/N phenomenon in the case of an overseas telephone call. There is almost always some hiss in the background of such a connection. The voices on the line are the *signal*, while the hissing sound is the *noise.* If the signal is much louder than the noise, it is possible to understand what is being said. This is a *high* S/N ratio. On the other hand, if the noise is almost as loud as the signal, it is not possible to understand; this is designated as a *low* S/N ratio.)

S/N ratios are measured in decibels, or dB. This is a logarithmic unit that allows very large ratios to be compressed into small units. In the case of process control:

- *Signal:* Controllable input of the process
- *Noise:* Uncontrollable variables which cause variation of the process

There are many specific formulas for calculating S/N in process control situations. Each is of the general form:

$$S/N = 10 \log_{10}\left(\frac{\bar{x}}{\sigma}\right) \qquad \textbf{(Eq 1)}$$

where σ is the standard deviation. Note that:

- A higher S/N ratio indicates a variable (or factor) with a corresponding large effect on the output characteristic of the part
- S/N measures change in both mean and/or variability
- Every time the S/N gains 3 dB, the loss by the loss function halves; thus a 3-dB change is significant

Tables 7(a) and 7(b) show the results of the mathematics as related to the characteristic of case depth. A depth of 4.83 mm (0.190 in.) was considered nominal.

Table 7(a) Signal-to-noise ratio analysis used to determine optimum process and noise factors required to obtain 4.83 mm (0.190 in.) average case depth in yoke-spline shaft

Experiment No.	Characteristic											Average case depth		Signal-to-noise ratio (S/N), dB
	Process factor									Noise factor				
	Scan speed		Power supply		Quench temperature		Quench pressure		Speed of rotation, rev/min

Table 7(b) Cumulative contributions to variability attributed to the individual characteristic and signal-to-noise ratio values listed in Table 7(a)

Characteristic	Variability attributed to individual characteristic, %	Contribution due to signal-to-noise ratio, %
Process factors:		
Scan speed	4.7	29.0
Power supply	11.2	40.0
Quench temperature	Insignificant	Insignificant
Quench pressure	Insignificant	Insignificant
Speed of rotation	Insignificant	Insignificant
Noise factors:		
Material hardenability	72.0	. . .
Station	Insignificant	. . .

The S/N ratios were used to pinpoint the optimum process factors to produce the desired 4.83 mm (0.190 in.) case depth. As listed in Table 6, these were (by experiment number):

Experiment No.	Process factor
A1	Scan speed: 110 s/m (36 spf)
B2	Power supply: 94% (750V)
C1	Quench temperature: 25 °C (80 °F)

D2	Quench pressure: 70 kPa (10 psi)
D3	83 kPa (12 psi)
E2	Speed of rotation: 36 rev/min
E3	60 rev/min

However, a very high noise factor was calculated. This means that 72% of the variation in case depth was directly attributable to material variation. Thus, for a 72% material factor:

Material	**Average case depth**	
	mm	**in.**
1	3.96	0.156
2	5.31	0.209

Therefore, the scan speed, power supply, and material hardenability combined accounted for 4.7% + 11.2% + 72.0% or 87.9% of the cumulative variability while quench temperature, quench pressure, speed of rotation, and station number together accounted for 12.1%o of the total variability.

The following general guidelines (applicable for a 1040 steel having midrange hardenability only) for case depth were derived from the experiment.

Process factors include:

- Scan speed: A 13 s/m (4 spf) speed change will change the average case depth by 0.48 mm (0.019 in.)
- Power: An 8% change in voltage will change the average case depth by 0.91 mm (0.036 in.)
- Quench temperature: A 25 °C (40 °F) temperature change will change the average case depth by 0.28 mm (0.011 in.)
- Quench pressure: Pressure in the range of 55 to 83 kPa (8 to 12 psi) has no effect on the case depth
- Rotation speed: No effect on case depth in the 10 to 60 rev/min range

Noise factors include:

- Material hardenability, the major factor (72%) affecting the case depth
- Case depth, which varied little from station to station

Additional Factors. Similar analyses were carried out for the other characteristics of surface hardness, distortion, and scale. Some of the observations are:

- The severity of the thermal cycle to which the shaft was subjected greatly influenced the spline size change. For example, shafts heated with the lowest heat 120 s/m × 90% V input (or 36 spf × 90% V) in combination with the slowest quench rate (50 °C × 55 kPa, or 120 °F × 8 psi), had significantly less spline distortion than the shafts heated with the maximum heat input, and quenched at the fastest rate
- The theory that a deeper case depth produces greater size change was *not* proven in this experiment (see Table 8)
- The material contribution to the spline size change was 53%, possibly due to hardenability differences, or to differing amounts of cold work in the various bars
- Analysis of total indicator runout (TIR) of the parts gave the same conclusions as those reached with spline size change
- The minimum scaling was achieved with the fastest scan times (less time exposed to oxygen at high temperature)
- Surface hardness was not significantly affected by the range of process factors allowed in the experiment

Table 8 Effect of average case depth on spline size distortion

Material	Average case depth		Spline size change	
	mm	in.	mm	in.
M1	3.73	0.147	0.038	0.0015
M2	5.66	0.223	0.013	0.0005

Overall Optimum Condition. Table 9 shows the preferred conditions when the process factors are taken into consideration as a whole.

Table 9 Signal-to-noise ratio analysis of process factors that produce optimum characteristic conditions in a yoke-spline shaft

Characteristic	Experiment No.[(b)]	Process factor								
		Scan speed		Power supply		Quench temperature		Quench pressure		Speed of rotation, rev/min

	C3	. . .	. . .	. . .	. . .	50	120	. . .	. . .	. . .
	D2	. . .	. . .	. . .	. . .	. . .	. . .	70	10	. . .
	E2	. . .	. . .	. . .	. . .	. . .	. . .	. . .	. . .	30

(a) TIR, total indicator runout.

(b) Underline denotes best signal-to-noise ratio for that variable.

Table 9, along with human interpretation, provides the information required to make a decision as to the best overall choice of a parameter combination, as follows:

Experiment No.	**Process factor**	
A1	Scan speed:	110 s/m (36 spf)
B2	Power supply:	94% (750 V)
C3	Quench temperature:	50 °C (120 °F)
D2	Quench pressure:	70 kPa (10 psi)
E2	Speed of rotation:	36 rev/min

It should be noted that a verification test is necessary to determine whether the predicted outcome will be attained. If the outcome of the verification does not meet the expected improvement, then, it must be concluded that the experiment was unsuccessful in locating the optimum parameter settings or that the dominant parameters were not located.

The final results after optimum parameter selection are shown in Table 10.

Table 10 Optimum characteristic parameters as determined by signal-to-noise analysis of a yoke-spline shaft

	Parameter								
	Effective case depth		Surface hardness, HRC	Spline size change		Out-of-straightness, TIR[(a)]		Heat treat scale	
	mm	in.		mm	in.	mm	in.	mg	oz
Average	4.78	0.188	56.3	0.02	0.0008	2.97	0.117	648	0.0229
Goal	4.83	0.190	58	0.00	0.0000	0.000	0.000	0	0

(a) TIR, total indicator runout

Conclusions. The conclusions that were drawn at the end of the exercise were:

- The relationships between the induction hardening process parameters and the resultant characteristics can be successfully established by the design of experiments method
- Both metallurgical properties and dimensional changes can be controlled to some degree in the induction hardening process
- The amount of prior cold working and/or hardenability of the 1040 steel bar is the most significant factor affecting variations in case depth (72%), surface hardness (18%), spline size change (53%), and TIR (12%)

The following recommendations resulted from this SPC analysis:

- The hardenability of 1040 steel should be controlled to an ideal diameter range of 24.4 to 32.0 mm (0.96 to 1.26 in.)
- The cold working operators should review methods of controlling and reducing residual stresses

Example 2 shows the general application of design of experiments techniques to locate and tune the vital process parameters. Other areas where this technique has been successfully utilized to improve process reliability include press quenching of gears, gas carburizing, and quenching of aluminum.

Monitor/Control Decisions

There are many process parameters of interest in almost any heat-treating operation. These fall into three categories:

- Those variables which *must* be closely controlled in order to have the process occur (for example, temperature, time, and so on)
- Variables that are known to affect the process but are either ignored or simply monitored manually because of the complexity or cost involved
- Variables which cannot be controlled at all (for example, natural gas composition, available heat input, and so on)

On a batch atmosphere carburizing furnace, for example, the common variables that can affect the carburizing process and should be compiled are:

- Temperature
- Atmosphere carbon potential (see the article "Control of Surface Carbon Content in Heat Treating of Steel" in this Volume)
- Time
- Endothermic gas flow (see the article "Furnace Atmospheres" in this Volume)
- Enriching gas flow
- Atmosphere circulation
- Quenchant properties (temperature and agitation)

While the first two on the list, temperature and carbon potential, will commonly be automatically controlled and the third, time, will usually be held fairly closely by either automatic or manual means, the last four on the list often go without notice *until a problem develops*, at which time they are examined.

In keeping with the idea that statistical process control represents *preventative* action (in that out-of-control indications should arise before out-of-tolerance conditions arise), these other critical variables should obviously be given more attention, possibly on an automatic, ongoing basis.

The decision to control, monitor, or ignore a given variable is a decision that must be made by taking into account the importance of the variable and the ease with which it can be measured. This decision is ultimately a balance of economic and quality considerations. The diagram in Fig. 6 shows a more complete picture of the number of possible variables involved.

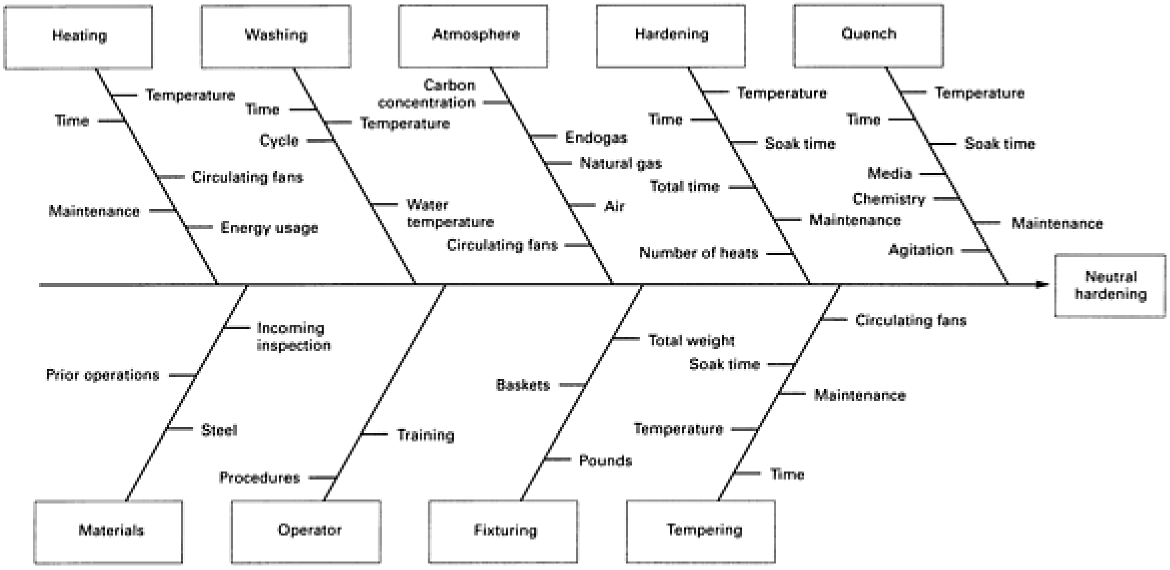

Fig. 6 Identification of heat-treating variables for the neutral hardening process

The subject of sensors and sensor technology becomes important at this point.

The focus of the data acquisition problem becomes one of finding sensors and sensor technology suitable for use in the heat-treating environment. It turns out that this is indeed a significant problem area for a variety of reasons that will be outlined later. In general, there are five critical areas of concern:

- Sensor selection
- Signal conditioning
- Control using the sensor
- Sensor maintenance

- Documentation and training

Sensor Selection. A sensor can be anything from a limit switch to a thermocouple to a pressure transducer to an electronic flowmeter.

Proper sensor selection begins with the identification of a process variable worthy of measurement. The cost of reliable measurement versus the importance of the process variable must be evaluated closely. Temperature happens to be a process variable that is usually extremely important, and a significant investment is usually made to ensure the accuracy of its measurement.

Time is also usually a critical variable, but ironically, it is still common practice to see it measured by a wall clock subject to an operator's convenience.

The signal conditioning process encompasses all those things that go into making the raw sensor data into a valuable bit of stored data. For example, the tripping of a limit switch may mean nothing by itself, but the time between two consecutive trips might be an extremely valuable piece of data.

Sensor maintenance has to be a major consideration. It does no good to put sensors on a furnace only to find that false readings are constantly coming up because of dirt build-up or other problems. Many times it is necessary to spend much more money on sensor insurance systems than on the sensors themselves. For example, an oxygen probe that constantly accumulates excessive soot in a high-carbon atmosphere may need an elaborate carbon burn-off system added to it just to get consistent and reliable readings.

Documentation and training are key elements because they determine the long-term success rate of sensor usage. The operators and maintenance people must be aware of the theory of operation and the limitations of the equipment.

Temperature Parameters. Temperature measurement and control is the most fundamental measurement in heat treatment and deserves separate consideration in this discussion.

Temperature Measurement. Temperature in the ranges of interest in heat treatment are generally measured by one of two methods: thermocouple or infrared pyrometer.

Because of its low cost, simplicity of construction, and inherent reliability, the thermocouple has always been and continues to be by far the most useful sensor in most situations. It is perfect for sensing gas temperatures, and even works well in vacuum furnaces by virtue of radiation. They are not very useful, however, for measurement of the actual temperature of parts going through a furnace.

Because thermocouples often fail slowly by losing accuracy and because two thermocouples inserted at the same time will often agree even as they are both failing, it is important to change thermocouples on a regular schedule and to alternate replacements.

Aside from the obvious process-related temperatures that are measured, it is possible that the temperature of nonprocess related items like cooling water temperature to bearings and door seals might be of interest. Thermocouples are most often used for these purposes.

The science of infrared temperature measurement has come a long way in the last 10 years. Most of this type of equipment is used in induction hardening but many have been applied with mixed results in enclosed furnaces. In these situations, results are usually better if the furnace does not use a hydrocarbon atmosphere, as the presence of soot in the optical path presents a problem.

Furnace temperature uniformity is always of tremendous concern, especially in vacuum applications where there is no convection to help even things out. While the process of making a furnace uniform with respect to temperature may be difficult, the actual uniformity results are easily documented with multiple thermocouples.

It is not at all out of the question to monitor uniformity by permanently placing thermocouples in several furnace locations and automatically calculating and alarming against their average and spread. This approach has been used for years with vacuum furnaces (where uniformity becomes more of a function of loading).

The observation of temperature measurements in a furnace under control gives some insight into how this might be handled from an SPC standpoint (see Fig. 7), where a control thermocouple is being held very closely to a setpoint (for a C_{pk} > 10), while a companion thermocouple in a different location is showing a C_{pk} = 1.2. The controlled thermocouple is of very little interest, as it will probably not deviate from the setpoint unless there is some drastic change. The subtle information from the monitoring thermocouple is of much more value in evaluating uniformity and the repeatability of uniformity which can be another problem.

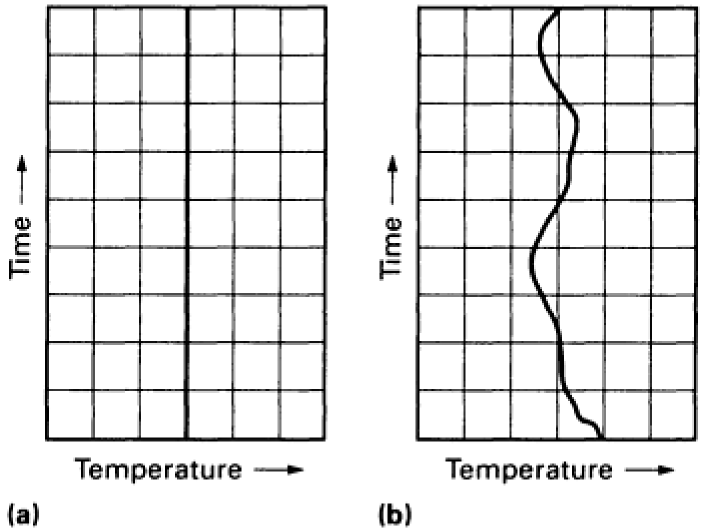

Fig. 7 Comparison of instrument temperature variations. (a) Controlling thermocouple, C_{pk} > 10. (b) Monitoring thermocouple, C_{pk} = 1.2

Combustion Efficiency. Because gas-fired burners have historically been the least expensive device to heat most nonvacuum furnaces, there has always been interest in attempting to keep them firing at optimum ratio. This was previously done using portable oxygen analyzers or with manual carbon dioxide checks. Most recently, interest in using low-cost automotive-style oxygen sensors has become possible.

Although there is nothing to prevent the *relative* measurement of burner efficiency from day to day with such techniques in an inexpensive format, it is very difficult to measure on an absolute scale that the burner is actually always firing at optimum ratio. This situation is the result of problems with sensor positioning and interpretation of results. For example, in a high-low fire system on a radiant tube in which the sensor is positioned opposite from the burner, the sensing system would have to ignore the first few seconds of high fire as the old exhaust gas is blown out. If the high fire cycle was very short, the sensor readings would mean very little. If the cycle is longer, the temperature of the sensor would change rapidly, making it necessary to provide a compensating thermocouple to make the sensor output meaningful. This complication requires a relatively high-cost measurement system to utilize the low-cost sensor.

Furnace Chamber Atmosphere. Measurement of various parameters associated with gases in a furnace chamber are of particular importance for controlling many heat-treating processes.

Gas Pressure Level. The manual measurement of pressure in a furnace atmosphere is usually done with a water manometer, with levels generally in the range of 0 to 25 mm (0 to 1 in.) water column. The reading is actually a differential reading between the inside and outside of the furnace. Inexpensive pressure transducers that produce high-level signals (for example, 4 to 20 mA) for this range are readily available, but care must be used to ensure lone-term reliability of this signal due to plugging or partial closing of tubing to the transducer.

Transducers which feature an analog display of the pressure reading as well as the retransmission signal are most useful when the signal must be trimmed for calibration. The transducer should have its own zero and span adjustments for maximum flexibility.

Furnaces in which the pressure is constantly varying over a wide range because of opening and closing doors or other upsets will require intelligent signal conditioning that ignores the peaks and valleys in the pressure.

Atmosphere pressure is sometimes controlled in a closed loop with an actuator-driven atmosphere effluent damper. This device also helps to keep the atmosphere pressure constant.

Vacuum Level. Measurement of vacuum level has been done with a variety of methods, but two of the most common have been the thermocouple gage for lower vacuum levels and the cold cathode gage for higher vacuum ranges.

Recently a fourth method has been added for measurement all the way down to 13 nPa (10^{-10} torr), based on a hot filament ionizing the residual gas. All methods except capacitance manometer are subject to error of the composition if the residual gas is different than expected.

A typical vacuum furnace will generally require at least two sensors to accurately cover the full range that the furnace is capable of operating within. Also, it is often desirable to check vacuum levels in various spots, including the foreline and vacuum chamber itself.

A microprocessor-based instrument that will automatically select the required sensor in the range of interest is required. These newer instruments also provide computer communications capability that makes data acquisition easy.

It is anticipated that a version of the zirconia oxygen sensor, discussed in the section "Analysis of Gas Composition" in this article may be applied successfully in vacuum furnaces in the future. This would represent a major step forward in vacuum technology, as low oxygen levels are desirable when high vacuums are used. The oxygen probe would then provide a direct measurement of this gas.

Additional information is available in the article "Heat Treating in Vacuum Furnaces and Auxiliary Equipment" in this Volume.

Process Gas Flows. Measurement of process gas flows in controlled atmosphere furnaces generated interest recently. There are several methods available, each varying widely in cost. The selection of a particular method must be made with extreme care because the cost of gas flow measurement must be kept in balance with the other data acquisition elements in the overall instrumentation plan.

The least expensive method to measure gas flows is with simple flow switch devices. These devices almost always operate on the principle of a pressure drop (and pressure switch) across a fixed orifice in the gas stream. Their limitation is that they can only sense whether flow above a certain fixed amount is present or absent. However, by combining two flow switches in the gas stream set at different points, it is possible to ascertain whether a gas flow is above the high limit, in the desired range, or below the low limit.

Flow switch arrangements are especially suited for gas flows that do not vary (for example, endothermic or exothermic generated gases and nitrogen) or even liquids like methanol.

Typical plumbing component costs for a dual flow switch arrangement might be in the $100 to $200 range for a single gas line. Control strategy using this technique is to have the data acquisition system sound an alarm whenever the gas flow has dropped out of the desired range, with human intervention required to correct the flow.

If an exact value of gas flow is required, there are two techniques:

- Electronic true mass flowmeters
- More familiar rotameter types with electronic adaptors

Both of these may require external power supplies and care in system wiring.

The true mass technique uses the principle of measuring the amount of heat that the gas stream can remove from a heated bulb of controlled temperature. This technique has the advantage of being inherently accurate (if the flowmeter has been calibrated against a known flow) regardless of pressure fluctuations. It has the disadvantage of being a blind technique, with the electronic signal (typically 4 to 20 mA) being the only indication of flow.

The rotameter technique, while slightly more expensive than the true mass technique (approximately $1500.00 per meter), has the advantage of having two outputs: a visual one by virtue of the float scale (see Fig. 8) and an electronic one by virtue of electronic position sensing of the same float assembly. The disadvantages of the rotameter technique lie in resolution and accuracy; the measurement is sensitive to temperature and pressure variations (good upstream regulation is required), and the electronic signal may only resolve to ±2.5% of scale. However, this technique is still preferred because of long-term calibration considerations.

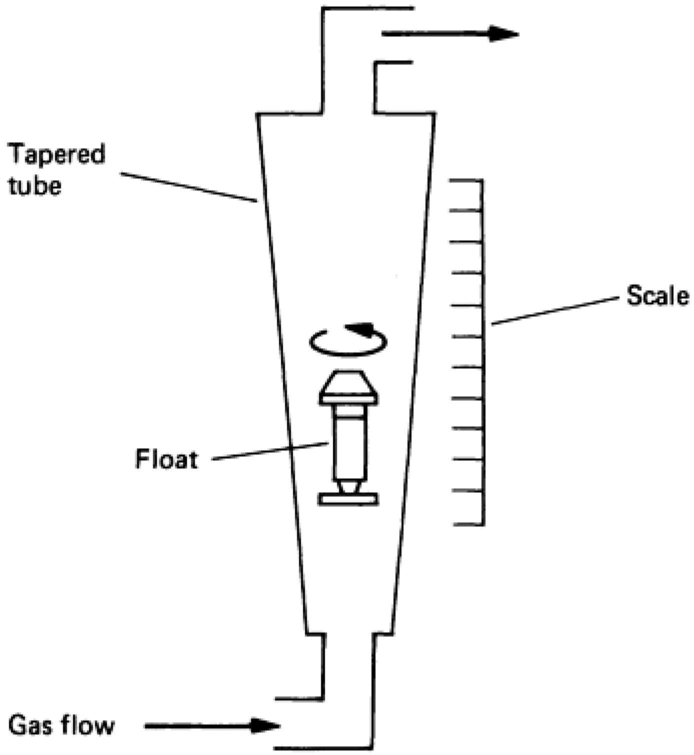

Fig. 8 Schematic showing key visual output components of a rotameter

Measurement of low liquid flows, such as in nitrogen-methanol systems, is best done with the rotameter system. However, the viscosity of methanol changes quickly with temperature, and for maximum accuracy it is necessary to electronically compensate the temperature readings from a rotameter-type device accordingly.

Control of gas flows is usually done with an adjustable port valve and motor actuator. The most easily installed and maintained motor actuator is one that accepts an electronic signal (for example, 4 to 20 mA) and positions itself accordingly. Motors that employ a slidewire feedback technique are not always desirable because of long-term maintenance problems.

One problem with motor-actuated control valves is that the flow is not proportional to the value position. For example, it is possible to have signals of 0% open and 100% open do just what is expected, while finding that the 50% open signal gives a measured gas flow of 20% of scale. This is due to a variety of factors, including linkage adjustment, pressure drops in the piping, and the inherent nonlinearity of valve ports.

Corrosive gases such as ammonia require stainless steel construction that makes these valves more expensive.

Another completely different technique of measuring and controlling gas flow that can be used in many cases is the pulse time-proportioning system. For example, if a simple on-off valve is set up in such a way that when the valve is open there is a fixed, known flow through it, then the average gas flow is always easily calculated by the formula:

$$\text{Average flow} = \frac{\text{Valve ON time}}{\text{Valve ON time} + \text{Valve OFF time}} \times \text{Flow when ON} \qquad \textbf{(Eq 2)}$$

If the ON and OFF time are automatically varied and kept short with respect to the furnace size, this type of arrangement will provide a most cost-effective, easily calibrated system for measuring and controlling gas flows. The power to perform ON and OFF time cycle control is easily found in many of the most powerful process controllers on the market today. In the case of two process gases that must stay in ratio with each other (for example, nitrogen-methanol), it is possible to design an electronic control system to measure both process gases and control one or both of them to maintain constant ratio, using the techniques outlined above. The cost of such a system can be very high, but varying methanol flow is a common problem that can significantly impact process results.

Analysis of Gas Composition. The following measurement techniques for the composition of furnace atmospheres have successfully been used:

- *Oxygen probe:* Good for measurement of oxygen levels below 0.01%, and with inference can be used to calculate percent carbon potential in a known CO gas, or percent water in a known H_2gas. Advantage of in-situ measurement and good reliability. Frequent calibration not required
- *Infrared absorption:* Good for measurement of CO, CO_2, or CH_4 concentration in ranges of interest in hydrocarbon atmospheres. Same unit can be configured to measure all of the above gases simultaneously if desired, which allows accurate calculation of percent carbon potential. Cost is high, with multiple furnaces usually routed to a single analyzer. Frequent calibration is required. Major disadvantage is that sample of gas must be transported to analyzer
- *Dew point:* If measured by variable pressure change/condensation method, results by inference can be used to calculate percent carbon potential against known carbon and hydrogen gas levels. Disadvantage is that measurements are physically difficult and operator technique and interpretation may play a major role. Sample must be transported to the analyzer. Although there are automatic dew point-measuring systems, none has worked for extended periods in hydrocarbon atmospheres without a significant amount of preventative maintenance having to be done on the system
- *Mass spectrometer:* Can determine the composition of gas completely, except for inaccuracies at low levels with some gases. Calibration is difficult. Other disadvantages are cost, required operator skill level, and sample transport. Rarely used on-line in heat treatment
- *Gas chromatography:* See mass spectrometer

While complex gas analysis systems have not yet found their way into day-to-day process control operations in heat treating, they may be of value in an off-line mode for a situation as shown in Fig. 9. Here the results of gas analysis, specifically heavy hydrocarbons, are plotted over the course of a year. The trend shows the shifting gas supplies (presumably as a result of demand). An on-site gas analysis could provide valuable information when evaluating furnace atmosphere quality problems.

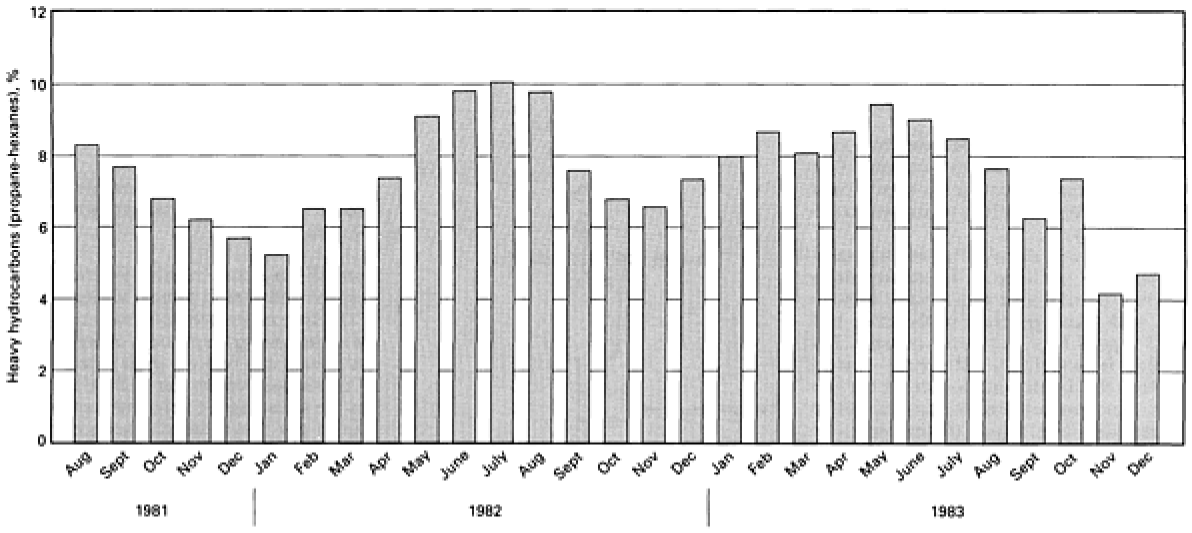

Fig. 9 Variation in natural gas composition monitored in the Canton, OH, area over nearly a 2 $\frac{1}{2}$-year period

Atmosphere Agitation. The measurement of atmosphere agitation has not been successfully done at this writing, but this certainly would be of interest, as failed atmosphere circulation systems are a common problem. A system based upon a windmill concept is the most obvious, but other possibilities exist, including measurement of heat flow into a cooled bulb in the atmosphere circulation path. In the not-so-distant future, a system will almost certainly have to be developed.

Quenching Parameters. The area of rapid cooling during a heat-treating process, generally referred to as quenching, has been perhaps the biggest source of the "black art label" put on heat-treating operations. Many heat-treating facilities have the latest microprocessors for furnace control. However, these facilities have virtually no monitoring capability for the quenching operations that can have as significant an effect on results as any other parameter (see Table 1).

Quenchant Bulk Temperature. The measurement of quenchant bulk temperature is generally the *only* measurement undertaken in most shops. Often this is a monitor-only function, with no feedback control of system heating or cooling involved.

From a data acquisition standpoint, it is interesting to look at the bulk temperature during the actual quenching operation, noting any changes. Typically the starting temperature and the highest temperature reached are recorded.

In low agitation quench tanks, care must be taken to ensure that the temperature measured is truly indicative of the bulk temperature.

Quenchant Viscosity. The viscosity of liquid quenchants, especially polymers, is an important indication of composition. In oils, it can be an indication of oil aging or contamination.

Viscosity may be measured in-situ, but the results will vary with temperature, making it necessary to compensate for variations in temperature.

Quenchant Media Composition. Measurement of composition (and contamination) of quenching media has become an important area of concern in recent years.

In the case of quench oils, the parameters of additive levels, alkalinity, oxidation or sludge content, and water content have come to be recognized as being of significant importance. Because the costs of these products have increased significantly in the last 15 years, much effort has been expended learning how to make a tank of oil last longer through the use of additives and cleaning. Unfortunately, none of the tests required for oil composition determination are suited to real-time data acquisition, except for water content analysis. Unfortunately, many commercially-available water-in-oil

analyzers are subject to frequent malfunctions and while required for safety reasons, are not really suited to the purposes being discussed here.

Solutions of various polymers in water have the common characteristic that the concentration of polymer (which combined with the degree of agitation determines quenching performance) is usually easily measured with temperature-compensated viscosity sensors, as mentioned above.

Solutions of salts and other additives in water are commonly monitored with specific gravity determination. While this test is easily done with a hydrometer in the lab, it is not so easy to do in-situ in an automated data acquisition environment.

Quenchant Agitation. While the primary heat removal rate in a quenching system is generally considered to be a function of the quench media, there is the significant modifying effect of agitation. Agitation of a quenchant is a parameter that is easily controlled with variable-speed propellers or pumps. However, measurement of this agitation, which may be different from time to time depending on load size and configuration, is another matter.

First, there must be agreement on what units agitation is to be measured in. Most people would agree that units of velocity (for example, feet per second) or volume (for example, gallons per hour) are logical, but this does not always account for the *pattern* of flow in a given load and how this pattern might change load to load, with identical velocities.

It is intuitive that measurement of pump or propeller and angular velocity and subsequent linear velocity calculation is not going to be indicative of what's really happening in the quench tank. (What if the propeller motor is still running but the propeller has fallen off, or the flow of quenchant is blocked somewhere else in the system?) It may then be necessary to place a sensor, commonly configured as a tiny free-spinning turbine, in the flow stream directly ahead of or behind the load to directly monitor the quenchant flow rate.

The problems with these systems are two-fold. First, the turbine may become clogged with solid contaminants and give a falsely low reading. Secondly, it is often difficult to position the spinner so that it can provide an accurate measurement.

Quenchant Cooling Efficiency. Perhaps the largest area of interest in terms of quenching parameter control is in the measurement of actual cooling performance of a quenchant with a standardized test. In the past few years, a number of quenching evaluation tests have been developed for laboratory use that operate by heating and quenching a probe with an embedded thermocouple into a sample of the quench media under test. The results are often presented as raw cooling curves, or perhaps as plots of instantaneous cooling rate against probe temperature (see Fig. 10).

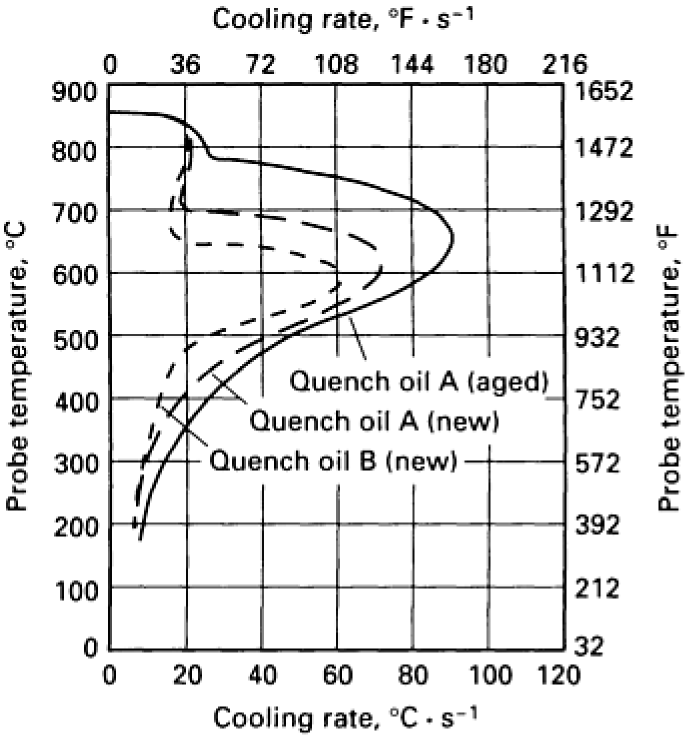

Fig. 10 Probe cooling rate curves for quench oils having approximately the same GM quenchometer and viscosity values

The availability and use of this equipment has led to a push for a standard quenchant evaluation procedure. Unfortunately, the SE tests are all manual and cannot to date be made in-situ by an automated data acquisition system.

Mechanical Motion Components. The idea of including mechanical items like doors, quench elevators, pusher mechanisms, and fans in the category of process data acquisition and statistical process control may seem a little strange. However, when one considers the impact of any of these items malfunctioning or failing during a process, it is easy to see that the consideration of these mechanical items has merit.

Fans and Pumps. Atmosphere and quench circulation/agitation systems are vital to the success and repeatability of any process. If the idea of measuring the *effect* of the circulation system (that is, atmosphere or quench velocity) is not practical, then the next best thing is to infer that all is normal by measuring some other characteristic of the circulation system.

There are several devices available capable of measuring fan and pump speeds:

- *Zero-speed switches:* Relatively inexpensive (that is, $300 to $400) devices are easily positioned near a driven rotating shaft or wheel so that rotation above a certain minimum speed can be verified.
- In the case of belt-driven devices, this is invaluable because it is the only way to detect belt breakage or slippage
- *Current switches:* Also inexpensive (that is, $200 to $300 per phase), these simply verify the presence of a current above a certain value. In the case of a belt-driven oil pump, normal operating conditions will see the motor drawing a current of perhaps 5 A. If the belt suddenly breaks, or the prop falls off, the motor current draw will quickly drop to perhaps 3 A. If a three-phase motor is involved, a decision as to whether all three phases be monitored must be made. Other applications for current switches include belt drive motors in belt furnaces, where increased current draw might mean a belt getting bound up
- *Current transducers:* Similar to the current switch, except a low-level signal (for example, 4 to 20 mA) is developed that is proportional to the current being drawn. The application of a current transducer over a current switch would be determined by the complexity of the data acquisition hardware available.

Current transducers are useful with quench oils, as they will show the current draw of the agitator rising and falling with oil temperature and load density

Belt and Rotary Retort Mechanisms. The measurement of belt speeds and feed rates on furnaces provides useful process information in that the product residence time as well as load sizes, densities, and their respective uniformity may be directly or indirectly measured or controlled. In the case of constant-rate mechanisms like furnace belts, there are several methods:

- *Tachometers:* Most obvious choice for measuring almost any motor-driven device. The advantage of tachometers is that they are very fast at providing information on otherwise slow-moving mechanisms. The problem with tachometers is two-fold: first, they are measuring the motion of a *driving* member instead of a *driven* member; and second, they usually rely on transmission of the reading by analog means, setting up more calibration problems
- *Limit switches:* Measuring any slow mechanical motion such as belt travel, drum rotation, or mechanism indexing is quite simple with a limit switch in combination with a known time base. For example, on a belt, a driven sprocket often provides a reliable spot to pick up a periodic pulse on the limit switch. The frequency or duration of this pulse can be directly related back to belt speed. The disadvantage of this type of technique is that the information sometimes takes quite a while to collect

Furnace Loading Rates. The limit switch philosophy applies to furnace loaders as well. We are able to obtain a pulse-type loader frequency based on the time between actuation of limit switches, in combination with an analog or even digital weigh scale. Useful statistics such as pounds per hour may be compiled and data logged, and process adjustment based on weight may be initiated.

Load Tracking. The tracking of loads through multitray furnaces or through multifurnace plant layouts is an idea that is rapidly gaining interest for documentation and SPC purposes.

The data acquisition system monitors relevant mechanical signals that determine when a tray has been moved from one position to another. The data being collected are sorted and assigned only to those trays for which they are applicable. For example, the computer record for a given tray in a large pusher furnace will end up containing the average temperature for zone 2 for the period during which the tray was actually in zone 2. Also present in the record will be the times that the tray entered and left zone 2.

The sorting and storing data using this concept will not be possible with many data acquisition systems currently available. Care must be exercised in equipment selection if this type of instrumentation is to be a requirement.

Mechanical Performance. There is a wealth of data available having significant impact on the process that can be gathered by simply watching and analyzing existing limit switches, resolvers, and signals already available on many furnaces.

For example, it may be desirable to measure and log the amount of time required to move a load from the hot zone to the quench operation. This result will vary over time and can warn of serious mechanical problems before they affect the process.

Looking at actual push times on a large continuous pusher furnace against *specified* times is often enlightening. Conversely, looking at the number of pushes made during a fixed time period may also be of interest.

Vibration Monitors. Any furnace that uses motors can develop an excess vibration due to an imbalance, bearing failure, and so on. Vibration sensors can be strategically mounted on the equipment to detect this problem before a catastrophic failure occurs.

Although rather expensive ($500 or more), units are available that can transmit a low-level signal that is proportional to the amplitude of the vibration cycle. The data acquisition system would have to be smart enough to ignore the sensor during heavy mechanical operations (for example, doors opening).

Signal conditioning can be described as the science of making sensor data useful. It has nothing to do with alarming the system. The basic requirement in dealing with furnace data is flexibility in conditioning options.

Discrete data is, very simply, ON-OFF data. For example, a fan is either running properly or it isn't; a gas flow is either in range or it isn't.

Conditioning of discrete data is usually a matter of telling the data acquisition system when the data are valid and when they are invalid.

Sometimes complex counting and timing schemes are required to coax the meaningful data out. This means that the primary vehicle for conditioning is software.

For example, a nitrogen flow switch is only valid if there is supposed to be nitrogen flowing. A quench cycle time measurement can only be done when a quench cycle is in progress.

Continuous (Analog) Data. A 1000 to 1200 mV signal from an oxygen probe is a good example of analog data. We may find that this signal is overly noisy and that some hardware low-pass filtering is required to smooth it out. The signal might be combined with another analog signal from a thermocouple (which has to be cold-junction compensated and linearized). This is typical of classic analog signal conditioning. The result of the combination is the calculation of a third piece of analog data, which is percent carbon. This final process is an example of advanced analog signal conditioning done in the digital domain.

Many analog signals need to be validated. For example, the reading from an endothermic flowmeter is only valid when endothermic gas is really flowing.

Closed Loop Control Monitoring. It should go without saying that any instrument used to control temperature in heat-treating operations should have computer communications capability for data acquisition purposes.

Most temperature control applications in heat treating are of the on-off type, such as electrical contactors for heating elements or high-low fire systems for combustion burners. Others are proportional, utilizing stoichiometric gas-air ratios for burners or variable current systems for heating elements.

All of these systems have a common effect of delivering a certain amount of energy to achieve and maintain the furnace at a given temperature. The amount of energy may be known by *direct* measurement with gas or electrical meters but *relative* measurements may also be made by more advanced instrumentation doing the control.

The amount of energy consumed is of course important from a cost standpoint. It is equally interesting, however, from the process/data acquisition standpoint. If the relative amount of energy required to heat and maintain a given furnace at a given temperature is known, then any additional energy consumed by any process run in this furnace must be absorbed by the load. This effect has been successfully utilized in helping to determine when loads are at heat, as shown in the following figures.

Notice in Fig. 11 how the heat input to the process drops down to some equilibrium value after the process has reached setpoint. This is the point at which heat input to the furnace equals heat loss through the walls and atmosphere effluent.

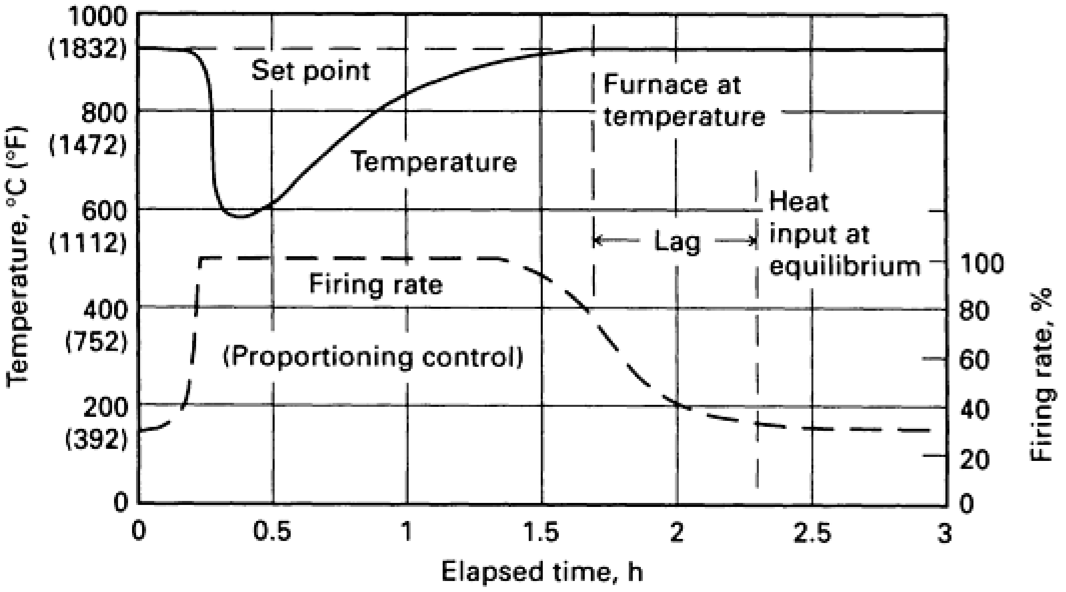

Fig. 11 Plot of furnace temperature versus elapsed time to show that heat input equilibrium lags behind attaining of setpoint temperature after furnace loading

When load size is varied, as happens in most shops, the process suffers because of a lack of input as to how this might affect the results. By taking into account a very inexpensively-acquired piece of information such as the percent output of a properly-tuned proportioning temperature controller, it is possible to begin compensating for load size by taking advantage of the fact that a heavier load requires more heat to reach setpoint.

The effect of load size on heat input is shown in Fig. 12. Notice that although the light and heavy loads have a relatively minor effect on how long it takes for furnace temperature recovery, load size has a potentially dramatic effect on heat balance equilibrium.

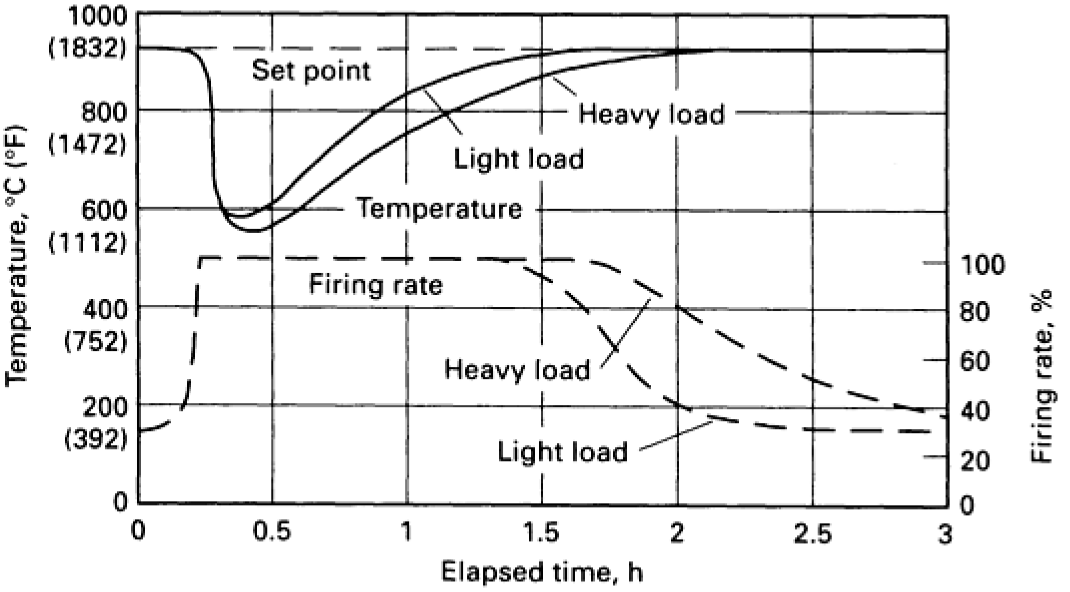

Fig. 12 Plot of furnace temperature versus elapsed time to show effect of load size on heat balance equilibrium

In terms of data acquisition, the heat input to a furnace is a piece of information that is usually easy to capture and might be of significant value in learning to more tightly control the process.

Computerization of SPC/SQC Systems

The ideal data acquisition system has the following capabilities:

- It has plenty of discrete and analog inputs, electrically isolated, with automatic, configurable linearization, filtering, and other conditioning options
- It is easily software-configured to perform both data acquisition and control tasks
- It is easily networked with other plant equipment if required

Figure 13 demonstrates how a deviation in the measured surface carbon in a carburizing process may or may not be traceable to a deviation in some process parameters that are being logged by an automated SPC system. In Fig. 13(a), a period of high surface carbon readings is observed, with a subsequent return to nominal.

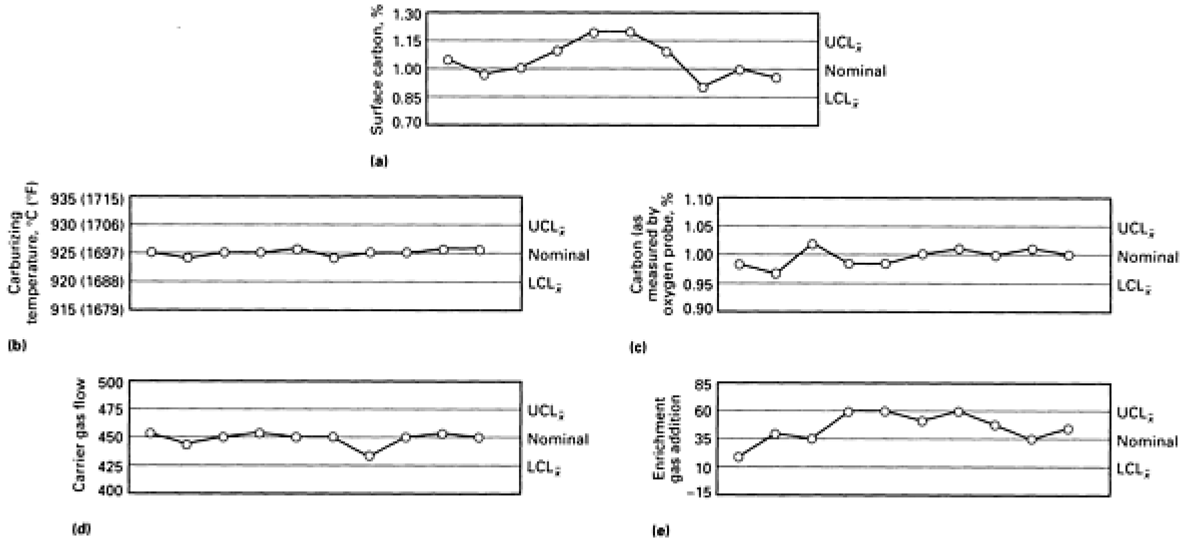

Fig. 13 Plot of several process-related characteristics for a carburizing process. (a) $\bar{x}$-chart of surface carbon concentration in carburized parts. (b) Average temperature during carburizing cycle. (c) Average carbon concentration measured by oxygen probe during carburizing cycle. (d) Average carrier gas flow during carburizing cycle. (e) Average enrichment gas addition. Note correlation of graphs (a) and (e). UCL$\bar{x}$, upper control limit on an $\bar{x}$chart; LCL$\bar{x}$, lower control limit on an $\bar{x}$chart

Figure 13(b) examines a controlled variable, temperature, and finds no deviation. (It could be argued that it is a waste of time and effort to chart this variable in this fashion because it could be handled much more efficiently with a simple deviation alarm in real time.)

Figure 13(c) looks at what *should* be the answer, the readings from the oxygen probe that was in control of the atmosphere carbon potential. Unfortunately, no deviation is noted because again, carbon potential is a controlled variable. The control system would have done anything in its power to keep that reading at setpoint at all times. It might be concluded from this chart that the oxygen probe control system was in error, perhaps because one of its base assumptions (for example, a fixed carbon monoxide concentration) was not as expected during the period in question.

Figure 13(d) shows a chart of carrier gas flow that will naturally show no significant deviation because the operator who is responsible for keeping it at the desired value is the same person who must chart it. (This points out that the automation of data collection is required if the integrity of the data is to remain unquestioned.)

Figure 13(e) gives a clue. It is noted that during the period in question, the enriching gas flow was at or near the upper control limit by action of the automatic oxygen probe control system. (Ironically, in years past, where control of atmosphere carbon potential was manual against a dewpoint-measuring instrument, this would have been picked up as a potential problem right away by an experienced operator. With the advent in the mid-1970s of automatic oxygen probe control systems, especially those with simple on/off control valving, the ability to monitor trends in enrichment gas usage was typically either lost or ignored. Newer microprocessor-based units restore this capability, along with alarms for high/low enrichment flow.)

It is possible to imagine a special case scenario where for some reason the gas equilibrium in the furnace was upset to the point where the control system was calling for more enriching gas than usual, which could have resulted in an excessive residual methane content in the furnace atmosphere, which in turn could have produced a higher surface carbon on the parts than the oxygen probe system indicated. A number of things could have been the root of this problem, such as a furnace leak, a sudden rise in relative humidity (sending the endothermic generator out of control), or a change in enrichment gas composition. The important point is that if there had been sufficient monitoring of the enrichment flow from the start, the problem could have been noted and possibly corrected before any loads were affected. This would have been a successful implementation of statistical process control in a batch situation.

Integration of SPC and SQC

Combining the disciplines of statistical process control, which focus on the process variables, and statistical quality control, which focus on resultant product quality, offers the potential for real-time process improvement. Computer capability is required to statistically analyze data in a fashion that will allow timely adjustments to the process.

As a product characteristic (as-quenched hardness, for example) is shown to be trending away from average, a special cause, such as oil quench temperature, may be identified quickly. The ability to compare process variable trend charts to the product characteristics trend chart, for the same time period, offers a valuable tool for continuing improvement of the heat treatment.

This can be valuable information even if no special cause can be identified among the monitored process variables to correlate with a change in the product quality. This may lead the heat treater to an uncontrollable variable more quickly, such as material.

Modeling and Feedback for Process Refinement

The use of complete theoretical process models in real-time process control is not as far-fetched as might be imagined in some cases.

Forging Applications. The technique has, in fact, been applied very successfully, for example, in forging. Here it is used to provide accurate control of billet temperature during reduction, where the billet heat content is a function of thermal losses to the environment and thermal gains from mechanical working. The complex real-time model used to continuously calculate the thermal gradients within the billet (and control auxiliary cooling) is in use in many mills today.

Carburizing Applications. It has also been applied in carburizing, where complex models of the chemical, transport, and diffusion reactions are used in combination with more complete process measurement to construct a theoretical carbon profile in real-time and to provide feedback control to the process (Fig. 14). If this type of model had been in use in the previously cited SQC surface carbon deviation example, the process would have remained under control during the period in question. The problem, of course, is economics. In order to make such a real-time model completely accurate, it is necessary to provide much more information to it than is available from a simple oxygen probe. A complete carbon monoxide/carbon dioxide/methane infrared system, or even a mass spectrometer, would be required. This type of expenditure is widely (and understandably) viewed as impractical.

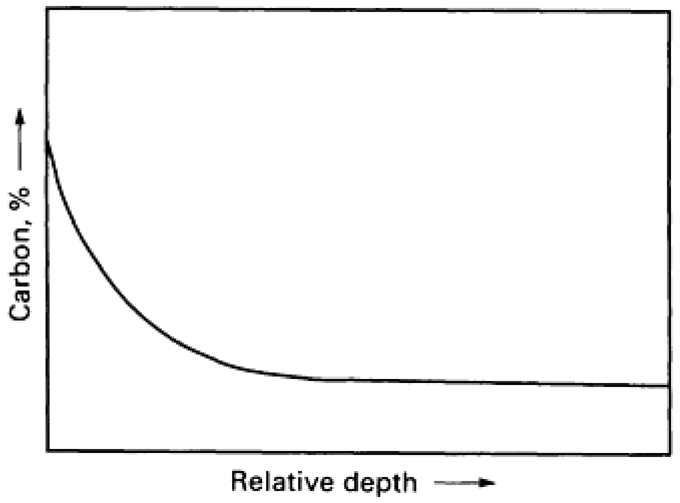

Fig. 14 Typical gas/solid reactions for the carburizing process showing carbon diffusion profile. Following diffusion and reaction of carbon monoxide, hydrogen, and methane gases, transport reactions at surface yield carbon dioxide, water, and hydrogen as byproducts.

Steel Hardening Applications. Other areas in heat treatment could benefit from real-time modeling. For example, the control of steel hardening is a function of many parameters that can be tied together by centralizing control of the process within a model built around a calculated continuous-cooling-transformation (CCT) diagram in a finite-element format for the material in question. The model could take into account the material analysis, initial microstructure, austenitizing temperature and time (and the resulting thermal gradient across the work piece just before quench), transfer time, quenching media type, agitation and temperature, and many other items. It would use real or calculated cooling curves superimposed upon the CCT diagram (Fig. 15) to determine final microstructure and hardness gradients. Another part of the model would specify (and of course monitor) the correct tempering temperatures and time required to achieve the desired finished results.

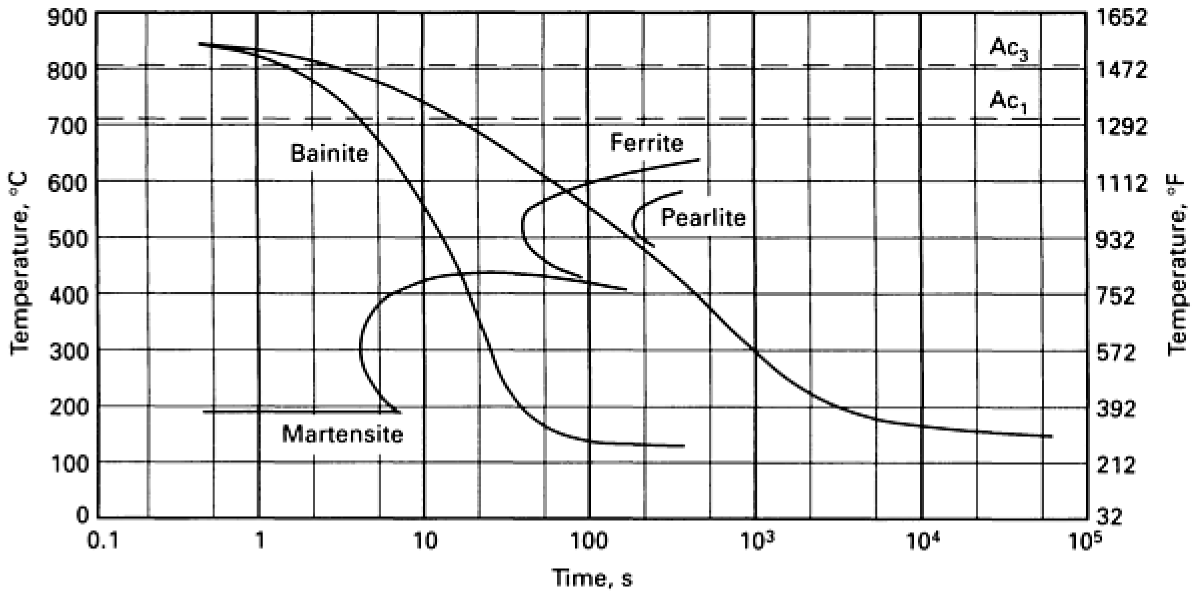

Fig. 15 Calculated CCT diagram from actual part composition with modeled part cooling rates. Ac_1: temperature at which austenite begins to form during heating. Ac_3: temperature at which transformation of ferrite to austenite is completed during heating

Quenchant Control. A model such as this would be extremely useful today in quenchant control. With the latest sophistication and standardization of quenchant evaluation methods, data such as those shown in Fig. 10 are now available. It has long been understood that trying to classify a quenchant by assigning it one number, such as in the electronic quenchometer test (the magnetic test method for the evaluation of quenchants), is convenient but often significantly misleading. A finite-element model for steel hardenability would be able to predict the difference in final microstructural and hardness results that would be obtained from the new versus aged oil in Fig. 10, for example. It would also allow "what if" testing of alternative oils, varying quenchant temperatures, and varying quenchant agitation.

Economic Considerations

The initiation of an SPC system always initially involves increased costs. In heat treating, as in most business environments, the economic benefit must be determined in order to justify this investment. In general, this benefit is derived from removing some of the traditional inspection plans that have been incorporated in the process to ensure that acceptable quality parts were produced.

From the acquisition and statistical analysis of sufficient data from the process, the improvements can be made in areas that make the most positive impact on product quality. Productivity improvements are also realized from knowing exactly how the parts need to be processed.

A classical example is soak time required to austenitize parts before quenching. By monitoring and analyzing the furnace heat input, the actual time the furnace reaches steady state can be determined. This method has replaced rules of thumb, such as one hour per inch of cross section for heat treatment. Improved productivity and energy conservation have resulted from the utilization of SPC systems.

In another situation, it was determined that the balance-beam scale-type loading mechanism for a continuous rotary retort furnace line operated within an accuracy of ±25% during the initiation of an SPC system. This led operators to underload the furnace in order to avoid overloading. The risk of overloading was that parts would distort excessively and not quench to maximum hardness. The loading system was replaced and upgraded to a digital load cell system with an accuracy of ±5%. The result was a 19% improvement in productivity.

Carburizing offers significant opportunities for productivity improvements through improved process control. If a typical carburizing specification requires a depth of 0.51 to 1.02 mm (0.020 to 0.040 in.), the traditional approach by the heat treater is to target 0.76 mm (0.030 in.) to give plenty of leeway for the uncontrollables. However, it is feasible to reduce the variation in the process so that the target can be reduced to 0.58 mm (0.023 in.) through SPC techniques. The resultant reduction in processing time results in a 25% increase in productivity.

True statistical quality control can be successfully and economically implemented today in a heat treatment shop to augment an existing SPC program. The major contributing parameters in each process must be identified and monitored or controlled depending on both economic and quality considerations. At some point in the future, today's investment in statistical process control or statistical quality control will pay off as the move to more complex process modeling for process understanding is developed.

Computerized Properties Prediction and Technology Planning in Heat Treatment of Steels

M. Gergely and S. Somogyi, Steel Advisory Center for Industrial Technologies, Hungary; T. Réti, Bánki Donát Polytechnic, Hungary; T. Konkoly, Technical University Budapest, Hungary

---

Introduction

COMPUTER SIMULATION is a method of computer application that is expected by heat treaters to yield great results in the future. In recent years, the establishment of prediction methods based on the phenomenological description and computer simulation of the transformation processes during heat treatment and the development of software for technological planning have been of major interest. The steady development of this topic is aimed at meeting the requirements of metallurgists producing basic materials, design engineers dealing with material selection and dimensioning, and technologists planning heat-treatment processes. In this article, the topic of computer simulation is restricted to quenched and tempered or case-hardened steels.

Basic Objectives of Computer Simulation

The development of computer simulation of heat treatments, which is obviously due to the widespread growth of computer miniaturization, has been motivated by several factors. Research in this field of computer simulation has been concentrated so far on two main areas of interest:

- Modelling of transformation processes and the prediction of microstructures and/or properties
- Developing program packages (designed in the majority of cases to be purchased on the market for direct industrial use) to help solve concrete tasks such as material selection, property prediction, and the design of heat-treating operations

These basic areas of interest are discussed briefly in the following paragraphs.

Material Selection. Design engineers, metallurgists, and heat-treatment technologists need to assess the effects of material selection on heat treatment, dimensional control, and distortion. Consequently, one basic objective of computerized modelling is the use of algorithms for material selection. This process may involve not only selection of the cheapest material or type of steel suitable for a particular application, but also the assessment of processing alternatives and their effect on manufacturing characteristics and properties.

Process Analysis and Optimization. By introducing computer methods, steel heat treatments can be analyzed and/or optimized in terms of product quality, property scatter, processing time, and energy consumption. For example, the energy consumption of a heat-treatment procedure depends on such factors as the temperature, duration, mass of charge, and equipment. A proper computer algorithm makes it possible to select the heat-treatment parameters that result in minimum energy consumption and optimum mechanical properties. Because of the many factors involved, reducing energy consumption is an optimization task that can be done only by applying a suitable simulation computer program.

Another important application of process analysis by computer simulation is in the area of product development and order bidding. During the development phase, time may be lacking for lengthy experiments, not to mention the ever-growing expenses of material testing in connection with heat treatment. Considerable time and expense can be saved by replacing heat treatment and time-consuming analysis by the computer simulation of heat-treatment processes. Furthermore, qualified labor force can also be spared to a certain degree.

On-Line Programs for Process Control and Monitoring. During recent years, the steady development of the control and monitoring of heat-treatment processes has called for, or rather, forced the development of new models and simulation processes. For example, the development of models and softwares for the prediction of carbon profile has been particularly encouraged by an up-to-date control of the processes during gas carburizing and by the monitoring of case properties. On-line heat-treatment programs can also assist in the monitoring and control of energy consumption.

Property Prediction. Both solving the problems during heat treatment and choosing the basic material and the set of characteristics can be hindered by the large number of property combinations. This is particularly true in the case of steel, which can be altered within broad limits merely by heat treatment (Table 1). These broad property ranges in Table 1, which are beneficial in some sense, can also be a problem for the user because it is difficult to decide which possible combinations of mechanical characteristics can be considered realistic, or realized at all, for heat treatment. Similarly, the type of heat-treatment technology that should be used and its degree of accuracy (that is, manufacturing probability) should be set to achieve a certain combination of characteristics.

Table 1 Range of property values attainable in quenched and tempered and case-hardenable steels

Property	Measured values
Hardness, HV (30 kgf)	130-700
Tensile strength, MPa (ksi)	400-2000

	(58-290)
Yield strength, MPa (ksi)	300-1800
	(43-261)
Elongation in 50 mm (2 in.), %	8-28
Reduction in area, %	5-68
Charpy impact, J (ft · lbf)	10-180
	(7-133)

Naturally, an experienced engineer or metallurgist is aware of the qualitative interrelations among the different properties and can decide off-hand which combinations obviously cannot be realized. For example, a tensile strength approaching the upper limit cannot be accompanied by the same degree of elongation. Yet, it can be quite complicated and time-consuming even for an experienced expert to choose an optimum combination of characteristics from the range of possible property variations. The situation is even more complicated if the variable of section thickness is added to the decision-making process.

General Description of Simulation Softwares

Simulation softwares can be classified either as on-line programs for process control or as programs to assist decision making and process analysis. The latter classification of software programs can be subdivided further into:

- Property prediction programs
- Process planning programs
- Material selection programs and their data bases
- Programs for special technical and economic problems in connection with heat treatment (programs estimating the energy consumption of a heat-treatment process or calculating the expenses of heat treatment, and so forth
- Finite-element analysis for modelling the effects of quench severity on distortion and dimensional control of parts

Examples of various types of available software for either on-line applications or the above-mentioned decision-making applications are listed in Table 2.

Table 2 Examples of available computer programs and data bases on the field of steel selection, microstructure, properties, and heat-treatment technologies

Name of the software	**Availability**	**Features**
Computerized materials properties storage, retrieval, and use		

Mat. DB	ASM International, U.S.A.	Materials data base management program containing the designations, chemical compositions, forms (sheet, bar and so forth), and properties (up to 40 properties). It is designed to select alloys on the basis of many characteristics
EQUIST 2.0	SACIT Steel Advisory Centre for Industrial Technologies, Hungary	Contains the chemical compositions, mechanical properties, application fields, and the international comparison (equivalent steels) of 6500 standard steels from 18 countries
Database SteelMaster	Dr. P. Sommer Werkstofftechnik GmbH., Germany	Contains compositions, mechanical properties, heat-treatment parameters, CCT diagrams, tempering charts for commonly used German structural and tool steels. The heat-treatment technologies designed by the user of the software can be stored and retrieved
PERITUS	Matsel Systems Ltd., Great Britain	This data base provides engineers with up-to-date information about the range of materials from traditional metals to new polymers. The range of information: mechanical and physical properties, environmental resistance, material forms, processing methods, trade names, and standards
AMETA	SACIT Steel Advisory Centre for Industrial Technologies, Hungary	This data base of individual measured steel properties contains data collected from laboratories of industry quality control departments. The range of data: steel designation, heat number, dimensions of the machine part, composition, heat treatment of the part, results of tensile tests, impact test results, measured Jominy curve of the heat, and other tests. The system makes statistical analysis of the data
KOR	SACIT Steel Advisory Centre for Industrial Technologies, Hungary	KOR is a corrosion information system, which contains a data base of 300 corrosive media, more than 15 000 individual corrosion dataset, 150 metallic structural materials, and 200 isocorrosion diagrams. Structural material selection is possible according to prescribed mechanical, physical, technological properties, or it is possible to find a suitable resisting material for a corrosive medium with given temperature and concentration. The system will also accept the user's own data
Computer programs for calculations of processes occurring in steels during heat treatment		
PREDIC & TECH	SACIT Steel Advisory Centre for Industrial Technologies, Hungary	Simulates the cooling, transformation of austenite in cylindrical, plate-shaped workpieces, Jominy specimens made of case-hardenable and quenched and tempered low-alloy steels and calculates the microstructure and mechanical properties in any location of the cross section of the workpiece taking into account the actual chemical composition, dimensions, austenitizing temperature, durations, cooling intensity of quenchant, tempering temperature, and time. The same program works as technology planning program if the prescribed mechanical properties and composition are given
AC3	Marathon Monitors Ltd., Great Britain	Hardenability model designed to predict the response to quenching of through-hardening and carburized low-alloy steels in terms of microstructure and hardness distribution
CETIM-SICLOP	Centre Technique des Industries Mechaniques PROGETIM, France	Contains a steel data base for the selection of structural and tool steels and calculates the mechanical properties along the cross section of workpieces
SteCal	Comline Engineering Software, Great Britain and ASM International	Calculates the heat-treatment response and properties of low-alloy steels from composition
PREVERT	Creusot-Loire Industries,	Calculates the microstructure and mechanical properties of quenched and tempered low-

	France	alloy steels from composition and heat-treating parameters
CHAT	International Harvester Company, U.S.A.	CHAT is a two-part system for selecting the optimum steel composition to be used where heat treating is performed to develop required engineering properties
MINITECH	Minitech Limited, Canada	The Minitech Alloy Steel Information System consists of twelve computer programs which generate a series of hardenability-related properties of steels, such as Jominy curves, hardenability bands, mechanical properties of hot rolled products, hardness distributions for quenched and tempered and carburized products
PREDCARB	SACIT Steel Advisory Centre for Industrial Technologies, Hungary	This computer program determines the gas carburizing technology and calculates the carbon profile and hardness distribution in the case and core on the basis of chemical composition, dimensions of the workpiece, cooling intensity of the quenchant, prescribed characteristics of the case
SIMULAN	Lammar, Ensam Bordeaux, France	Simulates the gas carburization and induction hardening process, and calculates the carbon and the hardness profile
CARBCALC	Marathon Monitors Ltd., Great Britain	Simulates the carburizing reactions between a steel and surrounding atmosphere. It calculates the carbon profile
CARBODIFF	Process Electronic, Germany	Monitoring of carbon profile during carburizing and prediction of hardness distribution after quenching of case-hardened steels
Carbo-O-Proof	lpsen Industries Ltd., U.S.A.	This software is able to optimize the carburizing process, calculates continuously the carbon profile, and regulates the process in accordance with program target values
SYSWELD	Framasoft, Great Britain	This system is based on finite-element technique and simulates the transformation processes in steel during heat treatment or welding. The program calculates the temperature distribution, microstructure, hardness, and stresses

General aspects of these simulation software packages are described below. In general, the "inner core," or essence, of different simulation programs for process planning or material selection contains in most cases a property prediction model, although this is not realized by the user. Property prediction softwares consist of module elements that form, in a chain-to-chain connection, a functionally comprehensive structure (see, for example, the modules described below in the section "Calculation of Microstructure and Properties"). Each module can be regarded as a submodel of a certain part of the total heat-treatment process. Knowing the necessary input data, this model provides a theoretical possibility for the simulation of processes taking place during heat treatment. The result of the simulation is output data. The reliability and accuracy of prediction softwares depend, of course, on the applied metallurgical model.

Development Trends in Computer Simulation Modelling

In the last 20 years there were many computerized data banks created in different countries that tried to help the metallurgists and material engineers with bibliographic (for example, METADEX) and factual (for example, Metals Datafile) data bases. To a certain extent, independent of this activity, but in the same time period, the property predictors were starting to be developed. Naturally, there were earlier calculation methods such as the well-known calculation of critical diameter with the Grossmann formulas, but the widespread growth of computer methods opened new options. The computer techniques made it possible to reevaluate the conventional formulas, to expand their application fields, and to develop more complex and accurate prediction methods.

During the last two decades in the field of heat treatment, various mathematical models with different accuracy and complexity have been developed. There are three general types of models used in property prediction and computer simulation of heat-treatment effects:

- Static models based on empirical formulas
- Dynamic models based on differential equations or differential equation systems
- Programs with both static and dynamic models

The static models are useful because of their simplicity, but their accuracy does not always satisfy demands and expectations. In most simulation algorithms and softwares, the static and dynamic models are mixed.

Static models are based on simple empirical formulas that can be derived from physical principles and observation or from statistical methods. Generally, statistical models use regression analysis.

A good example of a static model is the formulation or prediction of Jominy hardenability from austenitic grain size and chemical composition. This type of quantitative methodology (Ref 1, 2, 3), which has been a subject in the study of hardenability for several decades, is discussed in the article "Quantitative Prediction of Transformation Hardening in Steels" in this Volume.

Dynamic models are based on the solution of differential equations or differential equation systems. Examples of dynamic models include programs for predicting carbon and nitrogen profiles (Ref 4, 5, 6) as well as the phenomenological models developed to describe the transformation of austenitc under nonisothermal conditions (Ref 7, 8, 9, 10, 11).

Another important category of dynamic models is the use of finite-element analysis in predicting residual stress and distortion (Ref 12, 13, 14) or in determining suitable quenchants (gas, oil, or water) for a given alloy (Ref 12). Examples of programs based on finite-element analysis include:

- The CONTA program for calculating surface heat fluxes (Ref 15)
- The TOPAZ 2D program for calculating temperatures (Ref 16)
- The NIKE 2D program for calculating stresses (Ref 17)

Sophisticated dynamic simulation models, such as those based on finite-element analysis, are rather complicated to run and require expert knowledge. As far as the purchase is concerned, both the software and the hardware can also be rather expensive. Consequently, the development of prediction software is often first aimed at the accessibility of personal computer systems.

References to State-of-the-Art Applications

In the following paragraphs an attempt is made to outline some important results in computer simulation of heat-treatment processes without aiming at completeness. General overviews of these activities in the latter half of the 1970s are also given in Ref 18 and 19. Publications on the structure of the simulation models and softwares are often laconic and do not contain directly usable information. The reason for this is mostly that the publication of details would hurt business interests; the systems are also developed as commercial ventures, and parts of the programs are proprietary.

Data Base Systems. Data bases containing the main characteristics of several metal alloys are being marketed. Different kinds of information can be retrieved from these data bases (chemical composition, mechanical characteristics, continuous cooling transformation [CCT] curves, and so on). The data base can be loaded with the results of the process planning so that the user's own specially designed technology can be stored in the data base. Research workers at Minitech Ltd (Canada), for example, designed a software package to estimate various properties (for example, weldability, phase diagrams, hardenability) of low-, medium-, and high-carbon steels (Ref 18). Chrysler Corporation developed an interactive system that makes it possible for the designers and technologists to get material information on their own local computer terminal (Ref 18). Utilization of data bases of measured steel properties is discussed in Ref 20.

Recently, a program system was developed in CETIM Institute (France) for the planning of heat-treatment technology and for steel selection. The essential part of the software is a data base containing the chemical composition, mechanical properties, and Jominy curves of the most often used quenched and tempered and case-hardened steels as a function of section size (Ref 21).

Hardenability Prediction. As previously mentioned, quantitative prediction of hardenability has been a longstanding subject of theoretical and practical interest. A basic overview, along with prediction of isothermal transformation (IT) and CCT curves, is provided in the article "Quantitative Prediction of Transformation Hardening in Steels" in this Volume. Hardenability prediction is also covered in Ref 22, 23, 24, 25, and 26.

In applying a static model, Murry *et al.* (Ref 27) developed a computing method for predicting the hardness of cylindrical workpieces along the cross section after quenching. The input data are: chemical composition, austenite grain size, geometrical characteristics, and the cooling time from 700 to 400 °C (1290 to 750 °F). In the central laboratory of Creusot-Loire (Ref 18, 28), nonlinear multiple regression analysis was used to derive a series of formulas for the estimation of critical cooling rates from 700 °C (1290 °F). They also published equations to calculate the as-quenched and tempered hardness from the chemical composition and cooling rate from 700 °C (1290 °F).

The coworkers of the McMaster University (Hamilton, Ontario, Canada) starting from a metallurgical thermodynamic basis, developed methods for the computer-aided determination of equilibrium diagrams of multicomponent steel alloys and for the calculation of the starting curves (incubation time) of the isothermal transformation diagrams as well (Ref 19, 25, 29). They also investigated the tempering process and developed usable computer programs for the prediction of hardenability and its application in steelmaking.

Programs for material selection and/or analysis of heat-treatment processes usually contain a system for property or hardenability prediction. Liscic and Filetin (Ref 23, 24), for example, published a computerized process-designing system for the heat treatment of quenched and tempered steels. This system is suitable for the determination of technological parameters (austenitization and tempering temperature) knowing the steel type and the required properties. More sophisticated models based on finite-element analysis are also being investigated as a way of modelling distortion and analyzing quench methods (see, for example, Ref 12). A general review on the application of computerized information for steel selection and their heat treatments is given in Ref 30.

Analysis of residual stresses and distortion generally involves finite-element analysis of the internal stresses developed during transformation sequences. Typical examples are given in Ref 12, 13, 14 and 31. A method for calculating transformation sequences in quenched steels is given in Ref 32. For case-hardened steels, a software package has been developed for the prediction of residual stresses by tracing the transformation of the case and the core of the work-piece (Ref 33, 34).

Simulation of Case Hardening. New type models have been developed for the prediction of carbon and nitrogen profile during and after the gas carburizing and nitriding (Ref 5, 6, 35, 36, 37, 38, 39, 40, 41). In this field, calculation methods can be used to model case depth and hardness profiles (Ref 37, 42, 43). Ingham and Clarke (Ref 41) developed a well-applied computerized method for the prediction of microstructure and hardness profile of case-hardened parts. Methods of microstructure prediction are described in Ref 8 and 44.

General Concept of a Property-Prediction System

A detailed property-prediction system (PPS) used for simulating the metallurgical process occurring during heat treatment and predicting the microstructure and mechanical properties of quenched and tempered or case-hardened steels is described in this section. The system consists of several modules, which form a logical chain for property prediction.

Model Description

Before starting to design a PPS, one has to ascertain first those internal parameters (for example, Ac_3 temperature, transformation kinetic data, hardness values of the microstructural elements, and so on) that have the most determinative effects on the properties. Then the algorithm, the logical chain of these internal parameters, has to be stated and finally, the connections between the input data, the internal parameters, have to be investigated. If all of these connections are clear, mathematically formulated, and joined into a chain, one can handle this set of connections as a system.

The programs of the PPS are based on a phenomenological model of kinetics of transformation taking place in nonisothermal conditions. The program permits the prediction of the progress of transformations, of the microstructure, and of the mechanical properties as a function of time and of position in the cross section of the heat-treated workpiece. The equations forming the base of the model belong to three main groups as follows:

- *The differential equation of heat conduction:* By a numerical method, the temperature field in the given

workpiece is solved

- *The system of kinetic differential equations* for describing the transformation processes occurring in the microstructure
- *Equations describing the relation between the microstructure and properties*

Modelling of transformation kinetics can be done with differential equations such as:

$$\frac{\partial Y_j(\mathbf{r},t)}{\partial t} = g_j(Y_1, Y_2, \ldots Y_J, T, t) \qquad \textbf{(Eq 1)}$$

where t denotes time; **r** is the vector representing a given point of the workpiece (the position vector); T is the temperature, which is a function of time t and position **r;** Y_j (j = 1,2, . . . J) is a so-called microstructural parameter; and g_j = 1,2 . . . J is an appropriately selected real value function.

The microstructural parameters Y_j in Eq 1 are numerical quantities that may be interpreted within relatively wide limits. For example, Y_j may denote the volume fraction of the transformed phase, its average dimension, or the mean free distance between particles.

Relating Microstructure to Properties. The starting point for predicting mechanical properties such as hardness and yield point is that the properties are related to microstructural parameters. It was assumed that after transformation at a given location **r** in the workpiece, a numerical property P(**r**) of the steel may be calculated with a precision satisfying practical demands as a function of a small number of elementary microstructural properties p_j (j = 1,2 . . . M) according to the formula:

$$P(\mathbf{r}) = f_l(p_1, p_2, \ldots p_M) \qquad \textbf{(Eq 2)}$$

where f_1 is an appropriately selected function.

In most cases, the so-called generalized linear law of mixture represented by the following Stieltjes integral was used to calculate the elementary microstructural property p_j (j = 1,2, . . . M):

$$p_j = \int \chi(T, Y_j) dY_j \qquad \textbf{(Eq 3)}$$

where $\chi[T(\mathbf{r}, t), Y_j]$ is a suitably defined weighting function containing and summarizing the numerical information on the given property of the microstructural parameter Y_j. For more details, see Ref 45.

Calculation of Microstructure and Properties

The block diagram of a PPS program is shown in Fig. 1. The upper part of the diagram refers to the processes occurring during austenitization and quenching; the lower part refers to tempering processes. The "black boxes" of the quenching and tempering calculation unit are within the frames shown with dashed lines. The programs that form the system are numbered 1 to 12. The models and the parameters used as input to the modules are being developed continuously according to the latest experience and can be changed. Each module is described in this section.

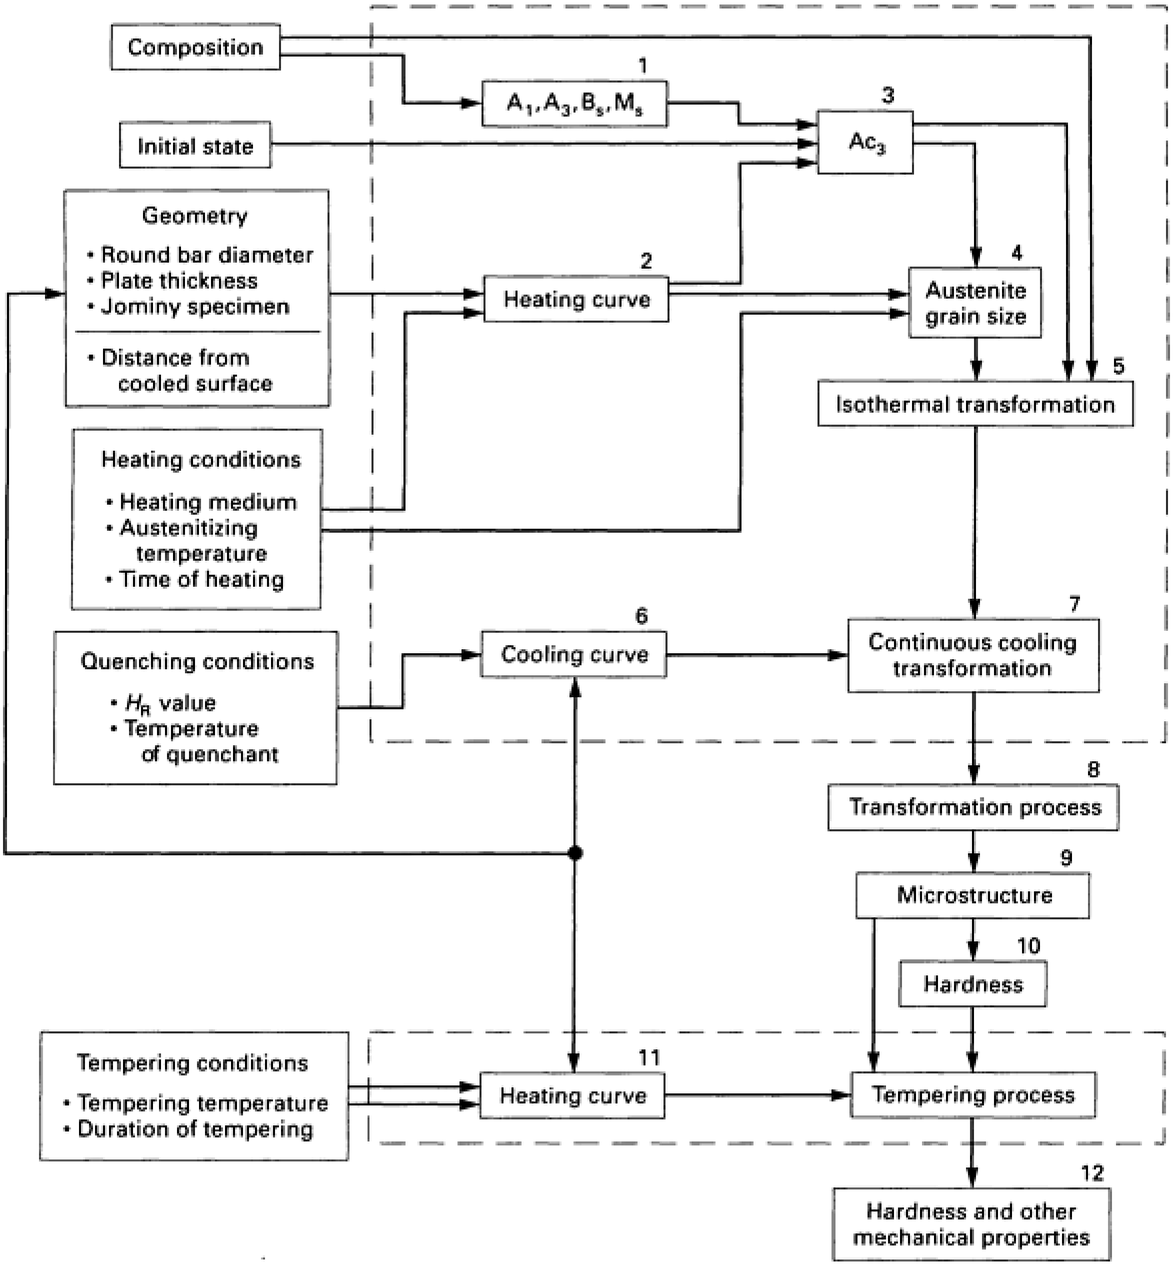

Fig. 1 Block diagram of the PPS simulation model

The input data are seen on the left side of the block diagram. They are as follows:

- Chemical composition of the workpiece to be hardened
- Initial state of the workpiece (annealed, normalized, quenched, and tempered)
- Geometry: shape and size of the workpiece (round bar or plate) characterized by its diameter or thickness, or Jominy specimen and the distance from the cooled surface to the point where the microstructure and properties are to be predicted
- Heating conditions: heating medium, austenitizing temperature, and the total time spent by the workpiece in the austenitizing furnace
- Quenching conditions characterized by the H_R value (relative heat transfer coefficient specifying the cooling severity, for example, in the case of oil, 0.3 to 0.6) and the temperature of the quenchant
- Tempering conditions given by the tempering temperature and the duration of tempering

Determination of Martensite Start (M_s), Bainite Start (B_s), and the Equilibrium (A_1, A_3) Transformation Temperatures from Compositions (Module 1). The chemical composition of the workpiece is first verified against the specified composition range of the steel type for which the predictor program was developed. From the composition, Module 1 then calculates A_1, A_3, B_s, M_s transformation temperatures by formulas based on dilatometrical measurements and regression analysis (Ref 46, 47). There are also numerous formulas in the literature for the estimation of these transformation temperatures (Ref 19).

Computation of the heating curve (Module 2) takes into account the furnace features. Calculations are based on the application of an approximate method developed to solve heat conduction problems for simple geometries.

In most practical cases, it is not necessary to expend much effort for the accurate calculation of the heating curve. The accuracy of the following Newtonian approximation can also satisfy the requirements:

$$T = (T_0 - T_a)\exp\{-\alpha_h t\} + T_a \qquad \textbf{(Eq 4)}$$

where T is the temperature in the given point of the workpiece; t is the time; T_a is the austenitization temperature; T_0 is the temperature at t = 0; and α_h is a constant, depending on the furnace, mass of workpiece, heating medium, quality of the surface, and agitation of the medium.

Calculation of Time and Temperature to Austenitization (Module 3). This module calculates the austenitizing temperature (Ac_3) to the nearest 20 °C (35 °F) and the time to reach the Ac_3 temperature. The Ac_3 temperature is determined--apart from the chemical composition--by the initial microstructure and the heating rate. The interactive computer program based on this model permits the user to select one of four of initial microstructures. The experimental results may be described with the following equation:

$$Ac_3 = A_3 + a\,v^{\frac{1}{3}} \qquad \textbf{(Eq 5)}$$

where v is heating rate at temperature A_3, and a is a parameter depending on the initial state of microstructure, that is, the finer the microstructure is, the lower the value of a. The value of the empirical parameter a is estimated by least squares analysis on the basis of grain growth diagrams of different steel grades (see Fig. 2 and the corresponding discussion of grain growth given below).

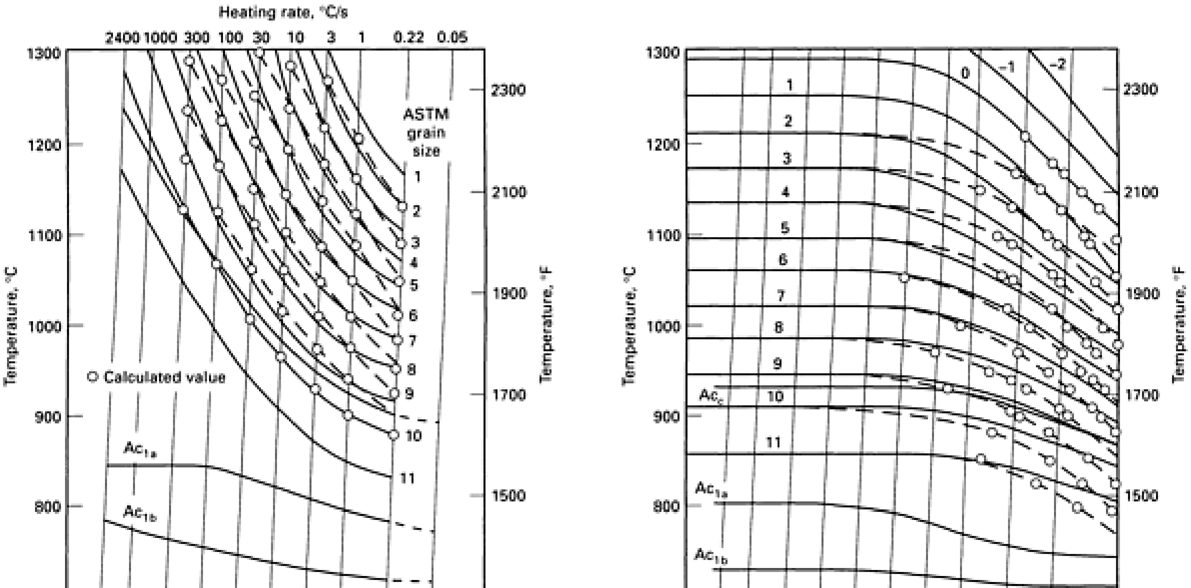

Fig. 2 Measured and calculated austenite grain growth diagrams of 90MnV8 steel (0.85-0.95% C, 0.15-0.35%

Si, 1.8-2.0% Mn, 0.07-0.12% V) during (a) continuous heating and (b) isothermal heating at 1.3 °C/s (2.3 °F/s)

For the chromium-molybdenum low-alloy steels with 0.5% C content, the numeric value of the *a* parameter can vary from 3 to 15, if the temperatures are measured in degrees centigrade. For example, in the case of a quenched microstructure, $a = 3$; for quenched and tempered state, $a = 5$; for the normalized state, $a = 10$; and for the annealed state, $a = 15$.

Computation of the austenite grain size (Module 4) also requires consideration of nonisothermal conditions. The extent of grain growth taking place during austenitization is known to have a decisive effect on the characteristics of steel; therefore, its prediction is a task of considerable practical interest (Ref 48).

Grain growth diagrams were worked out for the various types of steel on the basis of tests, but their usefulness was restricted by the condition that they must be valid for the case of isothermal or linear heating. It was shown (Ref 7) that using the data of the known austenite grain growth diagram valid for linear heating, a generalized kinetic function can be produced by calculation, which allows computed tracking of grain growth taking place at changing temperature, and thus prediction of grain size.

It was assumed that grain size D_a of steels at constant temperature T_c is described by an isothermal kinetic function of the following type:

$$D_a^N - k_0 \exp(-Q_a/RT_c)t = 0 \qquad \textbf{(Eq 6)}$$

After derivation, the generalized kinetic differential equation type (Eq 1) is obtained:

$$\frac{dD_a}{dt} = \frac{k_0}{N} \exp\left(-\frac{Q_a}{RT}\right) D_a^{1-N} \qquad \textbf{(Eq 7)}$$

The unknown parameters k_0, N, and Q_a of differential equation (Eq 7) can be estimated by regression analysis using measured data*. According to the published method (Ref 7), the average grain size D_a may be calculated with the generalized kinetic function:

$$D_a = \left[\int_0^t k_0 \exp\left(-\frac{Q_a}{RT}\right) dt + D_0^N \right]^{1/N} \qquad \textbf{(Eq 8)}$$

produced by integration of the generalized kinetic differential equation (Eq 7). Knowing the heating curve, the solution can be obtained by numerical integration of Eq 8, where D_0 is the initial grain size at Ac_3; N and Q_a are parameters depending on the composition; and R is the universal gas constant. The values of the parameters k_0, Q_a, and N may be determined by the method of least squares from grain growth experiments (Ref 7, 48).

Figure 2 shows two grain growth diagrams for steel 90MnV8 as examples. In Fig. 2, the solid lines represent the original test results taken from Ref 49, while the dashed lines show the results calculated with Eq 8. For this calculation, the time-temperature function had to be substituted before integration. The applied parameters were as follows:

$$k_0 = 6.087 \times 10^7$$
$$N = 2.44$$
$$Q_a = 317 \text{ kJ mol}^{-1}$$

Figure 2(b) shows the grain growth for the same steel but, for isothermal conditions, taking into account the heating rate as well. The coincidence of the grain sizes determined by measurements and those calculated by Eq 8 are satisfactory according to practical demands.

Calculation of TTT Diagram (Module 5). The characteristics of the isothermal time-temperature transformation (TTT) chart are calculated as a function of the chemical composition and austenite grain size, also taking into account the temperatures A_1, A_3, B_s, and M_s.

A complete mathematical description of the isothermal transformation, starting with nucleation and growth, is presently not possible for large volume fractions transformed (Ref 50). The reason is that an analytical description of the growth is not possible if the single nuclei touch each other. Therefore, in general, empirical descriptions are used that are appropriately fitted to the measured curves. Some of the applicable methods are listed below.

Avrami Estimate of Isothermal Transformation. One of the most frequently used equations for the isothermal transformation is Avrami's equation:

$$y = 1 - \exp\{-bt^n\} \qquad \textbf{(Eq 9)}$$

where y is the volume fraction of the transformed austenite; t is the time spent on the isotherm; and b and n are temperature, grain size, and composition-dependent constants, evaluated from the isothermal TTT diagram or from measurements with continuous cooling (Ref 50).

For calculations detailed below, the parameters b and n can be given in tabulated form, but also in mathematical form as functions of temperature, composition, and grain size.

Estimates of 1% and 99% Transformation. The second possibility is to define functions for the beginning (1% transformed austenite) and for the end (99%) of isothermal transformations. These curves can be described with equations of the following form:

$$t = f_2(C, D_a)\exp\{h_0 + h_1T + h_2T^2 + h_3T^3\} \qquad \textbf{(Eq 10)}$$

where C is the composition vector; D_a is the austenire grain size; T is the temperature; h_0, h_1, h_2, and h_3 are composition-dependent constants; and f_2 is a suitable selected real function.

Transformation Estimates from Isothermal Kinetic Differential Equations. In the PPS program discussed here, the information content of the traditional TTT charts is built into the program in the form of isothermal kinetic differential equations as follows:

$$\frac{dy}{dt} = Ky^{b_1}(1-y)^{b_2}\ln\left[\left(\frac{1}{1-y}\right)^{b_3}\right] \qquad \textbf{(Eq 11)}$$

where y is the relative amount of transformed products; K, b_1, b_2, and b_3 are appropriately selected parameters depending on temperature, austenite grain size, and composition (Ref 30, 32). The most important kinetic functions (Table 3) can be considered as special cases of Eq 11.

Table 3 Summary of most important kinetic functions for isothermal conditions

Source: Ref 32

Condition	Differential equation	Solution at $y(0) = 0$	Parameter
1	$y' = nK(T)(1-y)\left(\ln\frac{1}{1-y}\right)^{(n-1)/n}$	$\left(\ln\frac{1}{1-y}\right)^{1/n} = K(T)t$	$b_1 = 0$ $b_2 = 1$ $b_3 = (n-1)/n$
2	$y' = nK(T)y^{(n-1)/n}(1-y)^{(n+1)/n}$	$\left(\frac{y}{1-y}\right)^{1/n} = K(T)t$	$b_1 = (n-1)/n$ $b_2 = (n+1)/n$ $b_3 = 0$
3	$y' = nK(T)y^{(n-1)/n}$	$y^{1/n} = K(T)t$	$b_1 = (n-1)/n$ $b_2 = 0$ $b_3 = 0$
4	$y' = K(T)y^{2/3}(1-y)$	$\frac{1}{2}\ln\frac{1+y^{1/3}+y^{2/3}}{(1-y^{1/3})^2} + \sqrt{3}\tan^{-1}\frac{2y^{1/3}+1}{\sqrt{3}} - \sqrt{3}\frac{\pi}{6} = K(T)t$	$b_1 = 2/3$ $b_2 = 1$ $b_3 = 0$
5	$y' = K(T)y^{1/3}(1-y)$	$\frac{1}{2}\ln\frac{1+y^{1/3}+y^{2/3}}{(1-y^{1/3})^2} - \sqrt{3}\tan^{-1}\frac{2y^{1/3}+1}{\sqrt{3}} + \sqrt{3}\frac{\pi}{6} = K(T)t$	$b_1 = 1/3$ $b_2 = 1$ $b_3 = 0$
6	$y' = K(T)y^{-1}(1-y)^2$	$\frac{y}{1-y} + \ln(1-y) = K(T)t$	$b_1 = -1$ $b_2 = 2$ $b_3 = 0$

Source: Ref 32

Computation of the cooling curve (Module 6) at the given point of the workpiece can involve a simple method similar to the one described in Module 2, that is, to use a Newtonian cooling:

$$T = (T_a - T_q)\exp\{-\alpha_c t\} + T_q \qquad \textbf{(Eq 12)}$$

where T_a is the austenitization temperature; T_q is the temperature of the quenchant; and α_c is the geometry and quenchant-dependent parameter.

In the case of cylindrical workpiece and water cooling, the equation for calculating α_c can be suggested in the following form:

$$\alpha_c = \frac{A}{D^{1.726}\exp\{(B - 0.013D)[(D - 2X)/D]^3\}} \qquad \textbf{(Eq 13)}$$

where D is the diameter; X is the distance from the cooled surface; and A and B are agitation-dependent constants (Ref 46).

The computer program discussed here takes into account the individual geometry (plate, cylindrical workpiece) and calculates the cooling on the basis of the principles similar to one-dimensional un-steady-state heat conduction, which is formulated by the Fourier differential equation as follows:

$$\frac{\partial}{\partial r}\left(\lambda\frac{\partial T}{\partial r}\right) + \beta\frac{\lambda}{r}\frac{\partial T}{\partial r} + q_v = \rho C_p\frac{\partial T}{\partial t} \qquad \textbf{(Eq 14)}$$

where t is time; r is locale coordinate; $T(r,t)$ is temperature; q_v is rate of heat generation due to the austenite transformation; ρ is density; C_p is specific heat; λ is thermal conductivity; $\beta = 0$ for the plate; and $\beta = 1$ for the cylinder.

With the cylinder diameter and the plate thickness equal to $2R$, the corresponding boundary and initial conditions are:

At the surface ($r = R$) with $t > 0$:

$$-\lambda \left.\frac{\partial T}{\partial r}\right|_{r=R} = \alpha \left[T_q - T\left(R,t\right)\right] \quad \textbf{(Eq 15)}$$

At the centerline (r = 0) with $t > 0$:

$$-\lambda \left.\frac{\partial T}{2r}\right|_{r=0} = 0 \quad \textbf{(Eq 16)}$$

Elsewhere ($0 \leq r \leq R$) with $t = 0$:

$$T(r,t) = T_a \quad \textbf{(Eq 17)}$$

where α is the heat transfer coefficient; T_q is the temperature of the quenching media; and T_a is the initial austenitizing temperature.

In many cases, the heat generated in the workpiece during cooling is disregarded (q_v = 0). On the other hand, some simplifying assumptions are used relating to the surface heat transfer represented by Eq 15.

By introducing the relative heat transfer coefficient H_R defined as:

$$H_R = \frac{\alpha}{2\lambda} \quad \textbf{(Eq 18)}$$

then Eq 15 can be rewritten in the form:

$$-\left.\frac{\partial T}{\partial r}\right|_{r=R} = 2H_R \left[T_q - T\left(R,t\right)\right] \quad \textbf{(Eq 19)}$$

The parameter H_R (assumed to be constant) is formally equal to the widely accepted quenching factor proposed by Grossmann for characterizing the quenching power of different cooling media (Ref 22, 51).

The dimension of H_R is the reciprocal of length (1/m, or 1/in.). In heat-treating practice, the range of H_R is in the interval of 8 to 195 m^{-1} (0.2 to 5.0 $in.^{-1}$), where the 8 m^{-1} (0.2 $in.^{-1}$) is for an oil quenchant without agitation and the maximum value 195 m^{-1} (5 $in.^{-1}$) corresponds to a brine quench with strong agitation.

Starting with an appropriately selected cooling intensity H_R, it is very easy to generate the cooling curves for the workpiece of cylindrical or plate form. The disadvantage of this model approach is that the value H_R is not constant and varies during the cooling process. This fact may lead to computation inaccuracies, which must be taken into consideration.

A more exact and more complicated way to characterize in a quantitative manner the surface heat transfer process during quenching is based on the use of the boundary condition formulated as:

$$-\lambda \left.\frac{\partial T}{\partial r}\right|_{r=R} = \phi\left(T_s\right) \quad \textbf{(Eq 20)}$$

where ϕ is the surface heat flux as a function of the surface temperature T_s. The surface heat flux ϕ can be measured for different quenching conditions (for different quenchants, temperatures, agitations, workpiece geometry, and so forth). It can be stored in a data base and can be retrieved for practical computations (Ref 23, 52).

Modelling of Continuous Cooling Transformations (Module 7). Calculating the progress of the transformation process during continuous cooling from the TTT characteristics is a crucial part in property prediction. Estimation of the ferritic, pearlitic, and bainitic fractions during each step is based on published methods (Ref 53, 54). The principle of the method is described below.

In the first step, the isothermal kinetic differential equation is appropriately generalized in the form:

$$\frac{dy}{dt} = f_3(T,y) \quad \textbf{(Eq 21)}$$

where T = T(t) is the temperature as a function of time, and f_3 stands for a selected real function. In the second step, this equation is solved by a numerical method known as the recursive algorithm. The extension and generalization of this method was published in Ref 9.

The recursive algorithm for the well-known Avrami kinetic function was first formulated by M. Gergely (Ref 53, 54). The volume fraction of ferrite-pearlite and bainite are evaluated according to the Avrami expression defined by Eq 9. The cooling curve is approximated by a staircase, and the transformation is then calculated isothermally during each time step. The recursive algorithm is actually a special numerical procedure for solving the generalized kinetic equation (Eq 21). The verification of this is published in Ref 30.

For the calculation of the amount of martensite, a novel formula is used (Ref 8) instead of the well-known equation proposed by Koistinen and Marburger (Ref 55). According to Ref 8, the martensitic transformation can be described in the following differential form:

$$\frac{dy_m}{dT} = K_m\, y_m^{a_1}\,(1 - y_m)^{a_2}\left\{\ln \frac{1}{1 - y_m}\right\}^{a_3} \quad \textbf{(Eq 22)}$$

where y_m is the relative amount of martensite transformed from austenite; and K_m, a_1, a_2, and a_3 are composition-dependent parameters. The numerical values of these parameters for a quenched and tempered low-alloy chromium steel and six case-hardened steels are also published (Ref 8).

Determination of Microstructural Transformations (Modules 8 and 9). Information about transformation temperature definitions for the initiation of the ferrite-pearlite reaction and for the beginning temperature range, B_s, of the bainite reaction is first provided by Module 8. In practice, the beginning is defined as either 1 or 5%. Actually, the complete transformation curve is available as one of the outputs for further evaluation. On the basis of this curve, the temperatures belong to 5%, 10%, . . . 50%, . . . 95%, and the quantities of the microstructural elements can be displayed. Module 9 gives the microstructure, namely, the amounts of ferrite-pearlite, bainite, martensite, and retained austenite. The program uses definitions given above, for example, bainite is the transformation product obtained from austenite between the temperatures B_s and M_s.

Calculation of Hardness (Module 10). When the hardness after quenching is calculated on the basis of microstructure and the carbon content, many investigations are still necessary to ascertain the best rule of mixing. In the Creusot-Loire system (Ref 18) the hardness at room temperature of martensite, bainite, and ferrite-pearlite is calculated separately taking into account the chemical composition and cooling rate at 700 °C (1290 °F). Then a linear mixing rule is applied to get the final hardness.

The PPS model discussed in this section predicts the hardness by the help of the individual isothermal hardnesses of the microstructural elements (Ref 45). As mentioned in the description of Module 7, the solutions of the differential equation (the recursive formulas) trace the nonisothermal phase transformation. Consequently, in the calculation of the hardness after quenching, the transformed amounts of austenite on each isothermal step, and their individual isothermal hardness can be taken into account. The amounts of the microstructural elements are calculated by the help of the stepwise method. The individual hardnesses of the microstructural elements are taken from a hardness-temperature table or function valid for the actual steel, and the resultant as-quenched hardness H_q is composed from these components with the formula:

$$H_q = \sum_{i=1}^{v} y_i(T_i)H(T_i) + y_m H_m + y_a H_a \quad \text{(Eq 23)}$$

where T_i is the temperature of the *i*th step; $y_i(T_i)$ is the transformed amount at temperature T_i; $H(T_i)$ is the isothermal hardness; v is the number of isothermal steps, until temperature reaches M_s; Y_m is the volume fraction of martensite; Y_a is the volume fraction of retained austenitc; H_m is the hardness of martensite; and H_a is the hardness of retained austenite.

Tempering Computer Model (Modules 11, 12, and 13). Module 11 computes the heating curve to reach the tempering temperature. Modules 12 and 13 calculate the final hardness after tempering according to the published method (Ref 7), together with the prospective tensile strength, elongation, reduction in area, and impact energy (Ref 46).

The tempering of steels forms a significant part of practical heat treatment, and therefore its study and mathematical description are of greatest importance. Several generally applied methods are available for the isothermal case (see the discussion of the Creusot-Loire system in Ref 18). In the PPS model discussed here and other systems doing mathematical simulation, the calculation of hardness as a function of time with continuously changing temperature has to be solved. From computational considerations, it is assumed that the kinetic equation describing the change in hardness under nonisothermal conditions is of the form:

$$H_t = f_4 (P_g) \quad \text{(Eq 24)}$$

where H_t stands for the instantaneous hardness after tempering; f_4 is a suitably selected function; and P_g is the so-called generalized time-temperature parameter, which is applicable to the description of tempering processes with changing temperature (Ref 7, 9).

The form of the parameter P_g can be selected in many ways. For example, the generalized version of the widely used Hollomon-Jaffe parameter is:

$$P_{g,H} = \ln \int_0^t T \exp\{CT\} t^{T-1}\, dt \quad \text{(Eq 25)}$$

where C is a composition-dependent constant. It follows from Eq 25 that if the tempering temperature is constant, that is, $T = T_c$, the conventional Hollomon-Jaffe parameter:

$$P_H = T_c(C + \ln t) \quad \text{(Eq 26)}$$

is obtained as a special case.

As an example for an unalloyed steel containing 0.6% C, the kinetic equation that is valid for continuously changing temperature and describes the changing Vickers hardness (HV) of martensite during tempering is as follows:

$$H \text{ (in HV)} = 849 - 139.24 \times \left[\int_0^t T \exp(33.21\ T) t^{T-1} dt\right]^{4.48 \times 10^{-5}} \quad \text{(Eq 27)}$$

Using this method, a microprocessor-based system can be designed that continuously displays the instantaneous value of the required characteristic (for example, hardness), from measurement of the actual temperature of the piece during heat treatment. When the preset hardness value is achieved--using the programmability of the processor--a variety of interventions can be made to the heat-treatment process (Ref 56).

From Eq 24 a new type of tempering chart, of more general validity than before, may be obtained. This case used the generalized Dorn parameter defined as:

$$P_D = \int_0^t \exp(-Q_D/RT)dt \quad \textbf{(Eq 28)}$$

The tempering chart (Fig. 3) is composed of two independent parts. The lower part of Fig. 3 refers to isothermal heat treatment and shows the relationship of tempering parameter P_D to temperature and time. This chart can be applied to convert from one tempering time and temperature to any other, on the basis that combinations of tempering temperature and time having the same value of tempering parameter will produce the same hardness. The upper part of Fig. 3 represents the relationship between parameter P_D and the tempering hardness for 50CV2 steel (0.5% C, 1% Mn, 1% Cr, 0.15% V).

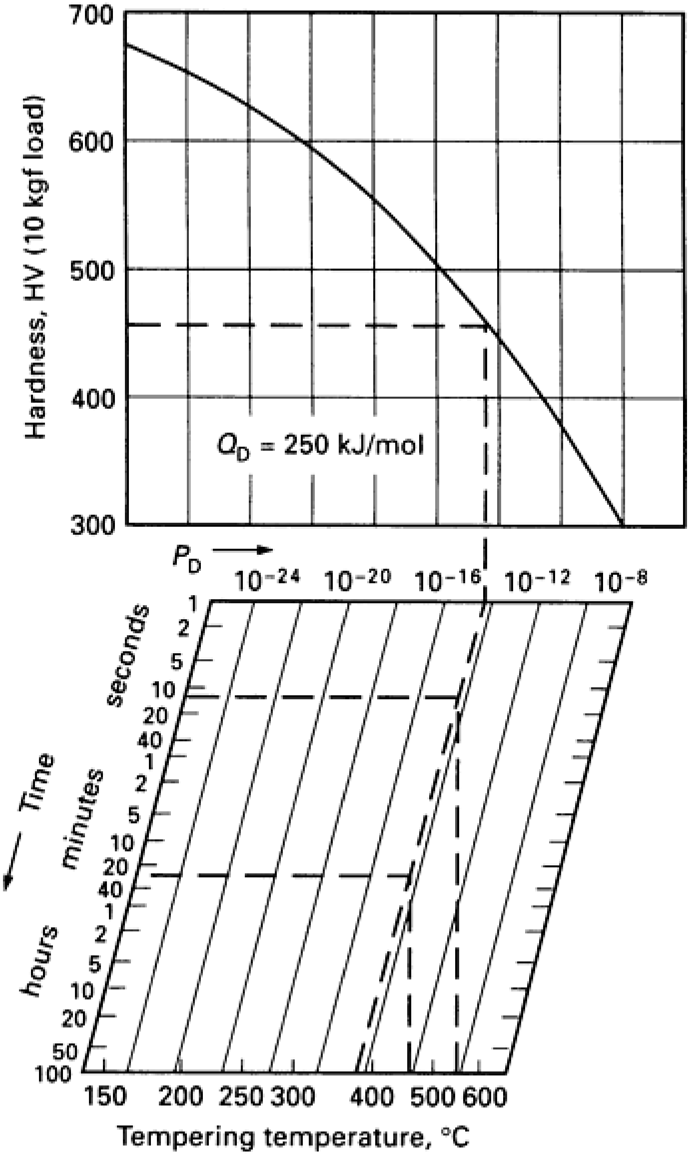

Fig. 3 Generalized tempering chart obtained using the generalized Dorn parameter (P_D) described in Eq 28

For tempering at varying temperatures, the value of the parameter P_D required to achieve the specified hardness may be determined with the aid of the upper part of Fig. 3. For isothermal tempering, the various time-temperature combinations for the given parameter value P_D, which may be used to achieve the specified hardness, may be read from the lower chart in Fig. 3.

In the kinetic function employed for the phenomenological description of hardness decrease occurring during tempering, the value of the apparent activation energy (Q_D = 250 kJ/mol) is essentially identical to the activation energy for the self-

diffusion of ferrite in steel that is not alloyed with molybdenum. It follows from this assumption that the lower chart in Fig. 3 may be used generally for all hardenable steels free of molybdenum. However, the upper chart representing the so-called master curve must be deduced and plotted individually for the various steel types from measured data.

Mechanical Property Estimates. Module 12 estimates not only the hardness, but also the other mechanical properties, namely the tensile strength, yield strength, elongation, reduction in area, and the Charpy value of the impact energy with the following formulas** (Ref 57):

$$R_m = 3.412 \text{ HV} - 64.3 \quad \textbf{(Eq 29)}$$

where R_m is the ultimate tensile strength in MPa, and HV is the Vickers hardness.

For the calculation of the yield point R (MPa), elongation A_{50} (%) in 50 mm (2 in.), reduction in area Z (%), and Charpy value KU (Joules), the equations below have been suggested:

$$R = (1.17 - 0.0007y_m)R_m + 3.72y_m - 484 \quad \textbf{(Eq 30)}$$

where y_m is the volume fraction of martensite in %.

$$A_{50} = 40 - (0.03 - 0.0001y_m)R_m \quad \textbf{(Eq 31)}$$

$$Z = 100 - (0.06 - 0.00024y_m)R_m \quad \textbf{(Eq 32)}$$

$$KU = 296 - (0.285 - 0.00098y_m)R_m \quad \textbf{(Eq 33)}$$

There are some other possibilities developed by utilization of the data base of individual steel properties published in Ref 20, 30, 57.

Examples of PPS Applications

Property prediction computer programs have been developed for solving the following tasks:

- Generation of CCT diagrams for cylindrical, plate-shaped parts, and for Jominy test pieces
- Prediction of microstructure and properties obtained after quenching and tempering with specified heat-treating parameters
- Computer-aided design of heat-treating methods
- Selection of steels with the aid of a computer in consideration of the part dimensions and of the required mechanical properties

The various types of computer programs, composed of modular elements for various purposes, may be run on different personal computers. Without aiming at completeness, some concrete examples of applications are described below.

Example 1: Types of Computer-Generated Outputs from the Simulation of Quenching and Tempering.

A simulation of quenching and tempering on a 100 mm (4 in.) diam steel cylinder was used to predict the microstructure and mechanical properties at 25 mm (1 in.) from the surface. The input data for the program were:

- Steel composition of 0.41% C, 0.25% Si, 0.75% Mn, 1.05% Cr, 0.13% Ni, 0.042% Mo, 0.04% V, and 0.15% Cu
- A prior normalized microstructure
- Austenitization at 850 °C (1560 °F) in a forced-air circulation furnace for 60 min

- Cooling in a quenchant at 20 °C (70 °F) having an H_R value of 39 m^{-1} (1.0 $in.^{-1}$)
- Tempering at 500 °C (930 °F) for 120 min

Figure 4 shows the output of the PPS program for the circumstances defined above. The program output provides the input data, predicted properties (Fig. 4a), the cooling curve (Fig. 4b), and the transformation of austenite (Fig. 4c).

Fig. 4 Sample output of a PPS program. C_v refers to the cooling rate at 700 °C (1290 °F); C_p represents the cooling time from the austenitizing temperature (T_a) to 500 °C (930 °F). All other abbreviations defined in text (see Eq 12 and 13)

Generation of Transformation Diagrams. By running the program with systematic changes in the input data for the distance from the cooled surface and the H_R value, a transformation diagram system can be generated from the calculated results for cylindrical, plate-type workpieces and Jominy specimen (Ref 30). Figure 5 shows this type of transformation diagram for two different H_R values as indicated in the diagrams. Similar transformation diagrams can of course be developed for core transformations as a function of product diameter.

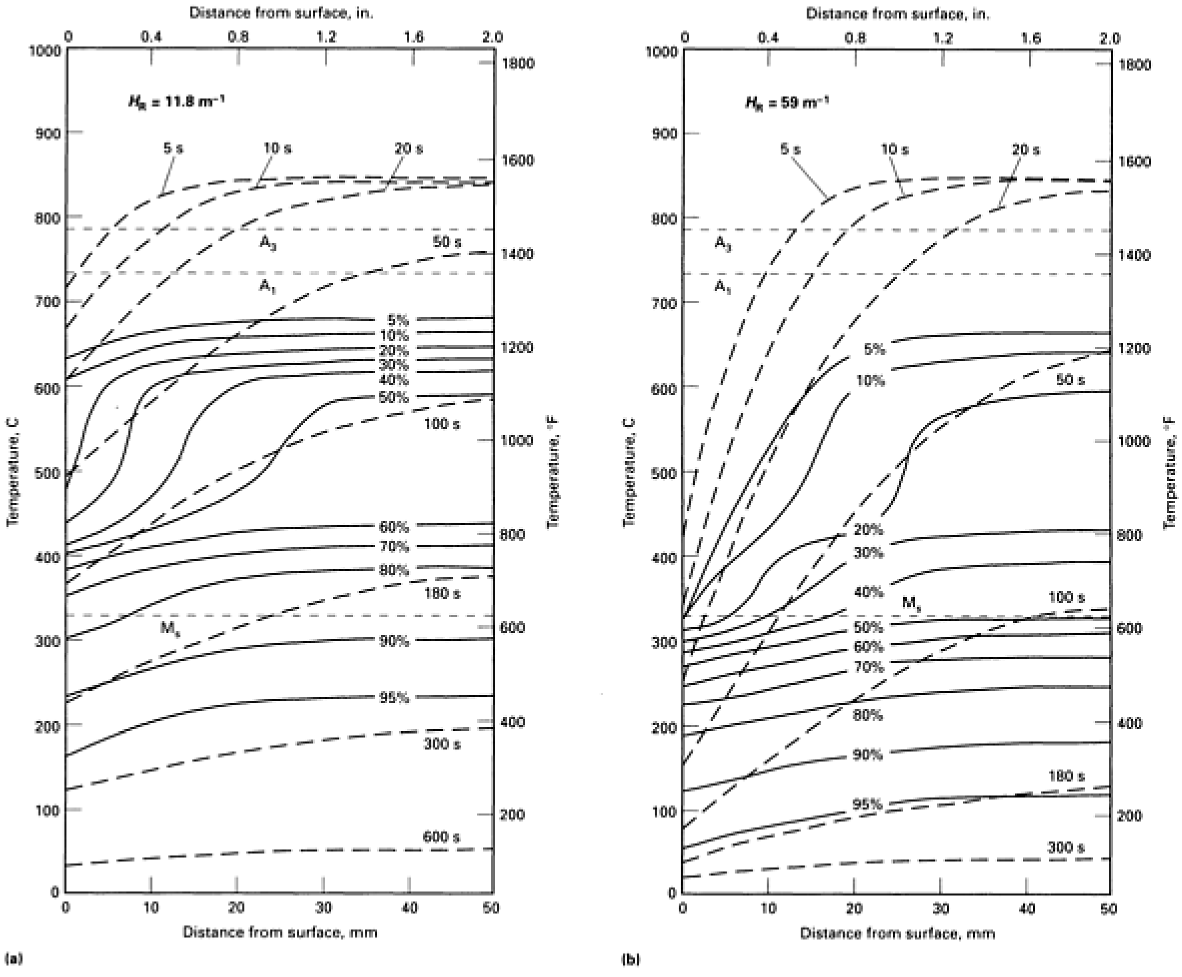

Fig. 5 Transformation diagrams generated by a PPS program for a 100 mm (4 in.) diam steel bar (0.41% C, 0.25% Si, 0.75% Mn, 1.05% Cr, 0.13% Ni, 0.042% Mo, 0.04% V, 0.15% Cu) with a prior normalized microstructure and with quenching intensities (H_R) of (a) 11.8 m^{-1} (0.3 in.$^{-1}$) and (b) 59 m^{-1} (1.5 in.$^{-1}$). The dashed curves represent temperatures at the indicated duration in seconds (s) and the solid lines represent the percentage of transformed austenite.

Microstructure and Property Generation. The percentage distribution of the reaction products at room temperature is shown in Fig. 6(a) and (b). The hardness distribution across the cross section after quenching and after tempering at 400 °C (750 °F), 500 °C (930 °F), 600 °C (1110 °F) for 2 his illustrated in Fig. 6(c) and (d).

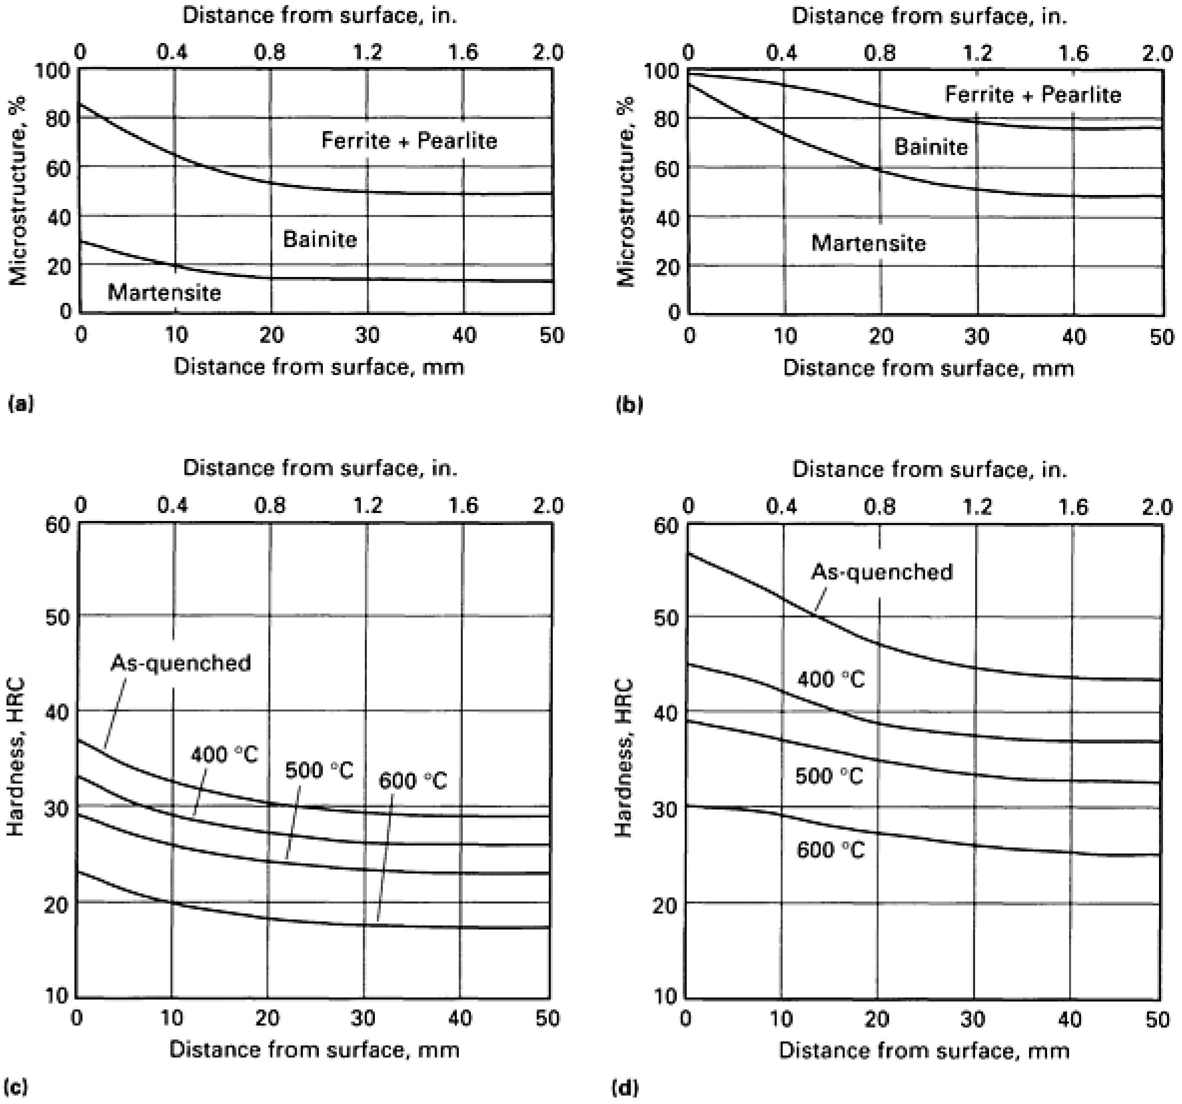

Fig. 6 Calculated values of microstructural constituents (a and b) and hardness values (c and d) from the transformation characteristics of Fig. 5

Figure 7 presents an alternative transformation diagram system used to determine core characteristics of cylindrical workpieces. Three different quench conditions are considered for 5140 steel specimens. In the first condition (see arrow 1 in Fig. 7), the user wants to know the starting temperature of the austenitc transformation in the core of 60 mm (2.4 in.) diam workpiece that has been quenched in a slow-cooling oil with H_R value of 11.8 m^{-1} (0.3 $in.^{-1}$). Starting with Fig. 7(b), arrow 1 has to be drawn horizontally until the line denoting a 60 mm (2.4 in.) diam is reached. The arrow is then continued vertically into Fig. 7(a) until the 5% ferritic transformation curve is reached. The arrow then travels to the left horizontally until the starting temperature, which is 660 °C (1220 °F), can be read.

Fig. 7 Calculated transformation diagram system for the core of cylindrical workpieces quenched in different media. See text for details.

In the second condition (arrow 2), the diameter of the specimen is the same, but the cooling intensity of the quenchant (H_R-value) is 31.5 m^{-1} (0.8 $in.^{-1}$). The user now wants to know the temperature in the core when the ratio of the transformed austenitc is 20%. Starting again in Fig. 7(b), the arrow begins horizontally to 60 mm (2.4 in.), then travels vertically into Fig. 7(a) until the 20% value is reached, which corresponds to a temperature of 425 °C (797 °F).

For the third condition (arrow 3), the user wants to know the core microstructure after quenching and the core tensile strength after tempering at 400 °C (752 °F). Once again, a 60 mm (2.4 in.) diam specimen is used, but the quenchant is water with H_R value of 40 m^{-1} (1.0 $in.^{-1}$). Starting again in Fig. 7(b), the arrow travels horizontally to the line marked 60 mm (2.4 in.) then turns vertically downward until the lines for microstructure (60% martensite and 25% bainite as indicated in Fig. 7c) and the tempering curve are reached. As indicated in Fig. 7(d), the tempered core has a tensile strength of almost 1300 MPa (188 ksi).

Figure 8 and Table 4 compare measured and calculated (PPS) hardness values and tensile properties for low-alloy steels similar in composition to the steel described in the above example. As indicated from these data, calculated and measured values closely correlate.

Example 2: Designing a Heat-Treatment Method.

This example describes a technology planning system for producing optimum properties of heat-treated steels. The goal was to achieve a specified yield point of 780 MPa (113 ksi) at 16 mm (0.6 in.) below the surface of a cylindrical steel specimen (0.42% C, 0.31% Si, 0.85% Mn, 1.02% Cr, 0.05% Mo, 0.07% Ni). Because applicable standards for this steel called for a yield point value of only 510 MPa (74 ksi) in the range of 40 to 100 mm (1.6 to 4 in.), the first question that had to be answered was whether the 780 MPa (113 ksi) value could be achieved with the available steel.

Figure 9 shows the flow chart of the technology planning system used to determine the most effective heat treatment/ property combination. The input data are shown on the left side of the flow chart. Important parameters addressed are:

- Chemical composition of the workpiece to be heat treated
- The initial state of the workpiece prior to heat treatment
- Geometrical and quenching conditions
- The required properties after heat treating

The predictor unit (PPS detailed above) starts the calculation. For this, it needs preselected initial process parameters. Then the predicted properties are compared with the required properties. If one of the calculated properties is less than the corresponding prescribed property, the process parameters are modified. The loop continues until the calculated properties are better than the required ones. Then the process parameters are printed. Table 5 outlines the heat treatment predicted to provide the desired properties.

Table 5 Calculated heat-treating parameters for the low-alloy steel workpiece described in Example 2

Parameter	Value
Input data	
Chemical composition	C = 0.42%
	Si = 0.31%

Example 3: Selection Program for Hardenable Steels.

The analysis of the mechanical properties of the different steel grades as well as the systematization of the derived relationships among these properties can be utilized in practical steel selection. This example describes a steel selection procedure for hardenable steel grades, which can be characterized by their Jominy end-quench bands.

Figure 10 shows the flow chart of the steel selector software. The left side of the figure contains the input parameters, the inner side contains the algorithm, the right side of the figure shows necessary data that are stored in a data base and are used by the program, and in the bottom of the figure the output data can be seen.

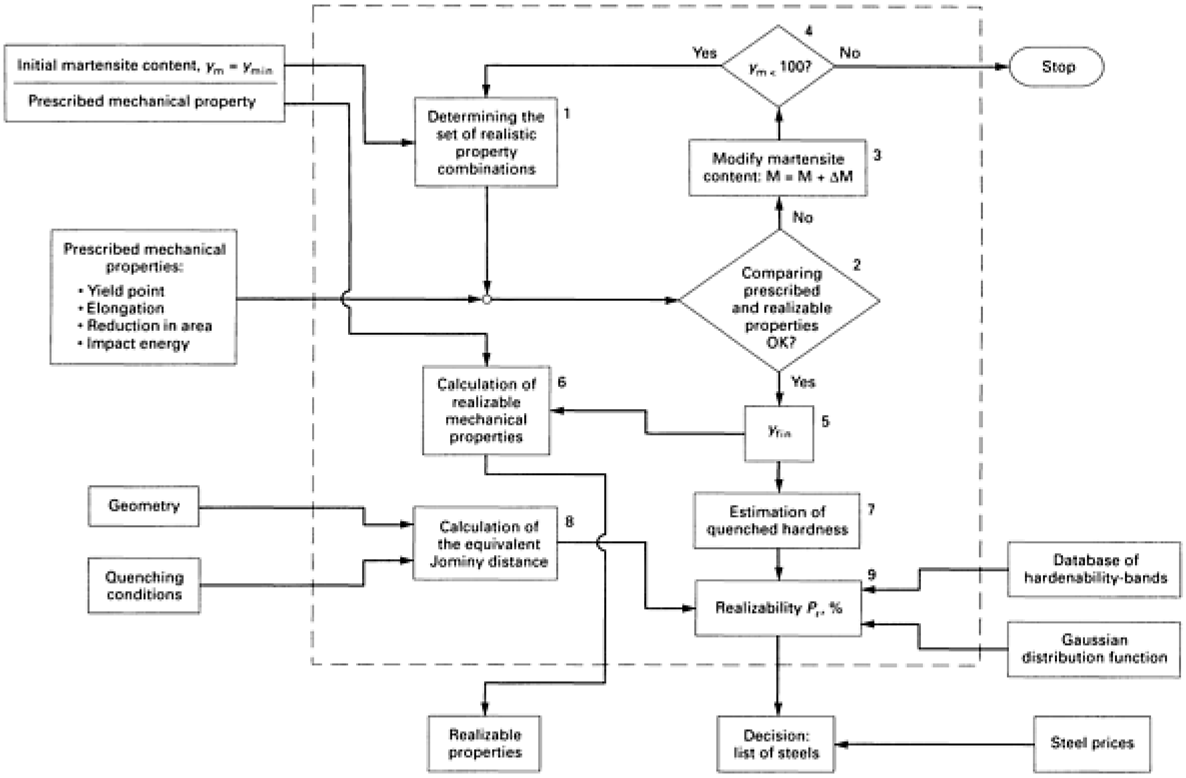

Fig. 10 Block diagram of a computer program used for the selection of hardenable steels

Suppose the following mechanical properties are prescribed: tensile strength (R_m), yield point (R), elongation (A_{50}), reduction in area (Z), and impact energy (KU). First, the knowledge concerning the steel properties and their correlations among each other are checked with formulas similar to Eq 30, 31, 32, and 33. The calculation is started with a predefined initial martensite content $y_m = Y_{min}$ and the given R_m value. According to the flow chart (Fig. 10), the output of Unit 1 is a set of realizable mechanical properties, calculated with the initial minimum martensite content on the basis of the prescribed tensile strength.

Unit 2 (Fig. 10) compares this output to the input requirements. If any of the requirements are not fulfilled, the initial martensite content has to be increased by a small amount Δy_m in Unit 3. The calculation is then executed with this martensite content, and the martensite content is increased again and again to the very y_{fin} value that satisfies the requirements. In this loop, it is controlled by Unit 4, whether the martensite content is less than 100%. If the martensite content reaches 100%, and the realizable properties still do not meet the requirements, it means that none of the case-hardened or quenched and tempered steels can be used to achieve the given properties. With this value y_{fin}, the realizable mechanical properties are then calculated in Unit 6.

The next decision in the selection procedure is based on the Jominy hardenability band (see Fig. 11). Unit 7 estimates the minimum hardness J_q, which has to be realized after quenching. This value is one of the inputs of Unit 9, which has the most important role in the decision procedure. The second input comes from Unit 8. For a given point on the workpiece, where the properties are prescribed, a distance E from the quenched end on the Jominy bar, where the quenching conditions are very similar, must be determined. This is called equivalent Jominy distance, E_e.

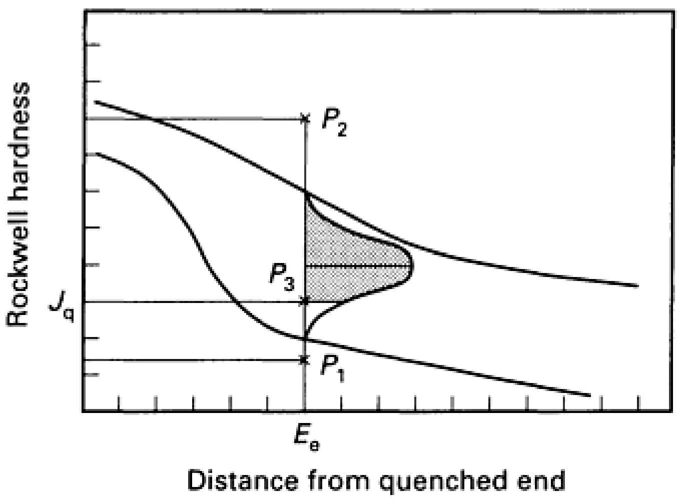

Fig. 11 Illustration of the hardenability parameters in the steel selection program

The calculated E_e and J_q values determine a point in the coordinate system in Fig. 11. Three possible positions of this point (E_e, J_q) may occur (Fig. 11):

- Point P_1 is below the hardenability band and even the lowest allowed hardenability curve will result in a higher quenched hardness than the necessary hardness J_q
- Point P_2 is above the upper curve of the hardenability band and meeting the prescribed hardness requirements with this steel is out of the question
- Point P_3 is between the two curves. Normally, it can be supposed that at this E_e Jominy distance, the hardnesses of the steel grade follow the Gaussian distribution (Fig. 11). The probability of achieving J_q hardness is proportional to the shaded area and can be calculated from the Gaussian distribution function. This probability in percentage is called realizability P_r

The Jominy bands of the standard steel grades are stored in a data base, from which Unit 9 retrieves them one after the other and calculates the realizability for every steel. It is reasonable to predefine a limit, for example 70%, and in case the realizability is less than this value, the steel grade will not be included in the list of steels, which will probably satisfy the hardness requirement. Another data base shown in the right side of Fig. 10 contains the price of the steels, which is displayed then together with the realizability to the designer's convenience.

Computer Prediction of Process Parameters for Gas Carburizing

Gas-carburizing practice involves either a single-stage or, even more so, a two-stage boost/diffuse technique to produce the desired carbon profile and hardness distribution on the workpiece surface. In what follows, a simulation program is outlined that helps the user in steel selection and the heat treater to minimize the total time required for one- or two-stage gas-carburizing processes controlled in terms of carbon potential. The block diagram of the program is shown in Fig. 12.

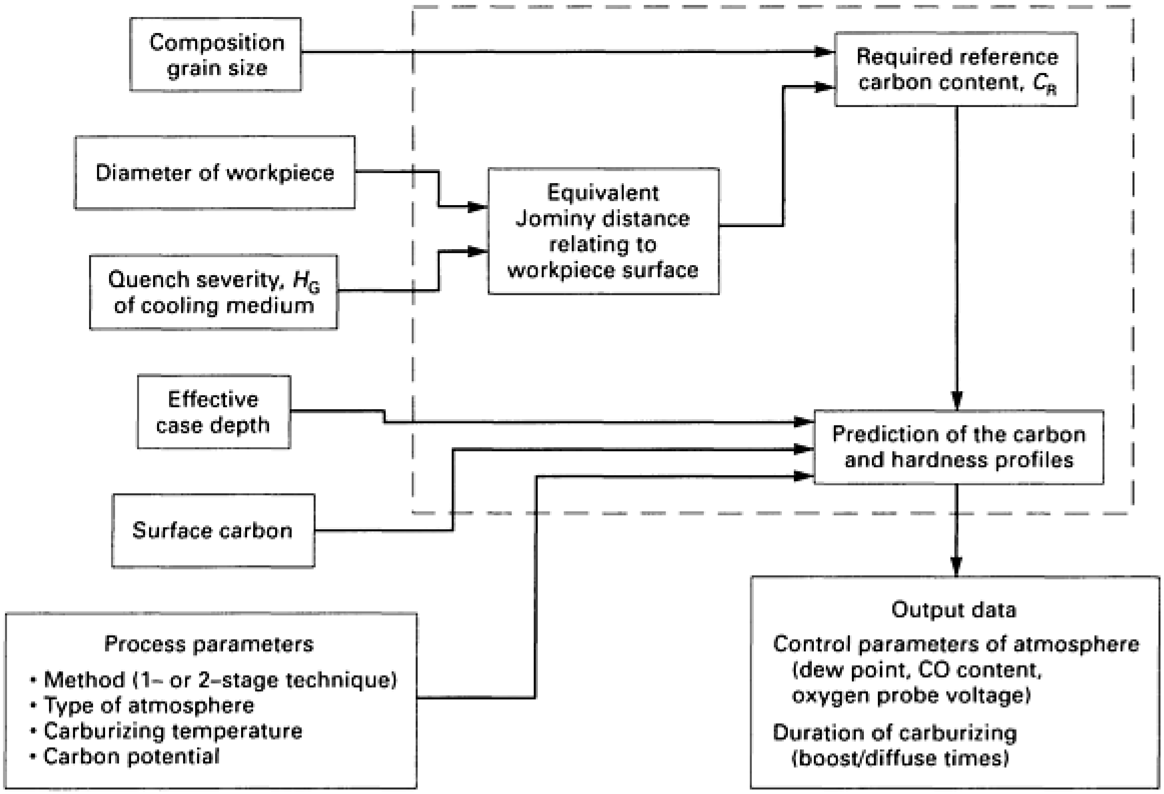

Fig. 12 Block diagram of the simulation model used for process planning of gas carburization

The computing algorithm simulates the total carburizing process, predicts the carbon and hardness profile after quenching and calculates the main process parameters of practical interest (Ref 35, 36). The input data on the left side of the block diagram are as follows:

- Data on the steel grade (chemical composition, grain size)
- Diameter of the workpiece (supposed to be a cylindrical bar)
- Quench severity of the quenchant used for quenching after carburizing (H_G = Grossmann quench factor)
- Effective case depth, *d*, defined in terms of either a prescribed reference carbon content, C_R, or as a depth to 52.5 HRC required after quenching
- Data on the process parameters such as technique of carburizing, type of atmosphere, carburizing temperature in the boost and the diffusion period, carbon potential, and so on

The output data are:

- Data on the atmosphere composition required to control the carburizing process (dew point, CO_2 content, oxygen probe voltage, and so forth)
- Calculated values of the time parameters of carburizing
- Predicted carbon profile and hardness distribution curve generated as a function of the distance below surface

The algorithm used to predict the hardness distribution on the basis of the calculated carbon profile is of particular importance in the applied model. The basic principle of this algorithm proposed by Wyss is demonstrated in two examples (Ref 37).

Example 4: Prediction of Case Hardness from the Carbon Profile of a Carburized Steel.

Assuming that the carbon profile has already been calculated (Fig. 13), the task now is to predict the hardness value HRC_1 in an arbitrarily selected distance d_1 = 1.25 mm (0.05 in.) below the surface on the basis of the corresponding case carbon content C_1 = 0.4%. As an example, let us take a cylindrical bar of diameter D = 50 mm (2 in.) made of case-hardenable steel, which must be quenched after carburizing in oil characterized by the quench factor H_G = 0.6. If the Jominy curves for the carburized steels are available, the unknown hardness value HRC_1 can be predicted using the relationship between the bar diameter D, the value H_G, and Jominy curves of the carburized steel.

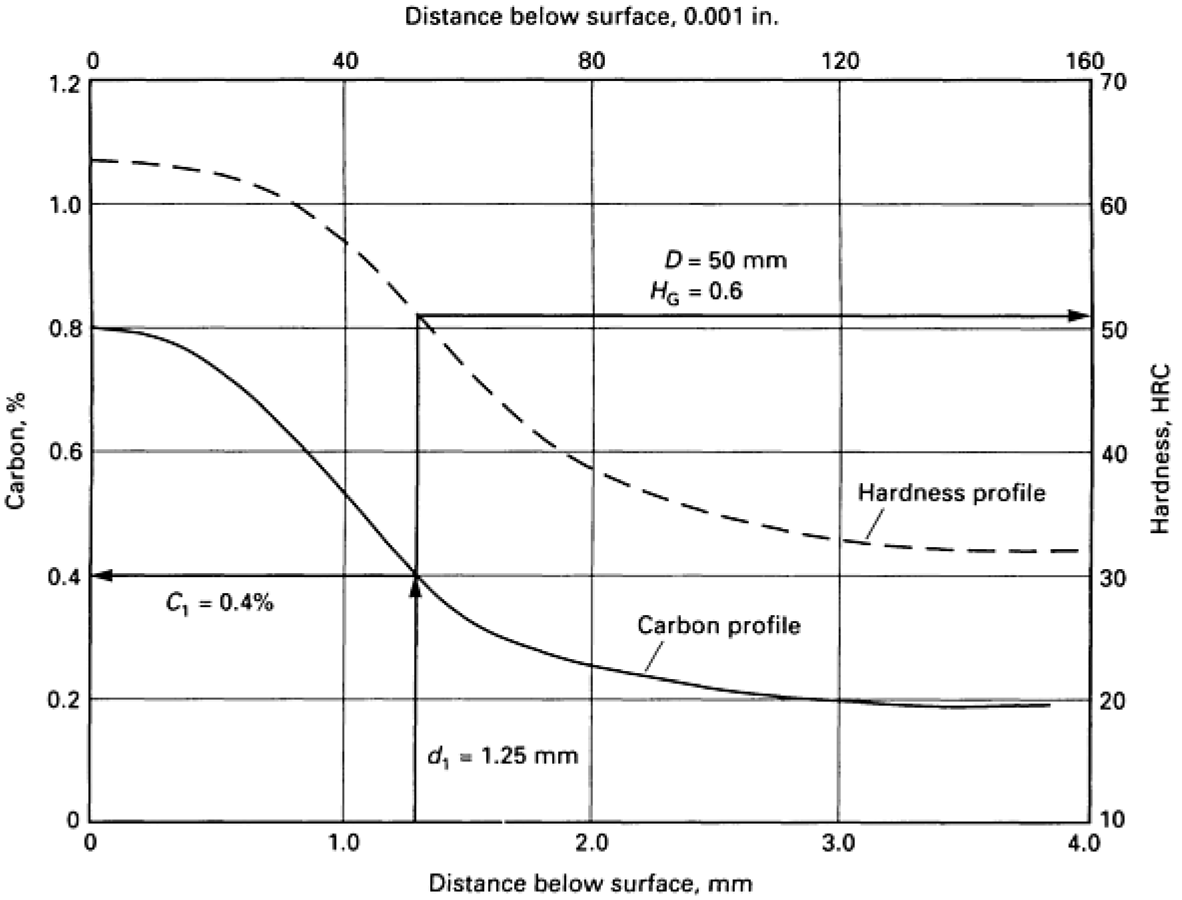

Fig. 13 Relation between the carbon profile and hardness in a carburized case

If the Jominy curve is not available, the Jominy curve of a steel in the composition range given below may be computed by the empirical formula derived by Just (Ref 2):

$$J_{6\text{-}80} = 95\sqrt{C} - 0.00276\,E^2\sqrt{C} - 12.28\sqrt{E} + 0.898\,E - 0.81G + 20\text{Cr} + 38\text{Mo} + 14\text{Mn} + 5.5\text{Ni} + 6.1\text{Si} + 39\text{V} + 96\text{P} - 13 \quad \textbf{(Eq 34)}$$

where E is the Jominy depth in mm, G is the ASTM grain size, and J is the calculated Rockwell hardness. This formula is applicable for steels with the following ranges: 0.13 to 0.55% C, 0.15 to 1.40% Si, 0.4 to 1.78% Mn, 0.11 to 2.07% Cr, 0 to 0.25% Mo, 0.01 to 2.02% Ni, 0.01 to 0.12% V, 0.008 to 0.035% P, and 6.5 to 10.5 ASTM grain size (G). The calculated Jominy curves for the steel described above with the core carbon content of 0.2% and a case carbon content of 0.4% are shown in Fig. 14.

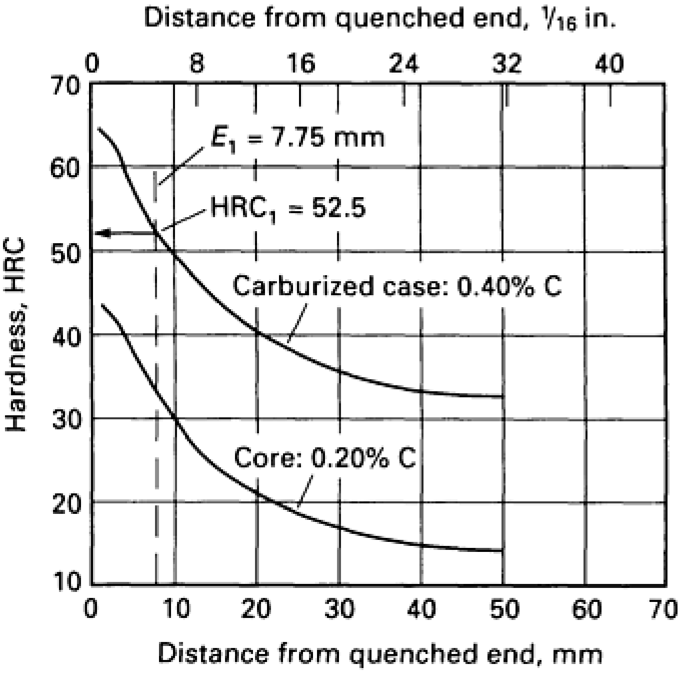

Fig. 14 Prediction of the hardness profile on the basis of computed Jominy curve of a carburized steel (0.20% C, 0.8% Mn, 0.6% Cr, 0.55% Ni, 0.20% Mo)

In order to determine the unknown hardness value HRC_1, the equivalent Jominy distance, E_1, must be determined. This Jominy depth, E_1, can be estimated on the diagram proposed by Grossmann (Fig. 15). This diagram enables the computation of the equivalent Jominy distance as a function of the bar diameter and the value H_G. The relationship between the E, D, and H_G can be represented by the following equation:

$$\log E = \left\{0.23581 - 0.28155 \ln H_G + 0.18904\sqrt{H_G} - 0.000052D\right\}\log D \qquad \textbf{(Eq 35)}$$

where the Jominy depth E and bar diameter D are in mm, and H_G value is in in.$^{-1}$. This formula is valid for 5 to 300 mm (0.2 to 12 in.) bar diameters and an H_G value of 8 to 80 m^{-1} (0.2 to 2 in.$^{-1}$).

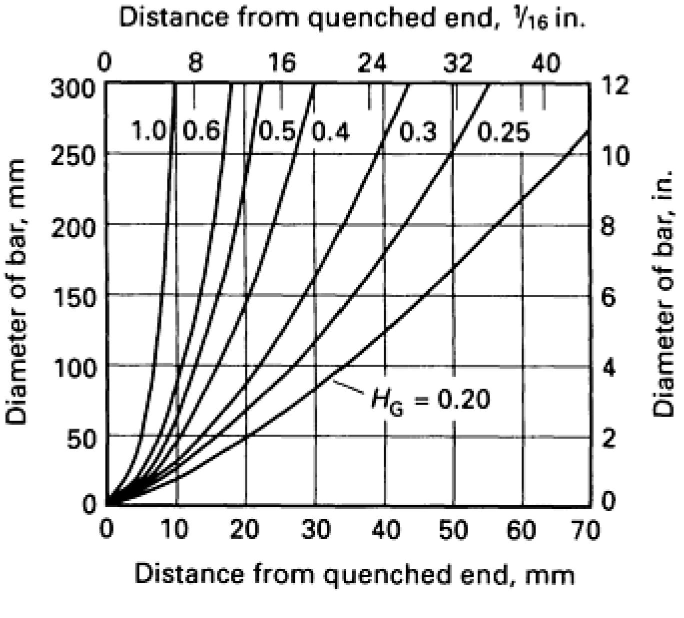

Fig. 15 Curves showing correlation between rates of cooling in the Jominy specimen and rates of bars cooled in various quenching media. The diagram applies to the surface of a cylindrical bar.

Substituting the corresponding values D and H_G into Eq 35, E_1 = 7.75 mm (0.3 in.) can be obtained. The use of the diagram in Fig. 15 leads to the same result. Knowing value E_1, the hardness belonging to distance d_1 can be obtained from the Jominy curve in Fig. 14, that is, HRC_1 = 52.5 HRC.

Example 5: Determination of Required Carbon Profile for a Specified Case Depth in a Carburized Steel.

If the effective case depth is defined as depth to a specified hardness such as 52.5 HRC (550 Hv), and is used as an input to the model, the reference carbon content C_R necessary to achieve that hardness must be calculated on the basis of the previously detailed considerations. It is clear that the required reference carbon content is determined by the chemical composition, grain size, bar diameter, and quench severity of the cooling media. In case of a given steel composition, the reference carbon content C_R depends on the bar diameter D and the H_G value of the quenchant. This conclusion is demonstrated by computation results for the 4820 steel (0.20% C, 0.65% Mn, 3.5% Ni, 0.25% Mo) in Fig. 16. The required value of C_R may vary significantly as a function of bar diameter and of the cooling power of the quenchant. In practice, the value of reference carbon content is chosen in the interval 0.33 to 0.45%. This is because if C_R is less than 0.33%, the necessary surface hardness cannot be achieved; on the other hand, if C_R is higher than 0.45%, the required carburizing time increases considerably.

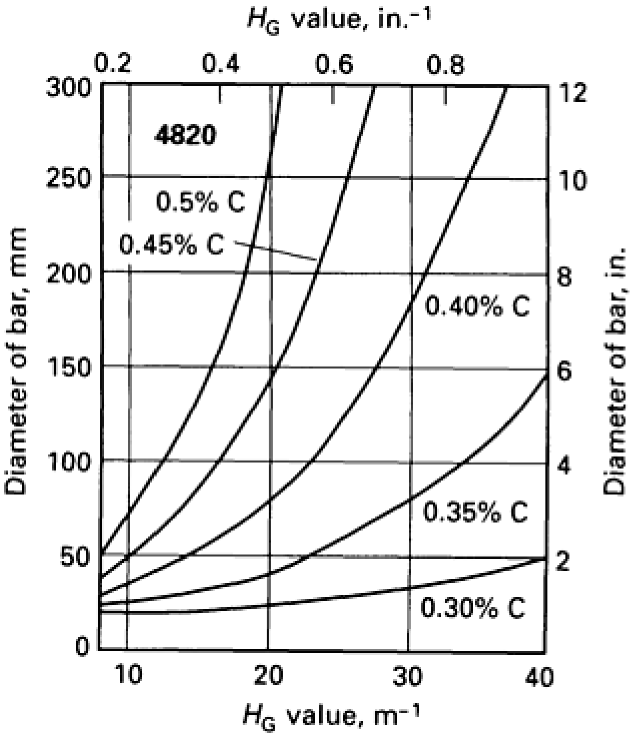

Fig. 16 Relationship between diameter of workpieces, Grossmann's quench factor, and the reference carbon content necessary to achieve the specified case hardness defined as 52.5 HRC (550 HV)

Analysis of Process Parameters. Simulation of gas carburization allows the analysis of different process parameters such as temperature, steel composition, carbon potential, part size, and treatment time. All of these variables affect the carbon profile, and the resulting case hardness for a given quench. By using the computer simulation, several kinds of carburizing cycles can be tested and compared, and there is no need for expensive and time-consuming heat-treatment experiments.

PREDCARB (Ref 35, 36) is an example of a simulation program developed for the analysis of gas-carburization cycles. A simulation run of this program was performed for 8620H steel (0.2% C, 0.28% Si, 0.8% Mn, 0.5% Cr, 0.55% Ni, 0.2% Mo) with the following input parameters:

- 50 mm (2 in.) diam bar
- Quench intensity of 24 m^{-1} (0.6 $in.^{-1}$)
- Atmosphere of 20.5% CO and 40.5% H_2 for both the boost and diffuse periods
- ASTM grain size of 7
- Effective case depth of 1.25 mm (0.05 in.) defined by a hardness of 550 HV (52.5 HRC)
- Surface carbon content of 0.8%
- Boost temperature of 900 °C (1650 °F)
- Boost carbon potential of 1.15%
- Diffuse temperature of 900 °C (1650 °F)

From these parameters, a 12.5-h boost period and a 1.3-h diffuse period were the predicted time periods necessary to achieve the specified case and hardness profiles shown in Fig. 17. These predicted process times can then be varied as a function of different process variables such as workpiece/specimen diameter, quench severity, core carbon content or the carbon potential during the boost phase.

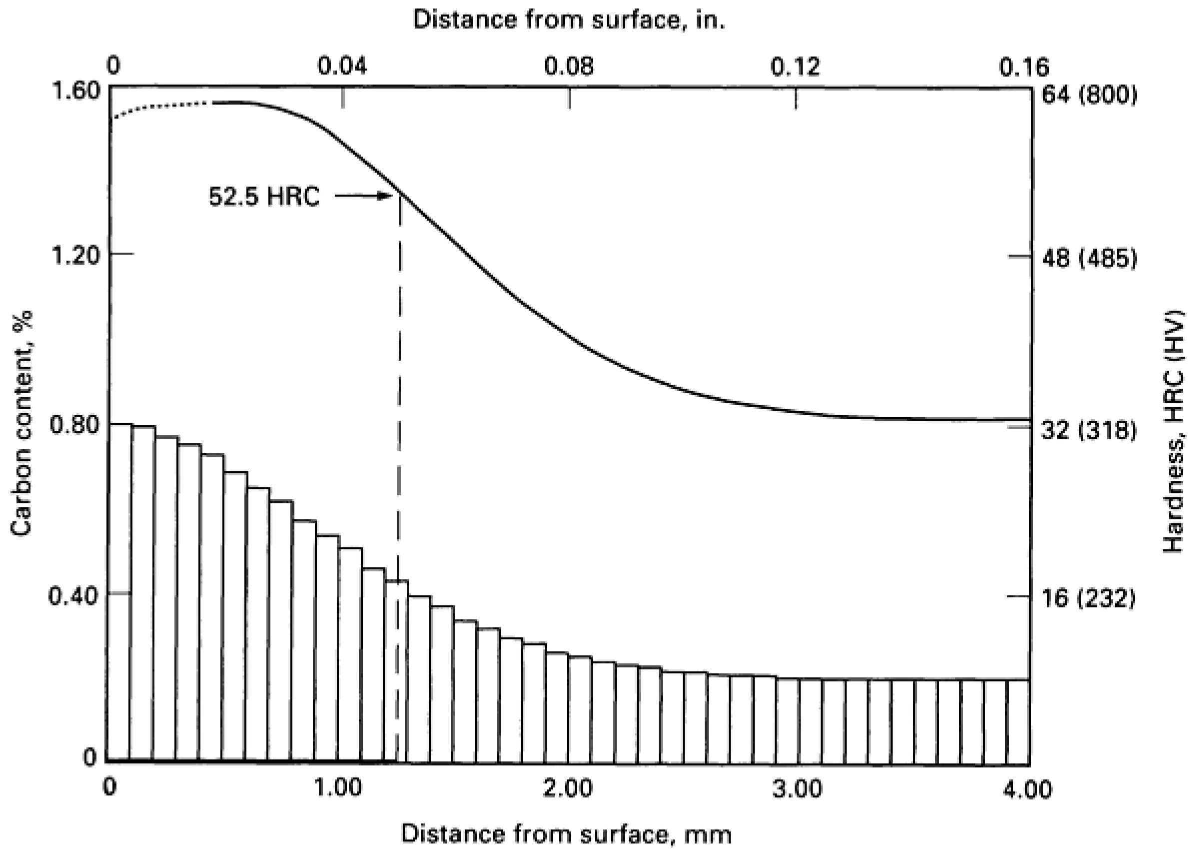

Fig. 17 Calculated carbon and hardness profiles for two-stage carburizing of an 8620H steel. The effective case depth of 1.25 mm (0.05 in.) is defined by a hardness of 52.5 HRC (550 HV).

For example, in order to demonstrate how the workpiece diameter and the H_R value influence the duration of a two-stage gas-carburizing process, Table 6 summarizes some computational results for the required boost time, t_A, the diffuse time, t_B, and reference carbon content. As indicated by these data, the time required for carburizing can be reduced considerably by decreasing the diameter of the workpiece or by increasing the quench severity of the cooling medium.

Table 6 Effect of workpiece diameter and quench severity on process times and reference carbon content during two-stage gas carburizing in endothermic atmosphere from natural gas. Effective case depth to 52.5 HRC is equal to 1.25 mm (0.05 in.)

Process parameters[(a)]	**Diameter of workpiece**			**Quench factor, H_R**	
	25 mm (1 in.)	**50 mm (2 in.)**	**100 mm (4 in.)**	**m^{-1}**	**$in.^{-1}$**
Boost time, h	13.6	19.5	. . .	11.8	0.3
Diffuse time, h	1.4	2.1	. . .	11.8	0.3
Reference carbon content, %	0.46	0.54	>0.6	11.8	0.3
Boost time, h	10.4	12.5	16.1	23.6	0.6
Diffuse time, h	1.0	1.3	1.7	23.6	0.6
Reference carbon content, %	0.41	0.44	0.5	23.6	0.6

(a) Required surface carbon content: 0.8%: Boost and diffuse temperature: 900 °C (1650 °F); Boost carbon potential = 1.15%; Diffuse carbon potential: 0.8%

Figure 18 shows the relationship between the core carbon content and the predicted process time for a carburized low-alloy steel (0.16% C, 0.32% Si, 0.49% Mn, 1.03% Cr, 3.04% Ni, 0.22% Mo). A nitrogen/methanol mixture (CO% = 19.7) was used during the boost stage; the diffuse period utilized pure nitrogen. Other carburizing conditions included:

- Boost/diffuse treatment at 930 °C (1705 °F) to produce a case depth of 0.8 mm (0.03 in.) based on a reference carbon content of 0.35%
- Boost carbon potential: 1.1%
- Diffuse carbon potential: 0.7%

As can be seen in Fig. 18, by increasing the core carbon content, the time of a two-stage carburizing process can be decreased and energy subsequently saved.

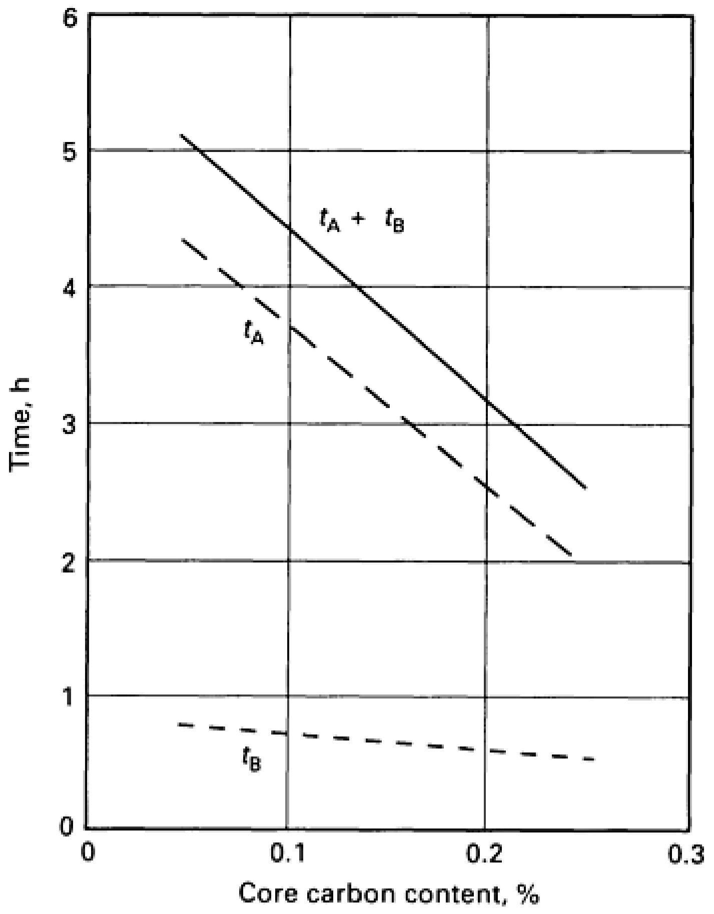

Fig. 18 Relationship between core carbon content of steel and predicted process times for two-stage carburizing in nitrogen/methanol-based atmosphere at 930 °C (1700 °F) (t_A = boost time, t_B = diffuse time, and t_A + t_B = total time)

Figures 19 and 20 compare measured and predicted (PREDCARB) values for hardness profiles, carbon profiles, and case depths for low-alloy steels similar in composition to the steel described in the above example. In Fig. 19, a steel bar (0.18% C, 0.34% Si, 0.91% Mn, 0.61% Cr, 0.4% Ni, 0.2% Mo) was given a boost/ diffuse treatment at 930 °C (1705 °F) using an endothermic atmosphere derived from natural gas to produce a case depth of 1.3 mm (0.05 in.). The case depth is defined as the depth that corresponds to the prescribed reference carbon content of 0.35% C.

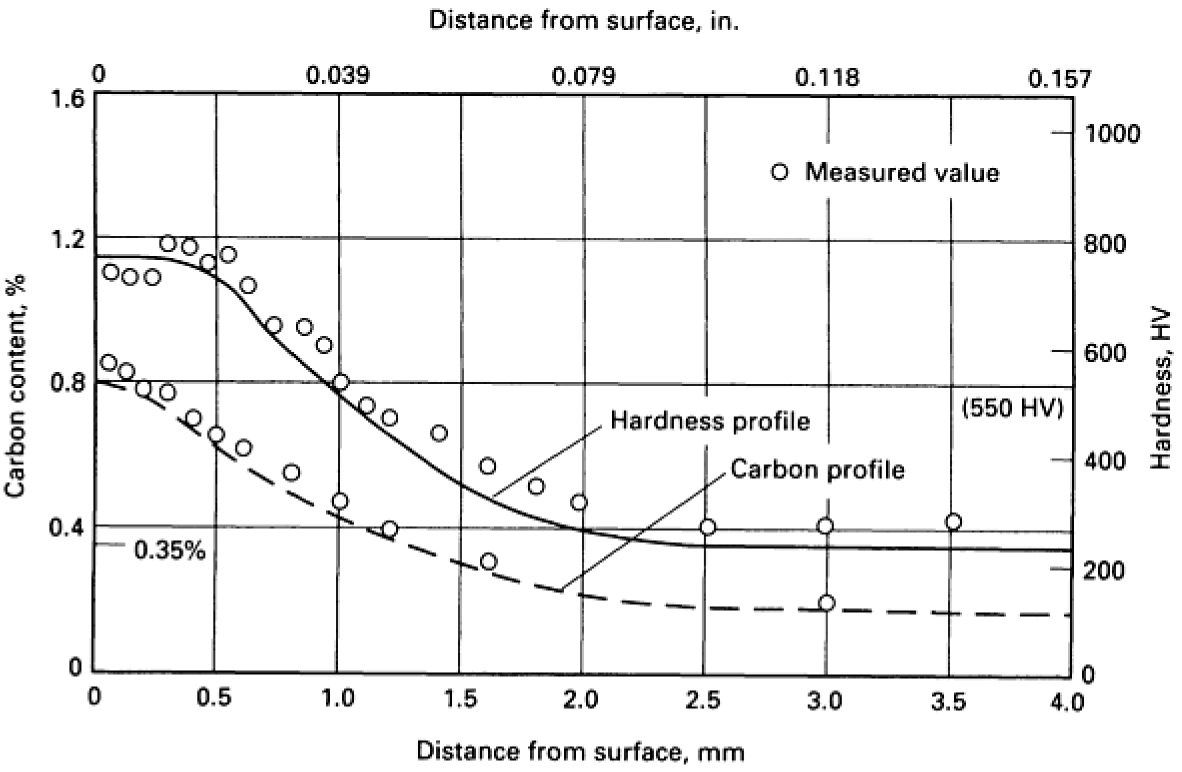

Fig. 19 Comparison of the measured and predicted carbon and hardness profiles in a carburized case of an oil quenched 50 mm (2 in.) diam bar. Steel composition: 0.18% C, 0.34% Si, 0.91% Mn, 0.61% Cr, 0.4% Ni, 0.2% Mo

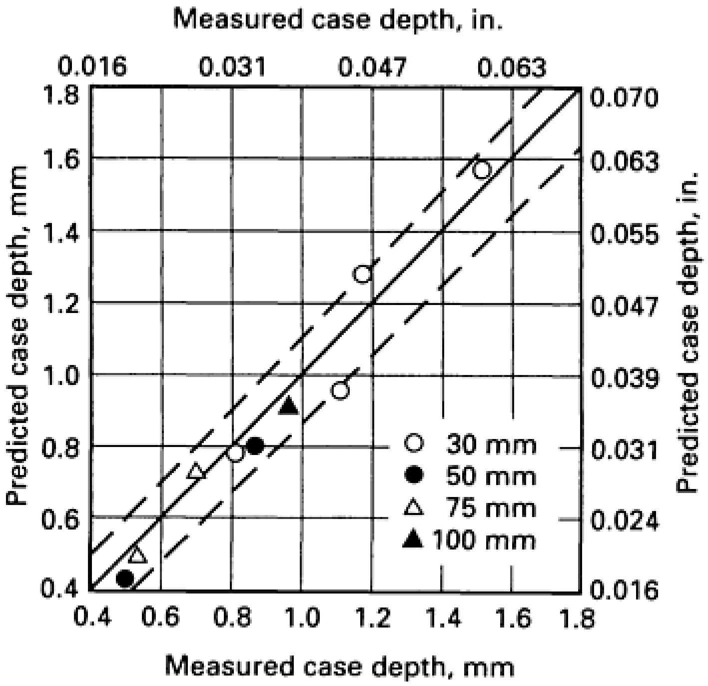

Fig. 20 Comparison of the measured and predicted case depths after boost/diffuse gas carburizing and oil quenching of low-alloy steels

Heat-treating parameters were:

- Boost conditions: 7 h at 1.06% carbon potential
- Diffusion conditions: 1.5 h at 0.78% carbon potential
- Quench from 850 °C (1560 °F) in oil
- Estimated quench severity: *H* = 0.25
- Oil temperature: 60 °C (140 °F)

Figure 20 compares the measured and predicted case depths taken from a variety of low-alloy steels after boost/diffuse gas carburizing and oil quenching treatments similar to those described in Fig. 19. The effective case depth was defined as the depth that had a hardness value of 550 HV measured with a 500 g load. The estimated quench severity was between 0.25 and 0.35. As can be seen in both Fig. 19 and 20, PREDCARB-predicted values closely matched the actual measured values.

Furnace Safety in Heat Treating

Revised by Raymond Ostrowski, Protection Controls, Inc.

Introduction

HEAT-TREATING FURNACES require safety procedures common to all industrial installations, but they also have requirements specific to the use of high-temperature energy sources and potentially explosive gases and liquids used as aids to chemical processing.

Because these heat-treating processes require careful control for optimum technical results and for safety, proper training of operating personnel is a primary consideration. Proper equipment design is also critical.

The information presented here is not intended to be interpreted as a safety standard but is offered only as a set of guidelines. Safety standards for furnaces are maintained by the National Fire Protection Association (NFPA), by the U.S. Occupational Safety and Health Administration (OSHA), and by insurance underwriters.

All equipment should be installed and operated with awareness of the potentials for fire and explosion and the hazards to operators and equipment. Equipment designs should ensure reliable, safe operation over the expected maximum life of the equipment.

Fuel-Fired Furnaces

Fuel-fired furnaces for heat treating have several major control requirements that depend on whether the process must be directly or indirectly fired; whether heat treating is to be done under a particular pressure or vacuum, or in a controlled atmosphere; and whether the product uses a special precoat or laminant. In all situations there are fundamental control variables, and instrumentation is available to identify and control change and drift, thus achieving the desired results.

The main control elements are the three requirements for proper combustion: a source of heat, an oxidizing agent, and time.

Fuel-fired furnaces can be automated to the extent that manual intervention is not required for normal operation. However, many processes and operations require manual control, thereby furnace controls range from almost completely manual devices to highly sophisticated computer-controlled devices.

The major control variables and types of instrumentation used in each instance are described below, in sequence, from startup through final cycle control.

Electrical Power for Fuel-Fired Furnaces

The safe use of electrical energy employed in heat-treating control processes requires adherence to National Electrical Codes and to local requirements of states and communities. Good practice dictates that a circuit breaker be positioned within view of the operator. Control cabinets must be designed to ensure that operators cannot inadvertently become a path to ground. Wiring type should be based on the environment of use, and wiring for all motor and control circuits should be contained in appropriate conduits. Numbers of wires within specific conduits should be governed by the fact that elevated temperatures may be encountered. All enclosures for electrical apparatus should be designed to protect the contents from the environment. The furnace should be grounded for proper control.

The source of electrical power to the furnace installation should be equipped with fuses. Each motor should also be equipped individually with fuses and protected with thermal-overload elements based on operating temperatures. Motor selection should be based on such conditions of use as temperature, weather, dust, dirt, atmosphere, and humidity. Manufacturers should be consulted on motor design and selection. Control-panel power should be fused and provided with externally operated switches to allow safe entry by authorized personnel.

Electronic-signal wiring from the flame-safety circuits should have its own conduit, free from the "noise" and induction present in normal power and control circuits. Thermocouple wiring also should be contained in its own conduit to avoid creating induced errors from such random sources as power lines, signal wiring, motors, and ballasts.

Control Circuits for Fuel-Fired Furnaces

Combustion-Air Blower Control. Combustion-air blowers must be interlocked with the combustion-limit circuits to shut down the process in the event of failure. The flow of combustion air must always be proven before and during a processing cycle with two independent sources of information. The motor should be protected from short circuits with fuses and from overheating or amperage draw with thermal breakers (heaters). The motor starter should be wired so that it will disconnect when any phase is interrupted or when the motor malfunctions. It should not be assumed that the blower is providing combustion air just because the blower motor is operating; combustion-air flow must be proven. At one time, an end switch, or rotary switch, on the motor was a common indirect method of gaining this information. A better method is to use a pressure switch in the air line for direct sensing. A sail or flag switch, although not quite as good because of the mechanical movements required, can also be used to directly sense air flow.

Programmable Controllers. The development over the last decade or so of high technology programmable controllers has been both beneficial and confusing to users. The ease and precision with which these devices monitor and control processes such as heat treating make them extremely attractive to industry.

However, until recently there existed no published guidelines for proper application of these controllers to combustion systems. When a programmable controller is used in conjunction with combustion safeguard circuitry on fuel-fired systems, the combustion safety interlocks, listed combustion safeguards, and excess temperature limits shall be wired to directly de-energize the fuel safety shutoff valve(s).

Gas-Pressure Control. Fuel must arrive at the burner in the correct quantity and at the correct time for safe combustion. Fuel pressure thus must be proven within an allowable range. Gas-pressure switches for both high and low gas limits are installed in the main gas lines. Visual pressure gages are also helpful to operators in setting burners and in verifying that the fuel is being supplied within the proper range and that pressure limit switches are not malfunctioning. Mercury-wetted relay pressure switches are recommended for their easy setup and maintenance and for their reliability.

Pressure Regulators. Pressure of gaseous fuel is most commonly regulated by pressure-regulating diaphragms. Good, safe design normally requires one regulator for pilot fuel and one regulator for main-burner fuel. The pilot gas, if taken from the main fuel line, should be drawn from a point between the gas supply and the regulator for the main fuel. Therefore, the pilot and main burner can be set up optimally, safely, and independently. The regulators should be vented to a safe location outside the plant to ensure safety if a regulator diaphragm is damaged in service. Good practice and manufacturers' recommendations show that diaphragm life can be substantial if regulators are shielded from thermal radiation and are used below their maximum design limits. Positive lockup regulators are recommended to prevent downstream pressure buildup during shutdown periods.

Valves. Blocking valves normally are closed valves that are energized only by the combustion-control circuits. The pilot-gas blocking valve is placed downstream of the pressure regulator and a hand-operated gas cock. A pipe union should be inserted just ahead of the electrically operated blocking valve to allow safe removal if repairs are needed. The blocking valve is opened to the pilot assembly only after the furnace is purged.

Purging of Fuel-Fired Furnaces

The furnace must be purged of any possible combustible materials. This is best accomplished by opening the furnace doors, which should be equipped with a limit switch to ensure that they are opened adequately. Once the doors are open, the combustion blower or exhaust fans can be timed to allow for a minimum of 4 standard cubic feet (0.11 m^3) of fresh air per 0.028 m^3 (1 ft^3) of furnace volume. This purge cycle is required for safe startup and is standard practice for all well-managed operations.

Pilot Control

Pilot assemblies can be of either the atmospheric or the blast type. The atmospheric type is similar to an atmospheric burner, in which the air is inspirated from the atmosphere by the gas stream.

In the blast type, air and gas are brought to a mixer under pressure. The gas is then reduced to atmospheric pressure and pulled into the mixer by the pressurized air stream. This is the most positive means of pilot-gas control.

Ignition

For ignition trials, a high-voltage transformer is used in conjunction with a spark plug designed for the pilot or burner assembly. The control circuit opens the pilot valve, and a spark is produced. The spark continues for a short period (normally 15 s) and establishes a flame that can be detected. If the flame is not established because the flame or signal is inadequate, the cycle returns to the purging stage.

The voltages normally employed are approximately 5000 to 6000 V, and the high-voltage transformer is normally mounted on the furnace and grounded to it. The spark in turn is grounded to the pilot assembly and then to the furnace; hence, a well-grounded furnace is an important safety requirement.

Ignition systems have no provisions for providing flame and should not be used in lieu of combustion safeguards. Safety standards specify that spark energy is to provide only a source of ignition.

Flame Detection

A thermocouple junction placed in intimate contact with the pilot flame is perhaps the most common means of flame detection, but thermocouples are useful only on very small pilot assemblies or burners (not to exceed 44 kW, or 150 000 Btu/h). The flame may no longer be present, but a hot burner block or refractory may retain heat and slow the rate of thermocouple cooling. Thus, thermocouple junctions are not recommended except for quench-tank heaters of the constant-pilot, open-grid burner design or for small atmospheric burners.

Flame electrodes, which are small anodes of heat-resisting alloy placed in intimate contact with the normal pilot flame, work on the principle that flame causes ionization within the burner atmosphere and thus allows a circuit to be formed to ground. The flow of a minute amount of current, at low voltage, is sufficient to sense and communicate the presence of a flame.

Flame electrodes are common on all industrial heat-treating furnaces where the flame is kept on ratio or slightly oxidizing. The flame electrode tends to become carbon coated in a reducing flame, a condition that can cause nuisance shutdowns.

Ultraviolet (UV) scanners are the third common device for sensing flame. They are normally dependable if the lens viewing the flame is kept clean. The UV scanners must not be used in any application where ultraviolet light is present from a source other than the burner in question. The UV scanner is a useful and practical device for any clean-flame, clean-furnace operation if it is located and aimed properly. A flow of clean, filtered cooling air across the scanner face aids in keeping it clean and cool, extending scanner life appreciably.

General Comments. Depending on the burner used, the application, and property-insurance requirements, it may be necessary to monitor both the main burner and the pilot flame independently.

Common and serious errors in flame detection are made by operators who circumvent flame-safety equipment rather than correcting the usually minor problems that cause nuisance shutdowns. Flame-safety equipment that uses totally enclosed relays is recommended over types with accessible relays that may be kept open with, for example, a piece of paper. This point, however trivial it may seem, has been profoundly recognized by those firms who have lost operators, furnaces, and product as a result of poorly designed flame-safety equipment that can be circumvented easily. Any employee found tampering with this equipment should receive disciplinary action, and all employees should be trained in the use of flame-safety equipment.

Burner Operation

The main fuel supply for fuel-fired heat-treating furnaces normally is natural gas, propane-air, propane, butane, or one of the fuel oils. Although this discussion centers on natural gas, the same principles apply to the other gases and oils.

The main gas valve may be fully automatic or of the manual-reset type, requiring an operator. The manual type is usually preferred when the furnace is run intermittently or when operators must perform some other function, such as opening doors. When the operator opens the valve, he is in effect making a conscious decision that conditions are ready for the main burner heat. The valve may be made automatic when the furnace is designed and interlocked to preclude an unsafe condition.

For furnaces with capacities greater than 422 MJ/h (400 000 Btu/h), it is recommended that a second blocking valve be inserted into the main gas line. Revised NFPA 86 standards for ovens and furnaces have removed the requirement for the vent valve. IRI (Industrial Risk Insurers) is the only insurance underwriter that requires the installation of a vent valve.

Burner Control. The gas-air ratio ordinarily is controlled to about 10 parts air to 1 part natural gas for good combustion efficiency. There are several devices involved in control of this ratio. Typically, the amount of blower air is varied by a butterfly valve to satisfy the demands of a temperature-control device. A pulse or static pressure line is connected from the combustion air line, downstream of the butterfly valve, to a proportionator valve located in the gas line. The gas is then regulated by the ratio-control valve in proportion to the air flow, and the air-to-gas ratio remains constant throughout the firing range. The devices used to regulate the ratio fall into two broad categories: the diaphragm type, or proportionator, which uses the pulse line to keep air and gas at a specified ratio; and the mechanical-linkage type. Both are effective and common but the diaphragm type is the more positive, because there are no linkages that can slip and require adjustment. Also, if air lines become dirty, resulting in a lessening of air pressure, the gas pressure will follow, maintaining the correct ratio.

Ratio control alone is not sufficient to ensure safe startup of the main burners. It is recommended that the burners be set to a low firing rate when the main burner is started. This can be done either automatically or manually. Once the main burners have been started, the furnace doors can be shut and the furnace brought up to temperature.

Temperature Control

Temperature-control devices fall into two categories: primary controls and process-limiting devices. Safe operation, especially when furnace practices require long cycles and little operator attention, dictates that limits be placed on the process. These limits should alarm and perhaps shut down the operation to prevent destruction of the product, the furnace, or the plant itself. Whether an analog device, a strip chart recorder, a digital readout, or a printout is used is a matter of operator preference and depends on the nature of the product.

The typical temperature sensor is either a thermocouple or a resistive temperature device (RTD). The thermocouple is most common. Several types of thermocouple junctions are available, with the choice depending on such factors as temperature range and furnace atmosphere. They are comparatively inexpensive and can be easily protected from atmospheres with protective wells, which are immersion tubes that project into the furnace zone to be controlled. RTDs, although more accurate than thermocouples by factors ranging from 10 to 1 up to 50 to 1, are expensive and less rugged. For most purposes, thermocouples are satisfactory. Some firms use heat-flow sensing to remotely ascertain interior temperatures and to provide an element of redundancy for protection of furnaces and their contents. Good temperature-sensing devices will detect failure of a thermocouple or RTD, cause the process firing rate to be reduced to its minimum rate, and perhaps provide an alarm.

Furnace temperature can be regulated by one of two very common procedures. Simple high and low firing rates are used when temperature can be allowed to vary within a fairly large range. More common in heat treating is the use of proportional control, wherein the temperature is held nearly constant through the use of a bridge circuit. This circuit balances the signal between the controller and the butterfly valve and holds the latter at the proper opening to maintain the desired temperature. The latter scheme, although more costly, is required for close control.

An excess temperature limit must be applied to all heating systems where it is possible to exceed a safe temperature limit. It shuts down equipment and alarms the operator of this condition.

Waste-Heat Recovery

Recuperative devices used for conserving energy present special problems in safety and control instrumentation. Typically, these recuperators use the products of combustion for preheating the combustion air. Shell and tube heat exchangers are normally used in this type of arrangement. Because preheated air becomes less dense, the air temperature must be sensed, and control of the gas-to-air ratio must be based on this temperature-density function. Experience with these devices has shown that such factors as poor design, poor gasketing, leaks in heat-exchange surfaces, overheating of burner blocks, and failure to allow for expansion and contraction have caused numerous operational problems that constitute safety hazards. Tracking of air-gas ratios can be affected by leakage of mechanical seals, and products of combustion can enter the combustion air. Therefore, it is recommended that oxygen analyzers be used periodically to check the combustion air immediately ahead of the burner block. This analysis will reduce the likelihood of erroneous and perhaps hazardous conditions in the furnace, will give clues to potential design changes needed, and will give warning of part deterioration. Further, it is recommended that heat-treating operators monitor the room atmosphere for carbon monoxide on a periodic basis. Although exhaust may be provided for products of combustion, and sufficient air exchanges may be occurring to satisfy state regulations, there may be a temperature inversion that can cause leaking of products of combustion inside the building, resulting in a potentially dangerous situation.

Supervisory Gas-Cock System

A supervisory gas-cock system is used to ensure a safe lightoff procedure on a manually ignited, multiburner furnace that does not have flame-safety equipment with a programmed sequence of piloting the main burners.

The system consists of specially designed gas valves that have inlet and outlet passages for checking a pressure medium such as air or gas. Air or gas--usually air from a combustion blower--can pass only through the valve when the valve is fully closed. When the individual burner valves and the main gas line valve are closed, the air flow enters a pressure switch that closes and completes an electrical or pneumatic circuit. This allows the main gas valve, usually of the manual-reset type, to be opened. The burners are then individually manually ignited.

Supervisory gas-cock systems are used on radiant-tube furnaces and other furnaces where flame-safety systems are difficult to apply. Fewer of these systems are being used on new furnaces because most burners now are adapted to flame safety and automatic ignition.

Electric Furnaces

Electric-furnace installations are made up of various electrical and mechanical components, many of which are water cooled and equipped with protective devices.

Furnace manufacturers generally issue instructions concerning safe practices, and these instructions should never be ignored. Potential hazards can be avoided by ensuring that operating personnel are trained thoroughly and that installations conform to safety practices and local codes.

Original equipment usually contains devices for preventing overloads and short circuits. In addition, ground detectors and surge detectors protect motor-generator units from faulty coil or transformer installations at heating stations and from breakdown of insulation in the generator windings.

Protective devices commonly used with induction-heating radio-frequency generators are as follows:

- Door interlocks
- Grounding devices to ground high-voltage circuit when furnace doors are open
- Warning lights
- Warning signs
- Circuit breaker for entire unit
- Overload relays
- Water-flow switches
- Water-temperature switches
- Time-delay relays (tube warmup)
- Grid overload relays
- Control-circuit overload relays
- Arc gaps on blocking and tank capacitors
- Surge protection
- Electronic crowbar

Operators should become familiar with these safety devices and should inspect them periodically to ensure their good working condition.

Electrical Power. Although motor generators account for the largest total power output of installed induction-heating equipment, vacuum-tube oscillators probably occur in the greatest number of units. Many small vacuum-tube oscillators are required to account for as many kilowatts as one 1250 kW, 3 kilocycle motor-generator set. Although many vacuum-tube oscillators for induction heating are made in small sizes, 25 kW and 50 kW outputs are also common ratings. Some have been constructed for special applications, with ratings as high as 500 kW. Many small composite (custom-built or homemade) vacuum-tube units are in use also.

Power Interlocks. Most systems produced by reputable manufacturers are designed to be completely fail-safe. These systems also have interlocks that automatically shut down the power supply if a fault develops during operation. The system cannot be restarted until the fault is corrected. Interlocking systems also are used to increase production of induction-heating machines.

Induction-heating machines are expensive; therefore, steps are taken to keep them busy as much of the time as possible. If a hardening process, for example, requires 5 s of heating, followed by 5 s of quenching (before the part is moved from the inductor), and if another 5 s are required on the average for the operator to load and unload the part, then the generator itself is only in use one-third of the time. Production can be increased appreciably by having the same basic equipment supply two or more individual work coils (Fig. 1). This can be done by arranging the control circuit so that if one of the work coils is demanding heat, none of the others can be started. If an operator pushes the start button at one station while another is heating, a relay withholds the actual start of heating until the first station has completed its high-frequency power demand cycle.

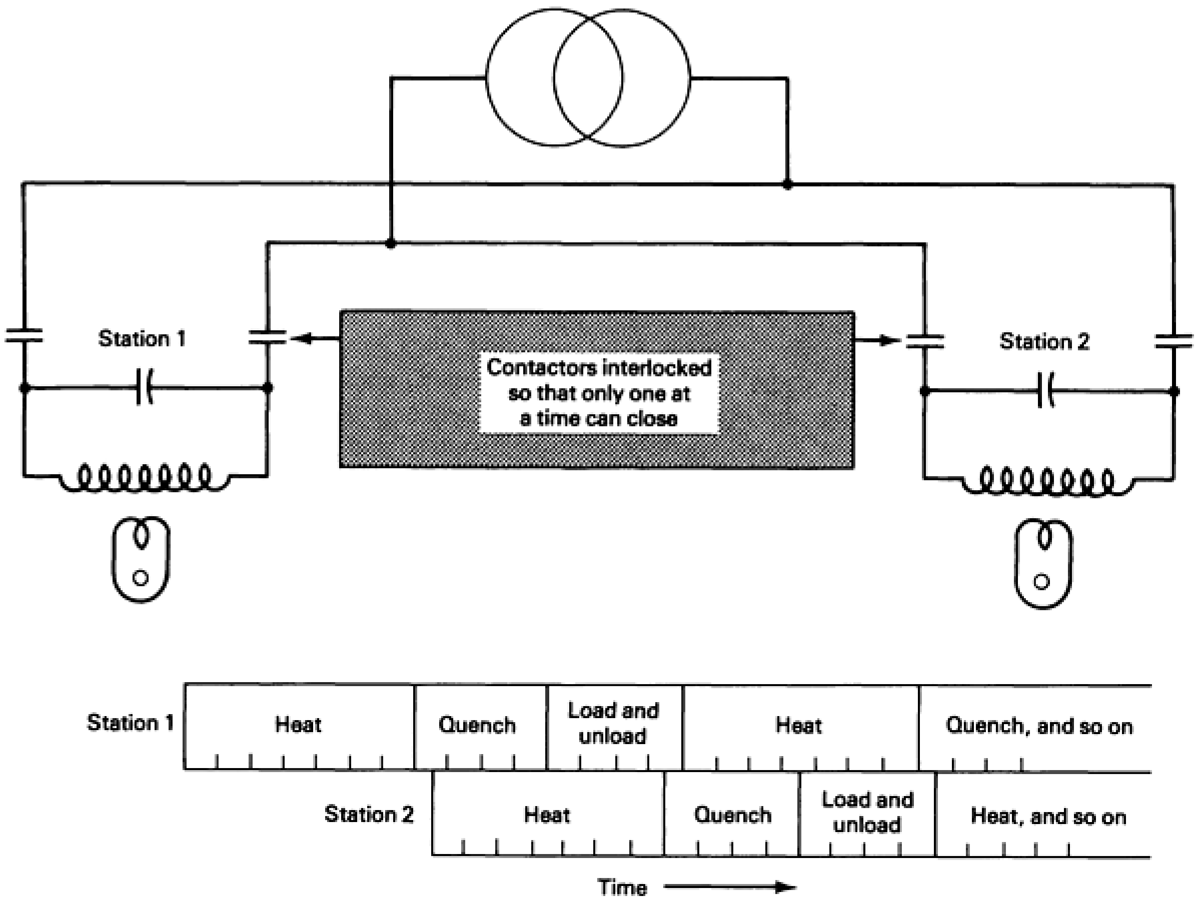

Fig. 1 Interlocked multistation operation of two work coils on an induction-heating machine. Assume that cycle is the same for both stations: heating, 7 s; quenching, 4 s; loading and unloading, 4 s.

It is also customary in the case of interlocked multistation operation of motor-generator equipment to preset the alternator field current for the various stations. Each station has its own field-adjusting autotransformer or potentiometer that is automatically switched into the circuit when that station has the power. This is feasible because with only one station on at a time, it is not necessary to use the same voltage at each.

Fixtures. As introduction of automated systems increases in induction heating, the need for safety controls increases beyond the greater need for such devices as power interlocks.

For example, with highly automated induction-heating machines, a part completely foreign to the part to be treated may enter the automatic feed hopper or bin. If the fixture tries to feed this part into the coil, mechanical jamming and damage may result. If the part does get pushed into the coil itself, assorted problems may result, especially if the unwanted part is larger than the inside diameter of the coil.

The greater the degree of automation, the greater the necessity for safety devices that further complicate the machine. Some automatic induction-heating machines incorporate templates through which the workpiece must pass before being fed to the more delicate parts of the mechanism. If the part touches the template, an electric circuit stops the machine until the error is manually corrected.

Spurious Radiation. Industrial heating equipment using radio-frequency energy is, in many instances, governed by rules of the Federal Communications Commission (FCC). FCC rules apply to induction-heating equipment operating at 10 kHz or above. Any operation whatsoever in frequency bands reserved for international distress equipment is strictly prohibited. One of these bands is from 490 to 510 kHz.

The best way for a user of induction-heating equipment to become familiar with the FCC rules is to acquire a copy of Part 18 of the rules and to study them carefully.

Vacuum-tube oscillators and some motor-generator equipment fall into the FCC-designated categories. The rules state that operation must either be within certain narrow frequency bands (in which any amount of energy may be radiated) or be restricted in field strengths. All such equipment must be certified by a competent engineer, such certification being based upon actual measurements of field strength made around the equipment. In some circumstances, prototype models of industrial high-frequency heating equipment may be tested at the manufacturer's plant and a certificate issued to cover other equipment of the same design. Even though a specific piece of equipment may have been properly certified, and even though its spurious radiation may fall below the prescribed limits, FCC rules state that if it interferes with communications equipment, further corrective action must be taken. The mere existence of a certificate, therefore, does not necessarily absolve the user of further responsibility.

Induction-heating machines sometimes rival the largest communications transmitters in output. The frequencies, and harmonics thereof, used by many induction-heating oscillators fall within the range used by their more delicate counterparts in radio and television services. If only a small portion of the power output of high-frequency heating machines was to be broadcast as unwanted (spurious) radiation, the results would be catastrophic.

Historically, dielectric heating machines have caused more interference than have induction-heating machines; they operate at higher frequencies and are more difficult to shield. However, induction-heating machines, especially vacuum-tube oscillators, have also caused trouble. It is necessary to observe certain precautions in their design and operation to ensure that they do not create interference. Reputable manufacturers of induction-heating equipment take precautions to protect users of their equipment from this type of trouble. They house their equipment in heavy steel cabinets and provide instructions that, if followed, will ensure conformity with FCC rules. However, it must be emphasized that the final legal responsibility for a piece of equipment lies with the user.

Maintenance. Electrical heat-treating equipment is expensive, and standby equipment generally is not maintained. Thus, preventive maintenance is critical, and availability of replacement parts is highly desirable.

Dust, dirt, moisture, and high ambient temperatures are the primary causes of electrical equipment failures; these conditions are commonly present in industrial locations where induction-heating units are installed. In any maintenance program, warnings should be highly visible and clearly stated. The following is a typical warning:

> "If the interlocks are disabled and the main circuit breaker is on with the door open, potentially lethal voltages are exposed. There is always 460 V ac present behind the control circuit breaker and on the line side of the main circuit breaker: care should be exercised at all times when the door is open. Power should be removed by opening the feed breaker or disconnect switch external to supply before working within cabinet. Solid-state circuit breaker board and isolator board are connected directly to 300 V ac. Turn off all breakers and allow one minute for capacitors to discharge before working on these boards."

Special Heat-Treating Processes

Certain special heat-treating processes using such systems as lasers, electron-beam heating, plasma carburizing, and ion nitriding have their own unique safety requirements in addition to standard safeguards associated with high-temperature processing.

Safety of personnel is paramount, but safety of equipment often ensures personnel safety. Thus, proper care and use of equipment cannot be overstressed and frequently becomes almost synonymous with safety.

In this section, ion nitriding and plasma carburizing are used as examples of special processes and the safety precautions related to them. For all heat-treating systems, however, special safety problems can be solved through sound training programs for operators and through effective and regular maintenance.

Plasma (Ion) Nitriding. In this system, also known as glow-discharge nitriding and as ionitriding, parts are connected to the cathode for processing, and the retort is the anode. After the retort is evacuated of atmospheric gases, nitrogen and hydrogen are bled slowly into it. The glow discharge is produced when the parts are heated by electric current to approximately 500 °C (930 °F), although specified temperatures can be as high as 565 °C (1050 °F).

The retort becomes heated by radiation from the parts; additional heat is not required. The glow discharge ionizes the nitrogen, and the electrical potential accelerates the movement of the ionized nitrogen toward the parts.

Although ion nitriding is faster and produces a more ductile and fatigue-resistant case with less white layer, the extra handling and precautions it requires are important factors in overall cost.

Plasma (Ion) Carburizing. The normal range of electrical power used for plasma-arc processing is 25 to 50 kW. Most systems are of fail-safe design and are interlocked to shut down the power supply automatically if a fault develops during operation.

One of the most serious hazards associated with plasma-arc operation is radiation caused by electromagnetic high-electron excitation. Such radiation ranges from radio frequencies to the far ultraviolet, and it includes infrared and visible radiant-energy light rays.

The radiation produced by the plasma is capable of producing severe eye and skin burns. The plasma should never be observed with the naked eye.

Furnace Protection. The primary safety feature of a surface ion-nitriding furnace is the arc-control system. Successful ion processing requires application of 300 to 1000 V dc to the workpiece. In these voltage ranges, the potential for an arc to form between the cathode and the anode is quite high during the initial part of the cycle. These arcs can be quite small; under certain circumstances, however, major arcs can occur that may be powerful enough to rupture vessel walls.

One method of controlling arcing and protecting equipment is to place a large resistance in series between the furnace vessel and the power supply. This prevents overloading of the power supply. An electrical device used to construct a type of arc-shutdown circuit is a silicon-controlled rectifier (SCR), which operates with a low-resistance load at steady voltage.

When an arc begins to form there is an initial rapid increase in current prior to formation of the arc. Upon arc formation, the voltage drops drastically (dv/dt); the SCR senses the voltage change (dv/dt increase) and increases the resistance, thus protecting the power supply. Additionally, the SCR is normally connected to another electrical device, such as a bridge rectifier. Once the change in voltage signifying arc formation is detected, the rectifier damps the current supply. This damping is normally sufficient to shut down the arc by allowing redistribution of the energy on the portion of the part that was arcing.

This type of circuit reacts after the arc has formed, however, and the potential for ruined workpieces or holes in anodes or vessel walls remains. This is a particular problem if the unit requires operators to manually shut down the power supply after observing dead shorts, formed by misloaded parts that create short circuits.

Arc Suppression. Some equipment used in ion nitriding and plasma carburizing does not rely on an arc-shutdown circuit as the primary safety factor. Rather, true arc-suppression circuits are employed. Such a circuit senses the change in current just prior to the formation of an arc and shuts off the power completely, preventing the arc from forming. The power is then proportionally ramped back on, allowing redistribution of energy.

In one system, a counter in the controlling microprocessor tallies the number of times the power is turned off and on.

If the potential for arcing is too large, as determined by the logic preprogrammed into the microprocessor as part of the executive command package, the system shuts down, prints a fault message on both the cathode-ray tube and data logger, sounds an alarm and siren, and activates a warning light. All this occurs automatically without an arc forming and protects both the part and the equipment. The microprocessor detects a dead short by sensing and reporting the rapid frequency of shutdown/startup cycles and prints a different short warning message, also with alarms, siren, and lights. This sequencing is also totally automatic and requires no operator interface. The equipment has a backup system that operates on the dv/dt principle. Additionally, all leads through the vessel wall that could carry current to the power supply are triple protected. As an example, the thermocouple has primary protection through an outer ceramic insulator. This is followed by a second powder ceramic insulator. The third protection is a high-voltage isolating amplifier between the thermocouple and the processor.

Thermocouples. The problems associated with passing a thermocouple, or any other lead, through a vessel wall in ion-processing equipment are as follows:

- The lead can become metallized, creating a pathway for catastrophic arcing. This problem becomes increasingly severe as a function of vessel use

- The material of construction used for seals through the vessel wall is quite critical. The conditions of ion processing can affect the sealing materials, allowing increased leakage as a function of vessel use
- Temperature uniformity throughout the entire workload in the vessel is quite critical. Proper design of thermocouple insulators that are calibrated to give true temperature readings, as well as proper design of fixturing, is necessary to achieve uniform temperatures

Fixture Design. Design of the fixture is critical to the successful application of ion processing. Poorly designed fixtures can allow overheated or underheated parts. If equipment without an arc-suppression circuit is used, parts can be ruined because of poor fixture design. The fixture often allows simple masking, and through proper design, can minimize or eliminate the hollow-cathode effect. This effect is signified by either failure of the glow to uniformly penetrate the interior surface of a hole or cylinder, or overheating and possible melting of the part, caused by overlapping glows.

Atmosphere Furnaces

Atmosphere furnaces must be considered in any discussion of furnace safety because of the potential explosion hazard produced by introduction of special flammable atmospheres.

Although many of these furnaces are supplied with inert gas purging and standby emergency purging, training of operators in manual burnout procedures is extremely important in the event of failure of automatic controls. These emergency instructions may vary with equipment design, and thus the importance of consulting and understanding emergency procedures, as outlined by the furnace manufacturer's instructions, should not be minimized.

Protective Controls. Protective devices should be installed and interlocked and should include the following:

- A safety shutoff valve on the atmosphere supply line to the furnace
- An atmosphere gas-supply-monitoring device that permits the operator to visually determine the adequacy of atmosphere gas flow at all times
- A sufficient number of temperature-monitoring devices to determine temperature in all zones of the furnace; these should be interlocked to prevent opening of the atmosphere-gas-supply safety shutoff valve until all zones are at or above 760 °C (1400 °F)
- An automatic safety shutoff valve for flame curtain burner supply gas; this should be interlocked to prevent opening of the valve when furnace temperature is below 760 °C (1400 °F)
- Audible and/or visual alarms to alert the furnace operator of abnormal conditions
- Manual door-opening facilities to permit operator control in the event of power failure

Operator Training. The most essential safety consideration is the selection of alert and competent operators. Their knowledge and training are vital to continued safe operation. New operators should be instructed thoroughly and required to demonstrate an adequate understanding of the equipment and its operations.

Regular operators should receive scheduled retraining to maintain a high level of proficiency and effectiveness, and all operators should have ready access to operating instructions at all times. An outline of these instructions should be posted near the furnace.

Operating instructions generally are provided by the equipment manufacturer, and these instructions include schematic piping and wiring diagrams. All such instructions should include procedures for lightup, shut-down, emergencies, and maintenance.

Operator training should include instructions in:

- Combustion of air-gas mixtures
- Explosion hazards
- Sources of ignition and ignition temperature
- Atmosphere gas analysis

- Handling of flammable atmosphere gases
- Handling of toxic atmosphere gases
- Functions of control and safety devices
- Purpose and basic principles of atmosphere-gas generators

This listing is intended only to serve as a guideline; specific requirements are covered in the following standard issued for furnaces: "Industrial Furnaces, Special Atmospheres," NFPA 86C, National Fire Protection Association, 1991.

Process Cooling

Heat treating of metals includes controlled cooling or quenching of the heated metal; metals are cooled from the specific treatment temperature in a variety of media that include air, oils, salts, water, and synthetic fluids.

As a general rule, furnace equipment does not include instrumentation for control of the safety aspects of the quench media. Normal practice in layout of plant and facilities will provide for isolation of air-cooling areas, for the usual pedestrian protection at pits, and for the necessary building protection should an uncontrolled conflagration occur because of the quenching operation. However, certain equipment can be specified to ensure safe and controllable operation in specific cooling processes.

The greatest concern exists for fires associated with oil quenching. All of the ingredients for a dangerous fire--fuel, oxygen, and a source of ignition--exist at the surface of an oil tank.

The most common type of fire occurs when movement of a hot workpiece is obstructed as it enters the quench oil. The result is sustained ignition and vaporization that continues as the liquid is locally heated above its flash point. Prompt immersion removes the source of local vaporization, and local flashing is extinguished by normal agitation of the oil.

A second type of fire occurs when the main body of oil is heated above the flash point because of malfunction of heating or cooling equipment, or when the quench load is greater than that for which the system was designed. When an ignition source is supplied, the resultant fire soon reaches full intensity and is very difficult to extinguish.

A third and less likely type of fire occurs because of material-handling accidents that involve spills on or near heated furnaces or cooling equipment.

Equipment is available for detection of fires and release of control media. Automatic water-spray systems are usually recommended in buildings of fire-resistant or non-combustible construction, and areas adjacent to quench-oil tanks can be protected with automatic sprinklers. Quench oil and water should not be mixed, however. High-value oils can be protected with automatic carbon dioxide or dry chemical systems. In general, these automatic systems are specified for centralized large-capacity quench-oil systems.

Special equipment is available for totally enclosed systems that operate in special atmosphere furnaces. However, the incompatibility of water and quench oil can be a source of trouble in these units. Water in oil rapidly turns to steam when locally heated beyond 100 °C (212 °F). This steam can cause violent boilover, increased pressure within the enclosed system, and forcible ejection of burning oil from small openings. Commercial safety equipment capable of detecting even small quantities of water in oil can be arranged to alert the furnace operator and to interrupt the quench process.

Quench-tank heating systems should be equipped with all safety devices normally used in conjunction with the chosen heating method. Overtemperature safety systems are essential. In addition, system interlocks between heating media actuators and both agitators and pumps will prevent local overheating of the bath.

Mechanical Equipment

Material handling cannot be separated from other safety considerations associated with heat-treating operations. Many mechanical operations must be performed before, after, and sometimes during the actual temperature-induced transformation that usually occurs while the work is in the heat-treating furnace. Doors must be opened and closed, conveyors started, rolls advanced, and mechanical handling equipment activated. All of these mechanical operations

constitute hazards of varying degrees of severity that must be evaluated. Some are serious enough to warrant the introduction of safety equipment to preclude serious injury of personnel and damage of expensive furnace equipment.

Furnace doors are often interlocked with other components of a facility through use of limit switches that prevent inappropriate opening or closing. For instance, in an atmosphere furnace, inner doors cannot be opened until proper vestibule ambient conditions have been restored after parts are removed. Interlocks on doors may include complex designs to prevent inadvertent opening during a power failure on a hydrogen atmosphere furnace. There are simpler designs that prevent closing of a door on a simple normalizing furnace before the extractor is removed. Some door interlocks are connected to pressure- or temperature-sensing devices. Such devices are used with vacuum furnaces in which inadvertent exposure of the molybdenum-graphite heating elements to air at high temperature would be disastrous. Moreover, without door interlocks, roller-hearth or walking-beam furnaces could advance workpieces into an unopened discharge-zone door.

Moving parts of furnaces represent potential hazards that can be neutralized rather easily with simple time-delay relays connected to audible alarms, which in turn are connected to the start buttons of electric motors. For instance, the conveyors on some large continuous furnaces cannot be advanced until an alarm has been sounded and a timer has allowed sufficient time for workmen to stand clear.

Charles F. Walton, Consultant

Introduction

CAST IRONS are alloys of iron, carbon, and silicon in which more carbon is present than can be retained in solution in solid metal. In common (unalloyed) cast iron (Fig. 1), the carbon that exceeds the solubility limit (shown by the lower dashed line in Fig. 1) precipitates either as graphitic carbon or as iron carbide.

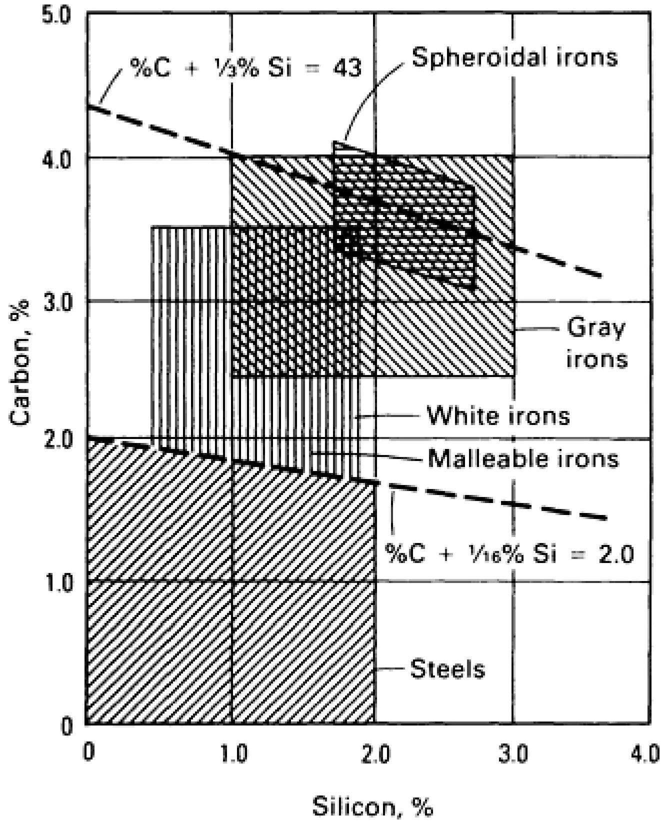

Fig. 1 Carbon and silicon composition ranges of common cast irons and steel. In addition to silicon, other elements may change the maximum solubility of carbon in austenite. Source: Ref 1

Types of Cast Iron. There are six basic types of cast irons and several varieties of each. Dependable heat treating requires information on the kind of material, its proximate composition and what is to be accomplished. The types of iron are classified as to how the excess carbon occurs in the microstructure:

- *White iron* is essentially free of graphite, and most of the carbon content is present as separate grains of hard Fe_3C. White iron exhibits a white, crystalline fracture surface because fracture occurs along the iron carbide plates. It is only stress relieved
- *Malleable iron* contains compact nodules of graphite flakes. These are called "temper carbon" because they form during an extended annealing of white iron of a suitable composition
- *Gray iron* contains carbon in the form of graphite flakes. Gray iron exhibits a gray fracture surface because fracture occurs along the graphite plates (flakes)
- *Ductile iron,* also known as spheroidal graphite iron, contains spherulitic graphite in which the graphite flakes form into balls as do cabbage leaves. Ductile iron is so named because in the as-cast form it exhibits measurable ductility

- *Austempered ductile iron* is a moderately alloyed ductile iron that is austempered for high strength with appreciable ductility. Its microstructure is different from austempered steel, and its heat treatment is a specialty
- *Compacted graphite iron* contains graphite in the form of thick, stubby flakes. Its mechanical properties are between those of gray and ductile iron
- *High-alloy iron* contains over three percent alloy content and is commercially classified separately. High-alloy irons may be a type of white iron, gray iron, or ductile iron. The matrix may be ferritic or austenitic and not have the usual transformation

Differentiating Gray and Ductile Irons. These two types of irons are sometimes confused. Identification is important in heat treating because of the typically lower silicon content and frequent alloy content in the higher strength grades of gray iron.

Ductile iron castings have a definite ring when struck with a hammer, but it is not the clear ring of steel. Gray iron castings have a damped sound. Breathing on a fresh surface (filed, ground, or machined) of ductile iron releases the smell of acetylene gas. It is formed by moisture reacting with the magnesium carbide in ductile iron.

The critical transformation temperature range for iron is mainly influenced by its silicon content. The carbon content, either combined or total, is not important. Silicon raises the transformation temperature range. The lower temperature of the critical range for cast irons can be estimated using the following formulas:

$$\text{Critical temperature, °F} = 1350 + 50\ (\%\text{Si}) - 45\ (\%\text{Mn})$$

$$\text{Critical temperature, °C} = 730 + 28\ (\%\text{Si}) - 25\ (\%\text{Mn})$$

In addition, silicon in iron decreases carbon solubility in austenite and tends to dissociate iron carbide. Thus, the carbon content of pearlite in iron can be appreciably lower than in the plain carbon and low-alloy steels. Depending on the silicon content and the cooling rate, the carbon content of pearlite varies and can be as low as 0.50% with 2.5% Si.

Heat-Treating Effects. The primary microstructure of cast irons can be modified by heat treatment. In the absence of chromium, iron carbide can be dissociated into austenite and graphite at annealing temperatures, but the shape of graphite cannot be changed.

The matrix can be internally decarburized or carburized either by depositing graphite on existing sites or by dissolving carbon from them. At temperatures approaching the critical temperature, silicon can cause the iron carbide (Fe_3C) in pearlite (called the combined carbon content) to dissociate into ferrite and carbon. The carbon diffuses to and deposits on the graphite already present in the microstructure. This reaction could be considered to be internal decarburization. The effect can be reversed by heating to above the critical temperature. In a very short time, austenite becomes saturated with carbon that is dissolved from the graphite.

The following articles in this Section of the Volume discuss the heat treatment of gray irons, ductile irons, malleable irons, and high-alloy irons. Compacted graphite irons are not typically heat treated.

Heating Equipment

Heat-treating furnaces for iron castings should be designed and operated to provide uniform heating throughout the load. The temperature measurement and control should be of the castings, not the furnace. Special programs are usually necessary for castings of complex shape with internal walls. The metallurgy of iron allows only a narrow temperature range for satisfactory results.

Iron tends to form a protective atmosphere in a tight furnace or box. Cast iron chips from the machine shop are used as packing material for other metals because the graphite and silicon in iron react with free oxygen in the atmosphere. A protective atmosphere should be used for finish machined parts. Heavy oxidization is especially undesirable for iron because a subscale of iron silicate is formed in the surface metal. This is not readily removed by grit blasting, especially in internal passages. Only molten salt electrolysis (Kolene process) can clean all casting surfaces.

The flame and induction hardening of surfaces on iron castings can be successfully and consistently accomplished, but the process must be closely controlled because the allowable temperature range is narrow. For example, a small variation in line voltage to the travel motor on a lathe way hardener caused irregular results.

Because of the brief time that the iron is above the critical temperature in surface hardening, it is best if the matrix microstructure of the iron is all pearlite or tempered martensite. A small amount of ferrite adjacent to graphite in the microstructure will cause no problem because it will dissolve carbon from the graphite very rapidly. Alloyed iron is not necessary or desirable for surface hardening because alloys slow the transformation upon heating as well as upon cooling. Alloys are sometimes used to minimize the amount of ferrite in the matrix. This is satisfactory if the time during which the surface metal temperature is above the critical temperature is adequate to allow complete transformation to austenite.

Quenching

Small- and medium-sized castings that do not have a high-stress-inducing shape can be normalized by cooling in open air or with fans. As soon as they have transformed (become magnetic), the castings should be placed in a furnace at 540 to 590 °C (1000 to 1100 °F) for equalization and slow cooling to minimize residual stress. Castings and machined components of suitable shape can be oil quenched and tempered in the usual way. Because of the relatively high hardenability of iron, it is never water quenched except in surface hardening.

Retained Stress in Iron Castings

Most iron castings are essentially free of internal stress as-cast. Molding sand is a very good insulator and retains much of the heat it absorbs from the iron when the iron solidifies at 1090 °C (2000 °F). When the solid iron goes through the critical transformation temperature, an additional amount of heat is liberated from the iron. The additional heat in the casting counteracts undercooling and tends to equalize the temperature throughout the casting. This is commonly referred to as mold stress relieving. Thus most iron castings that are cooled in a sand mold to below 425 °C (800 °F) are essentially free of internal stress.

There are castings, however, in which one section has much thicker metal and cools at a much slower rate than another section. Such castings can retain stress if, due to their shape, the more rapidly cooling portion restrains the contraction of the slower-cooling section. For example, a typical gear blank has a relatively thick outside section in which the teeth are machined. The hub is also comparatively thick, but the web between the two is usually not as thick. If the heat from the two heavy sections keeps the thinner metal between them from cooling too rapidly, the final casting will be essentially stress free. On the other hand, a brake wheel for an elevator is similar in shape to a gear blank except that the exterior rim may be appreciably less massive than the hub. Because the rim can cool more rapidly than the hub, by the time the hub finally cools and contracts, the rim is already cool and firm. Thus, tensile stress is developed in the web between the rim and the hub. This is especially undesirable in a brake wheel because in use the rim is heated by friction. Heat expands the rim and increases the tensile stress in the web. Such a casting should be given a controlled stress-relief heat treatment. The heavy hub must be heated at the same rate as the thinner rim to avoid cracking the casting.

Structural castings for precision machinery often have internal walls (frequently with internal and external walls of comparable thicknesses). This type of casting can be essentially stress free if it is allowed to cool to below 425 °C (800 °F) in the mold. The stress relieving of complex castings requires extended furnace time for both heating and cooling. The furnace program should be established by observing the temperature readings from thermocouples attached to inner and outer portions of the casting. These two temperatures should not differ by 100 °C (200 °F) during heating and by 50 °C (100 °F) during controlled cooling.

Retained Stresses. Evaluation of retained stresses in a casting is usually made when the casting changes dimensions during machining. Stresses in a casting can be accurately evaluated in two ways. A foil strain gage can be applied to the surface of a casting at a critical location. The metal on which the gage is mounted is trepanned or otherwise cut out of the casting. Gage readings before and after removal indicate the retained stress. In the second method, a casting can simply be sawed, and any change in the thickness of the kerf observed. This is more useful for smaller castings.

Stress Relief. The relief of residual stress is accomplished by heating the iron to a temperature at which the stress is relieved by rapid creep. Of course, complex shapes must then be cooled uniformly so that stress is not reintroduced. Vibration has been promoted as a method for providing stress relief to iron castings. This procedure has not been demonstrated to be successful in a valid test.

The temperature at which stresses are relieved within a reasonable time depends on the strength of the iron. Higher-strength irons require higher-stress-relieving temperatures. However, the use of higher temperatures has a limiting factor. As the temperature of the iron is increased above 540 °C (1000 °F), there is an increasing tendency for the combined carbon (pearlite) in the matrix to dissociate into ferrite and carbon. The carbon diffuses to and precipitates on the existing graphite. Thus the combined carbon in the matrix is reduced, and the hardness of the iron is decreased. The rate of precipitation of graphite at a temperature is increased by a higher silicon content and reduced by the presence of alloys. Generally, a successful stress-relief heat treatment decreases the hardness of the iron a small amount.

Hardness Measurement

All cast irons are heterogeneous alloys and have constituents of widely different hardnesses. A test of hardness in iron, except for microhardness, is a weighted average of the hardnesses of the constituents. The commonly used standard Brinell hardness test using a 10 mm diam ball and a 3000 kg load makes an impression that is large enough to provide a good average hardness even on a coarse structure. When other hardness tests with smaller indentation are used, several values should be taken and averaged.

The conversion of hardness values from different methods of testing is influenced by the material being tested. The hardness conversion tables in Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook* are generally satisfactory. Figure 2 and Table 1 give examples of conversion values and show the deviation from the conversion table for steel.

Table 1 Comparative hardness values for quenched and tempered ductile irons

Iron	HB[(a)]	HRC converted from HB[(b)]	Observed HRC[(c)]	Microhardness, HV[(d)]	HRC converted from HV[(b)]	HRC converted from HV minus observed HRC
1	415	44.5	44.4	527	50.9	6.5

In a comparison of the hardness of graphite-bearing irons with the hardness of other metals (especially in regard to machinability or wear resistance), the effect of the graphite in lowering the indicated hardness should be noted. Figure 3 shows the influence of the amount of graphite in flake form (gray iron) on the indicated hardness. Although ductile iron contains more graphite than do the machinery grades of gray iron, the graphite in ductile iron is in compact spheres and has less effect on hardness and other properties.

Heat Treating of Gray Irons

Revised by Bela Kovacs, Applied Process, Division of the Atmosphere Group, Inc.

Introduction

GRAY IRONS are a group of cast irons that form flake graphite during solidification, in contrast to the spheroidal graphite morphology of ductile irons. The flake graphite in gray irons is dispersed in a matrix with a microstructure that is determined by composition and heat treatment. The usual microstructure of gray iron is a matrix of pearlite with the graphite flakes dispersed throughout. In terms of composition, gray irons usually contain 2.5 to 4% C, 1 to 3% Si, and additions of manganese, depending on the desired microstructure (as low as 0.1% Mn in ferritic gray irons and as high as 1.2% in pearlitic). Other alloying elements include nickel, copper, molybdenum, and chromium.

The heat treatment of gray irons can considerably alter the matrix microstructure with little or no effect on the size and shape of the graphite achieved during casting. The matrix microstructures resulting from heat treatment can vary from ferrite-pearlite to tempered martensite. However, even though gray iron can be hardened by quenching from elevated temperatures, heat treatment is not ordinarily used commercially to increase the overall strength of gray iron castings because the strength of the as-cast metal can be increased at less cost by reducing the silicon and total carbon contents or by adding alloying elements. When gray iron is quenched and tempered, this is usually done to increase resistance to wear

and abrasion by increasing hardness with a structure consisting of graphite embedded in hard martensite. The most common heat treatments of gray iron are annealing and stress relieving.

Although the size of the graphite flakes in gray irons is unaffected by heat treatment, the size does have a marked influence on the carbon kinetics during heat treating. In castings with fine graphite flakes, the carbon diffusion paths are shorter, and ferritization or normalization is achieved in a shorter time than in those castings with large graphite flakes. Castings with fine graphite flakes not only are easier to heat treat, but also display superior mechanical properties. The factors that affect the graphite morphology achieved during casting are discussed in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Chemical composition is another important parameter influencing the heat treatment of gray cast irons. Silicon, for example, decreases carbon solubility, increases the diffusion rate of carbon in austenite, and usually accelerates the various reactions during heat treating. Silicon also raises the austenitizing temperature significantly and reduces the combined carbon content (cementite volume). Manganese, in contrast, lowers the austenitizing temperature and increases hardenability. It also increases carbon solubility, slows carbon diffusion in austenite, and increases the combined carbon content. In addition, manganese alloys and stabilizes pearlitic carbide and thus increases the pearlite content. Further, manganese reduces pearlite spacing and generally slows the heat-treating process.

Annealing

The heat treatment most frequently applied to gray iron, with the possible exception of stress relieving, is annealing. The annealing of gray iron consists of heating the iron to a temperature high enough to soften it and/or to minimize or eliminate massive eutectic carbides, thereby improving its machinability. This heat treatment reduces mechanical properties substantially, however. It reduces the grade level approximately to the next lower grade; for example, the properties of a class 40 gray iron will be diminished to those of a class 30 gray iron. Figure 1 shows the effect of full annealing on the tensile strength of class 30 gray iron arbitration bars. The degree of reduction of properties depends on the annealing temperature, the time at temperature, and the alloy composition of the iron.

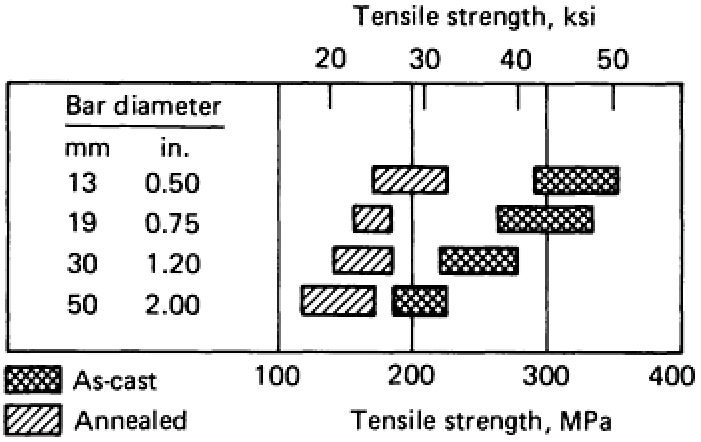

Fig. 1 Effect of annealing on tensile strength of class 30 gray iron. Specimens were arbitration bars from 31 heats. Bars were annealed at 925 °C (1700 °F) for 2 h plus 1 h per 25 mm (1 in.) of section over 25 mm, and cooled at a maximum rate of 160 °C/h (285 °F/h) from 925 to 565 °C (1700 to 1050 °F). Cooling continued from that level at a maximum rate of 130 °C/h (230 °F/h) to 200 °C (390 °F); bars were then air cooled to room temperature.

Gray iron is commonly subjected to one of three annealing treatments, each of which involves heating to a different temperature range. These treatments are ferritizing annealing, medium (or full) annealing, and graphitizing annealing.

Ferritizing Annealing. For an unalloyed or low-alloy cast iron of normal composition, when the only result desired is the conversion of pearlitic carbide to ferrite and graphite for improved machinability, it is generally unnecessary to heat the casting to a temperature above the transformation range. Up to approximately 595 °C (1100 °F), the effect of short times at temperature on the structure of gray iron is insignificant. As the temperature increases above 595 °C (1100 °F),

the rate at which iron carbide decomposes to ferrite plus graphite increases markedly, reaching a maximum at the lower transformation temperature (about 760 °C, or 1400 °F, for unalloyed or low-alloy iron). This is indicated in Fig. 2, which shows the structure of unalloyed gray iron in the as-cast condition (Fig. 2a) and after being held for 1 h at 760 °C (1400 °F) per inch of section (Fig. 2b). Heating to a higher temperature for the same period of time may be detrimental to the annealing process if it causes partial or complete transformation to austenite.

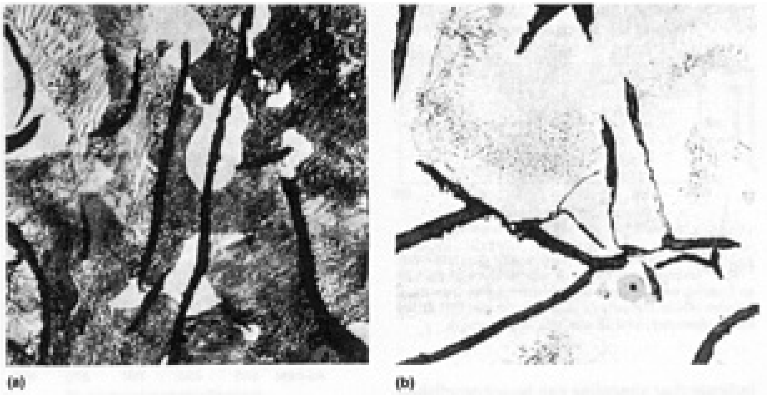

Fig. 2 Conversion of as-cast pearlitic structure of unalloyed gray iron to ferrite and graphite by annealing. (a) As cast; 180 HB. (b) Annealed 1 h at 760 °C (1400 °F); 120 HB. Magnification, 500×

For most gray irons, a ferritizing annealing temperature between 700 and 760 °C (1300 and 1400 °F) is recommended. The furnace temperature profile must be such that castings are sure to reach the set temperatures. Precise temperatures within this range are determined by the exact composition of the iron. When machining properties are of primary importance, it is advisable to anneal several samples at various temperatures between 700 and 760 °C (1300 and 1400 °F) in order to determine the temperature that yields the lowest final hardness.

The casting must be held at temperature long enough to allow the graphitizing process to proceed to completion. At temperatures below 700 °C (1300 °F), an excessively long holding time is usually required. At temperatures between 700 and 760 °C (1300 and 1400 °F), holding time varies with chemical composition, and may be as short as 10 min for unalloyed irons. If an unusually low rate of cooling is used, the time at temperature may be further reduced.

Although the rate of cooling per se is not of great importance to the annealing process, slow cooling is recommended if the stress relief that automatically occurs during annealing is to be retained as the casting cools to room temperature. A cooling rate ranging from as high as 110 °C/h (200 °F/h) to 290 °C (550 °F) is satisfactory for all except the most complex castings.

Medium (full) annealing is usually performed at temperatures between 790 and 900 °C (1450 and 1650 °F). This treatment is used when a ferritizing anneal would be ineffective because of the high alloy content of a particular iron. It is recommended, however, that the efficacy of temperatures at or below 760 °C (1400 °F) be tested before a higher annealing temperature is adopted as part of a standard procedure.

Holding times comparable to those used in ferritizing annealing are usually employed. When the high temperatures of medium annealing are used, however, the casting must be cooled slowly through the transformation range, from about 790 to 675 °C (1450 to 1250 °F).

Graphitizing Annealing. If the microstructure of gray iron contains massive carbide particles, higher annealing temperatures are necessary. Graphitizing annealing may simply serve to convert massive carbide to pearlite and graphite, although in some applications it may be desired to carry out a ferritizing annealing treatment to provide maximum machinability.

The production of free carbide that must later be removed by annealing is, except with pipe and permanent mold castings, almost always an accident resulting from inadequate inoculation or the presence of excess carbide formers, which inhibit normal graphitization; thus, the annealing process is not considered part of the normal production cycle.

To break down massive carbide with reasonable speed, temperatures of at least 870 °C (1600 °F) are required. With each additional 55 °C (100 °F) increment in holding temperature, the rate of carbide decomposition doubles. Consequently, it is general practice to employ holding temperatures of 900 to 955 °C (1650 to 1750 °F). However, at 925 °C (1700 °F) and above, the phosphide eutectic present in irons containing 0.10% P or more may melt.

The holding time at temperature may vary from a few minutes to several hours. The chill carbide (white iron) in some high-silicon, high-carbon irons can be eliminated in as little as 15 min at 940 °C (1720 °F). In all applications, unless a controlled-atmosphere furnace is used, the time at temperature should be as short as possible because at these high temperatures gray iron is susceptible to scaling if moisture is present in the furnace atmosphere.

The cooling rate chosen depends on the final use of the iron. If the principal object of the treatment is to break down carbides and it is desired to retain maximum strength and wear resistance, the casting should be air cooled from the annealing temperature to about 540 °C (1000 °F) to promote the formation of a pearlitic structure. If maximum machinability is the object, the casting should be furnace cooled to 540 °C (1000 °F), and special care should be exerted to ensure slow cooling through the transformation range. In both instances, cooling from 540 °C (1000 °F) to about 290 °C (550 °F) at not more than 110 °C/h (200 °F/h) is recommended to minimize residual stresses.

Effect of Alloy Content on lime at Temperature. Certain elements, such as carbon and silicon, accelerate the decomposition of pearlite and massive carbide at annealing temperatures. Therefore, when these elements are present in sufficient percentages, the time at annealing temperature may be reduced. In an investigation of the decomposition of pearlite at various temperatures in irons containing 1.93 and 2.68% Si, it was determined that the pearlite always broke down more rapidly in the higher-silicon iron and that this iron could be effectively annealed over a greater temperature range. For example, at an annealing temperature of 750 °C (1380 °F), the complete breakdown of pearlite occurred in the higher-silicon iron in 10 min, whereas 45 min were required for the lower-silicon iron. This shows the pronounced effect of silicon as an aid to the diffusion of carbon to the flakes present in the iron.

On the other hand, the pearlite-promoting elements (antimony, tin, vanadium, chromium, manganese, phosphorus, nickel, and copper) delay pearlite decomposition. The percentage increases in the time required to decompose pearlite that are affected by 0.10% additions of five of these elements are:

Element	Increase in time, %
Manganese	60
Nickel	30
Copper	30
Chromium	200
Phosphorus	30

Normalizing

Gray iron is normalized by being heated to a temperature above the transformation range, held at this temperature for a period of about 1 h per inch of maximum section thickness, and cooled in still air to room temperature. Normalizing may be used to enhance mechanical properties, such as hardness and tensile strength, or to restore as-cast properties that have been modified by another heating process, such as graphitizing or the preheating and postheating associated with repair welding.

The temperature range for normalizing gray iron is approximately 885 to 925 °C (1625 to 1700 °F). Austenitizing temperature has a marked effect on microstructure and on mechanical properties such as hardness and tensile strength. The tensile strength and hardness of a normalized gray iron casting depend on the following parameters:

- Combined carbon content
- Pearlite spacing (distance between cementitc plates)
- Graphite morphology

The graphite morphology does not change to any significant extent during normalization, and its effect on hardness and tensile strength is omitted in this discussion on normalizing.

Combined carbon content is determined by the normalizing (austenitizing) temperature and the chemical composition of the casting. Higher normalizing temperatures increase the carbon solubility in austenite (that is, the cementite volume in the resultant pearlite). A higher cementite volume, in turn, increases both the hardness and the tensile strength. The alloy composition of a gray iron casting also influences carbon solubility in austenite. Some elements increase carbon solubility, some decrease it, and others have no effect on it. The carbon content of the matrix is determined by the combined effects of the alloying elements.

Pearlite Spacing. The other parameter affecting hardness and tensile strength in a normalized gray iron casting is the pearlite spacing. Pearlite spacing is determined by the cooling rate of the casting after austenitization and the alloy composition. Fast cooling results in small pearlite spacing, higher hardness, and higher tensile strength. Too high a cooling rate may cause partial or full martensitic transformation. A combination of high normalizing temperature and high cooling rate promote martensitic transformation. Martensite is detrimental to machining. The addition of alloying elements may change hardness and tensile strength significantly. These changes, however, are mainly due to the change in carbon kinetics caused by these elements and not as much to the addition of the elements per se.

Partial control of hardness can be exercised during normalizing by allowing castings to cool in the furnace to a temperature below the normalizing temperature. Figure 3 shows the results obtained with gray iron rings that were heated to 955 °C (1750 °F) and then furnace cooled to different temperatures before being removed from the furnace and cooled in air. These data also indicate that annealing can be accomplished by cooling castings in the furnace to 650 °C (1200 °F) and then air cooling. However, if stress-free castings are desired, they should be cooled in the furnace to below 455 °C (850 °F) before being removed.

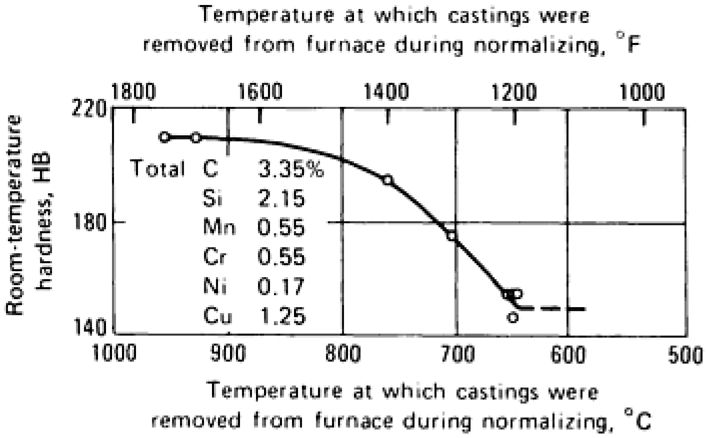

Fig. 3 Room-temperature hardness of gray iron after normalizing. Effect of temperature at start of air cooling on hardness of normalized gray iron rings 120 mm ($4\frac{3}{4}$ in.) in outside diameter, 95 mm ($3\frac{3}{4}$ in.) in inside diameter, and 38 mm ($1\frac{1}{2}$ in.) in length

Additional effects of normalizing, as a function of alloy content and carbon equivalent, are shown in Table 1. Bars 1, 3, 4, 6, and 7 are essentially free of alloying elements, except for residual amounts. Bars 1 and 3, characterized by high as-cast strength and low carbon equivalent, virtually regained their as-cast strength as a result of normalizing for $1\frac{1}{2}$ h at 900 °C (1650 °F), air cooling, and stress relieving at 540 °C (1000 °F). The same treatment lowered the strength of bars 4, 6, and 7, all of which had higher carbon equivalents and relatively low manganese content. Bar 2 showed an increase in strength because of the high stabilizing effect of the molybdenum, nickel, and manganese contents. Bar 5, despite a high carbon equivalent, greatly exceeded as-cast strength because of its manganese, chromium, molybdenum, and nickel contents.

Table 1 Influence of alloy content and carbon equivalent on typical properties of gray irons before and after normalizing

Bar	Composition, %									Carbon equivalent, %	As-cast			Normalized		
											Tensile strength		Hardness, HB	Tensile strength		Hardness, HB

7	3.42	2.44	0.42	0.058	0.56	0.063	0.058	0.057	0.108	4.23	215	31	187	180	26	143

The effect of alloy content on hardness after normalizing is shown in Fig. 4 for two alloy irons with different carbon equivalents and nickel and chromium contents. Again it is evident that alloy content has a stabilizing effect in the graphitizing annealing range and serves to increase hardness when the austenitizing temperature ranges from about 790 to 980 °C (1450 to 1800 °F). Thus it can be concluded that normalizing serves to restore as-cast properties to gray iron--or, if the carbon equivalent is sufficiently low, even causes these properties to be exceeded--and that the alloying elements chromium, molybdenum, and nickel enhance the strengthening effect of normalizing.

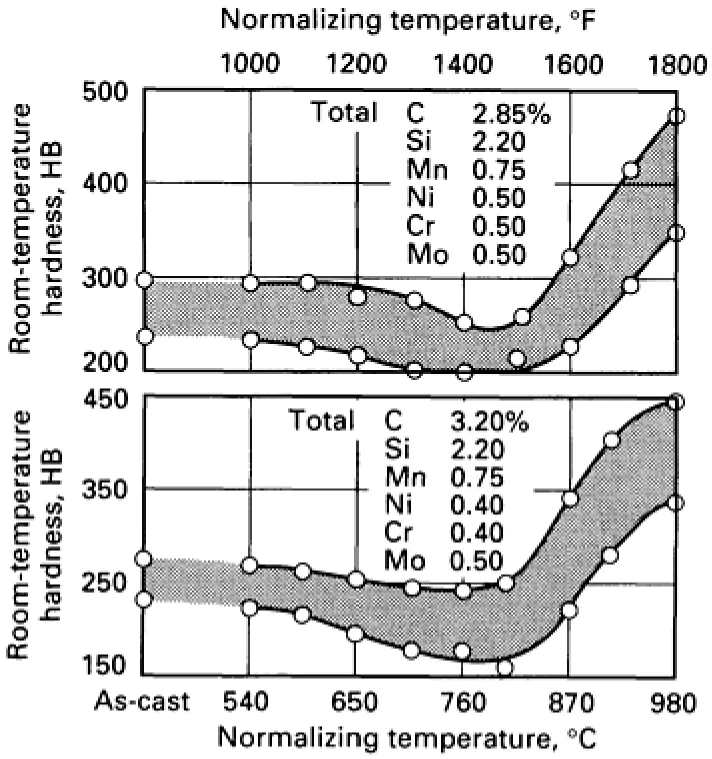

Fig. 4 Room-temperature hardness of two different alloy gray irons held at normalizing temperature 1 h for each 25 mm (1 in.) of thickness and air cooled on wire mesh screen. From production and experimental data

Hardening and Tempering

Gray irons are hardened and tempered to improve their mechanical properties, particularly strength and wear resistance. After being hardened and tempered, these irons usually exhibit wear resistance approximately five times greater than that of pearlitic gray irons.

Furnace or salt bath hardening can be applied to a wider variety of gray irons than can either flame or induction hardening. In flame and induction hardening, a relatively large content of combined carbon is required because of the extremely short period available for the solution of carbon in austenite. In furnace or salt bath hardening, however, a casting can be held at a temperature above the transformation range for as long as is necessary; even an iron initially containing no combined carbon can be hardened.

Unalloyed gray iron of low combined carbon content must be austenitized for a longer time to saturate austenite with carbon. Figure 5 shows the relationship of hardness to holding time for small quenched specimens. With increased time, more carbon is dissolved in austenite, and hardness after quenching is increased.

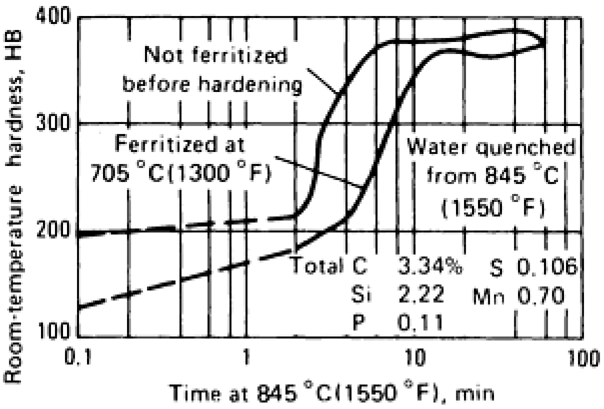

Fig. 5 Effect of austenitizing time on room-temperature hardness of quenched gray iron specimens. Specimens were 32 mm ($1\frac{1}{4}$ in.) in diameter by 19 mm ($\frac{3}{4}$ in.) in thickness.

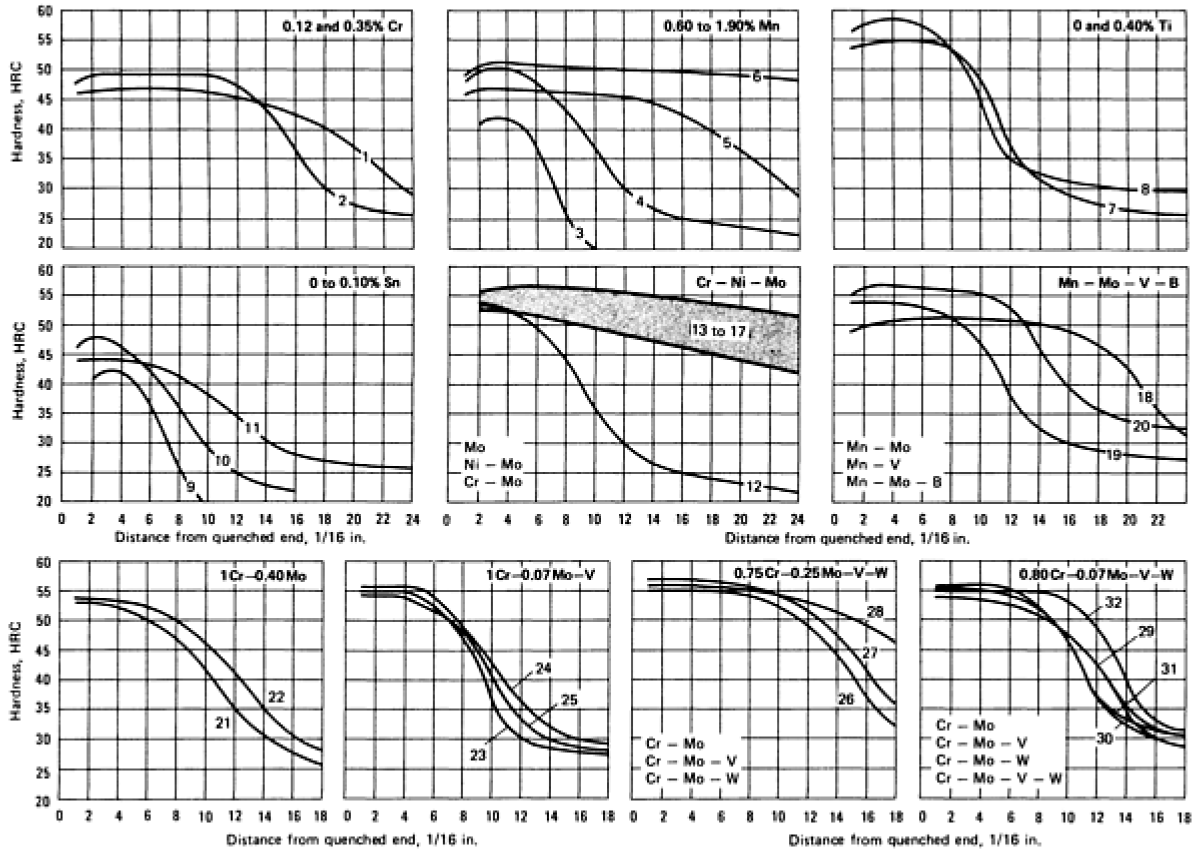
Because of its higher silicon content, an unalloyed gray iron with a combined carbon content of 0.60% exhibits higher hardenability than a carbon steel with the same carbon content. However, because of the effect of silicon in reducing the solubility of carbon in austenite, unalloyed irons with higher silicon contents necessarily require higher austenitizing temperatures to attain the same hardness.

Manganese increases hardenability. Approximately 1.50% Mn was found to be sufficient for through hardening a 38 mm ($1\frac{1}{2}$ in.) section in oil or for through hardening a 64 mm ($2\frac{1}{2}$ in.) section in water.

Manganese, nickel, copper, and molybdenum are the recognized elements for increasing the hardenability of gray iron. Although chromium, by itself, does not influence the hardenability of gray iron, its contribution to carbide stabilization is important, particularly in flame hardening. Figure 6 shows the effects of various combinations of elements on hardenability.



Iron	Composition, %										Austenitizing temperature	
	Total C	Si	P	S	Mn	Cr	Ni	Mo	V	Other	°C	°F

Fig. 6 Effects of alloying elements on hardenability of gray iron. Irons 1 through 20 were induction furnace melted and poured into standard dry sand molds 30 mm (1.2 in.) in diameter. Alloy constituents for irons 21 through 32 were added to 205 kg (450 lb) ladles, from which the metal was poured into automotive-camshaft production molds. Standard end-quench hardenability specimens were machined from these castings, austenitized for 1 h at the temperatures indicated, and then water quenched.

Treatment Cycle

Austenitizing. In hardening gray iron, the casting is heated to a temperature high enough to promote the formation of austenite, held at that temperature until the desired amount of carbon has been dissolved, and then quenched at a suitable rate. Heating for austenitizing may be accomplished in a salt bath or in an electrically heated, gas-fired or oil-fired furnace.

The temperature to which a casting must be heated is determined by the transformation range of the particular gray iron of which it is made. The transformation range can extend more than 55 °C (100 °F) above the A_1 (transformation-start) temperature. A formula for determining the approximate A_1 transformation temperature of unalloyed gray iron is:

$$°C: 730 + 28.0 (\% Si) - 25.0 (\% Mn)$$
$$°F: 1345 + 50.4 (\% Si) - 45.0 (\% Mn)$$

Chromium raises the transformation range of gray iron. In high-nickel, high-silicon irons, for example, each percent of chromium raises the transformation range by about 10 to 15 °C (20 to 30 °F). Nickel, on the other hand, lowers the critical range. In a gray iron containing from 4 to 5% Ni, the upper limit of the transformation range is about 710 °C (1310 °F).

Provided that recommended limits are not exceeded, the higher the casting is heated above the transformation range, the greater will be the amount of carbon dissolved in the austenite (Fig. 7) and the higher will be the hardness of the casting after quenching (Table 2). In practice, temperatures as much as 95 °C (175 °F) higher than the calculated A_1 transformation temperature are used to ensure full austenitizing. However, excessively high temperatures should be avoided because quenching from such high temperatures increases the danger of distortion and cracking and promotes the retention of austenite, particularly in alloyed irons.

Table 2 Effect of austenitizing temperature on hardness of various oil-quenched gray irons

Composition, %									Hardness, HB, of as-cast iron	Hardness, HB, after oil quenching from

(a) Total carbon.

(b) Combined carbon

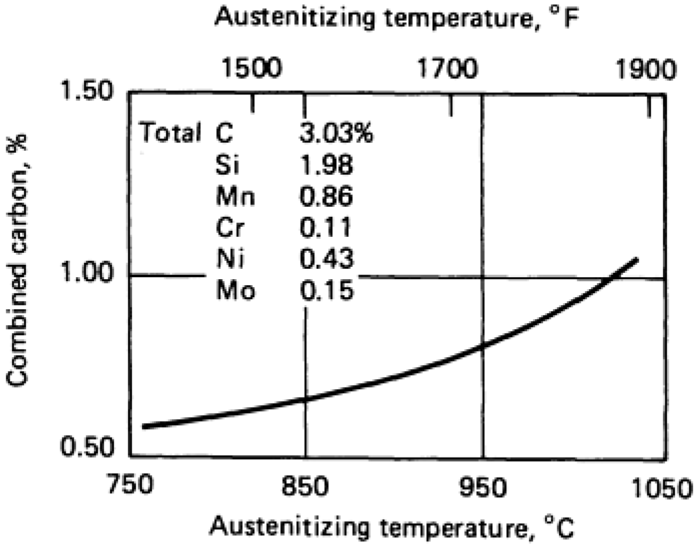

Fig. 7 Increase in combined carbon with increase in austenitizing temperature for gray iron. Specimens were furnace heated and water quenched. Combined carbon by difference

Castings should be treated through the lower temperature range slowly, in order to avoid cracking. Above a range of 595 to 650 °C (1100 to 1200 °F), that is, above the stress-relieving range, heating may be as rapid as desired. In fact, time may be saved by heating the casting slowly to about 650 °C (1200 °F) in one furnace and then transferring it to a second

furnace and bringing it rapidly up to the austenitizing temperature. As little as 20 min per inch of section may be sufficient time at temperature.

Quenching. Molten salt and oil are the quenching media used most frequently for gray iron. Water is not generally a satisfactory quenching medium for furnace-heated gray iron; it extracts heat so rapidly that distortion and cracking are likely in all parts except small ones of simple design. Recently developed water-soluble polymer quenches can provide the convenience of water quenching, along with lower cooling rates, which can minimize thermal shock.

The least severe quenching medium is air. Unalloyed or low-alloy gray iron castings usually cannot be air quenched because the cooling rate is not sufficiently high to form martensite. However, for irons of high alloy content, forced-air quenching is frequently the most desirable cooling method.

A casting of nonuniform section should be quenched in such a way that the heavier section enters the quenching bath first. During quenching, agitation is desirable because it ensures even temperature distribution in the bath and improves quenching efficiency. Because as-quenched castings at room temperature are sensitive to cracking, they should be removed from the quench bath as soon as their temperature falls to about 150 °C (300 °F) and tempered immediately.

Tempering. After quenching, castings are usually tempered at temperatures well below the transformation range for about 1 h per inch of thickest section. As the quenched iron is tempered, its hardness decreases, whereas it usually gains in strength and toughness (Fig. 8 and 9) (Table 3).

Table 3 Composition of gray irons in Fig. 8(d)

Iron	Composition, %					
	TC[(a)]	CC[(b)]	Si	Cr	Ni	Mo

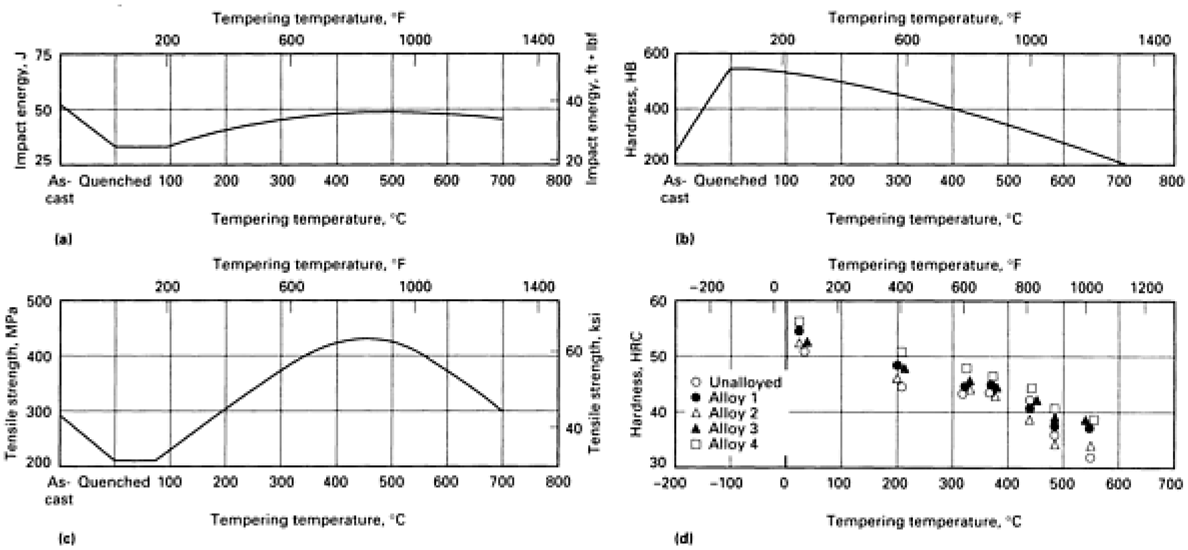

Fig. 8 Effect of tempering temperature on gray iron. (a) to (c) Changes in mechanical properties of hardened low-silicon unalloyed gray iron. (d) Hardness of gray iron specimens quenched in oil from 870 °C (1600 °F) and tempered. Each point on this chart represents an average of five hardness readings. For compositions of irons, see Table 3.

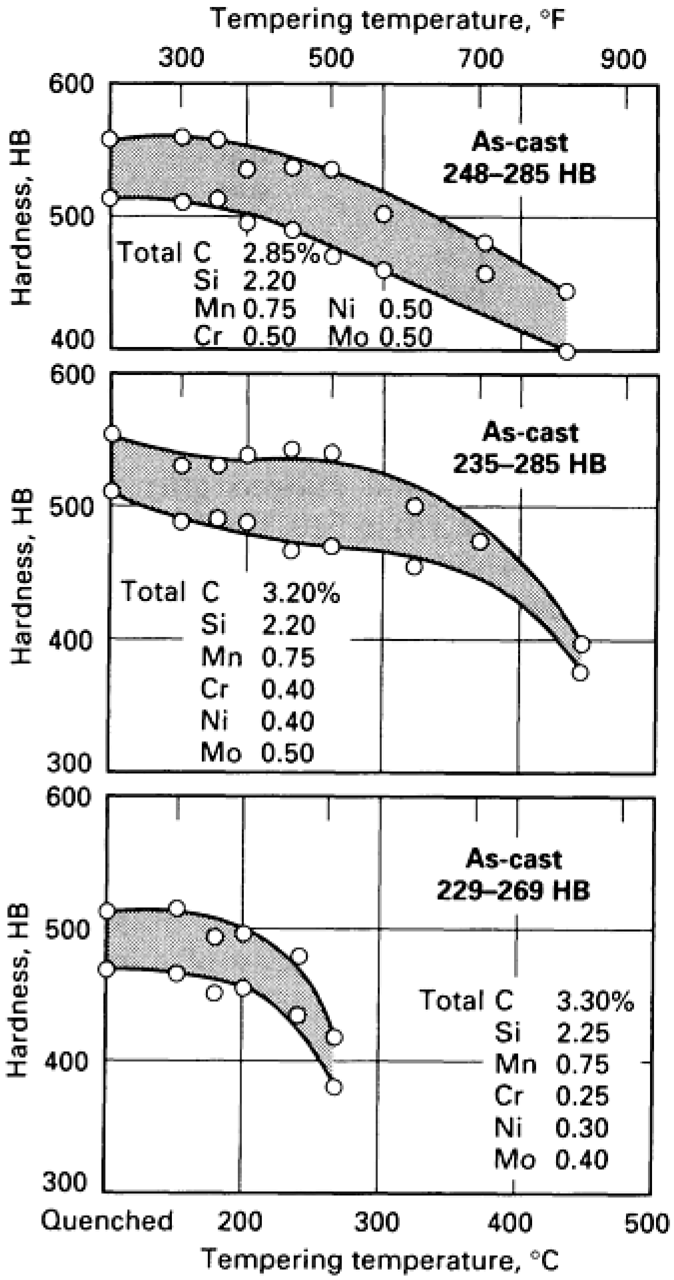

Fig. 9 Influence of alloy content on hardness of quenched and tempered gray iron test castings. Castings were normalized to the same hardness range before being austenitized for hardening and were oil quenched from 850 °C (1560 °F).

Applications

Examples of the quenching and tempering temperatures used and results obtained for four different production parts made of gray iron are discussed below.

Example 1. Unalloyed gray iron valve guides were heated in an atmosphere-controlled furnace and held for 1 h at 885 °C (1625 °F). The guides were then quenched in oil that was maintained at about 60 °C (140 °F). An as-quenched hardness of 45 to 50 HRC was obtained. After tempering at 480 °C (900 °F), hardness was 30 to 34 HRC.

Example 2. Valve guides made of gray iron containing 3.40% C, 2.40% Si, 0.21% Cr, and 0.50% Cu where heated to 870 °C (1600 °F) and held at this temperature for 1h. After being oil quenched from this temperature, the guides were tempered for 1 h at 495 °C (925 °F). Hardness distributions after quenching and after tempering, for 25 guides, are shown in Fig. 10.

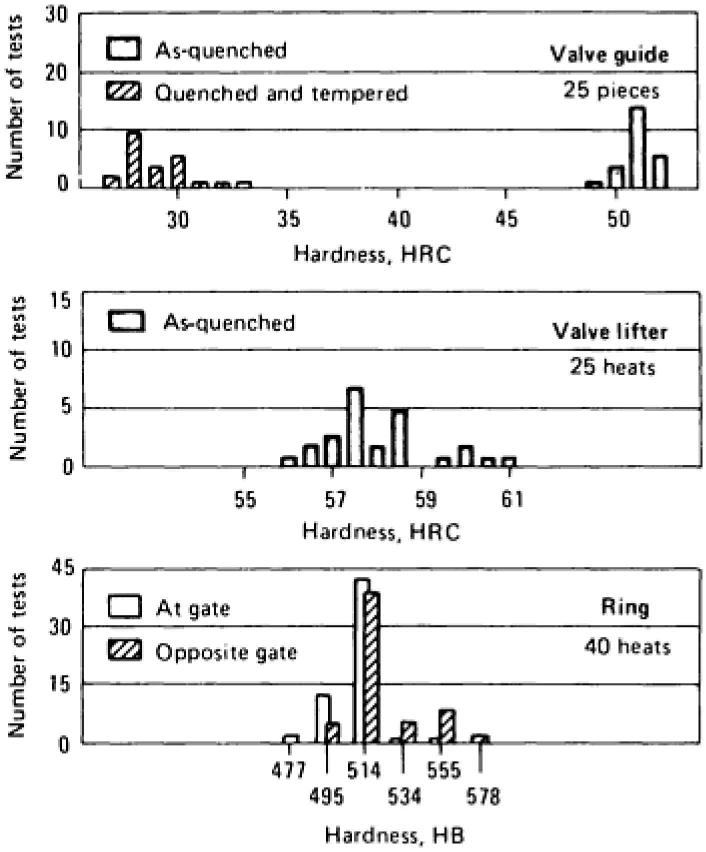

Fig. 10 Distribution of hardness for quenched and tempered production parts made of gray iron

Example 3. Automotive valve lifter castings made of gray iron containing 3.10 to 3.30% C, 2.10 to 2.40% Si, 1.00 to 1.25% Cr, 0.40 to 0.70% Ni, and 0.50 to 0.70% Mo were heated in a gas-fired radiant-tube conveyor furnace. A controlled atmosphere of endothermic generator gas was used to prevent decarburization of the machined surfaces. The castings were held for 45 min at 855 °C (1570 °F), quenched in oil at 55 °C (130 °F), and tempered for 3 h at 150 °C (300 °F) to a hardness of 55 to 61 HRC. The hardness readings were made 1.6 mm ($\frac{1}{16}$ in.) off center from the tappet face. A distribution of hardness values representing castings from 25 heats is given in Fig. 10.

Example 4. Ring-shape castings 65 mm (2.5 in.) in outside diameter by 20 mm (0.75 in.) high by 6.4 to 13 mm (0.25 to 0.5 in.) in wall thickness, made of a hardenable gray iron, were heat treated in groups and sampled for response to heat treatment. These castings were heat treated by holding for $\frac{1}{2}$h at 850 °C (1560 °F) and then oil quenching. Hardness data for 20 consecutive lots representing 40 heats are shown in Fig. 10. Each casting was tested at and opposite the gate.

Properties

The sections below describe some of the effects of tempering on properties. Additional information on the properties of gray irons is contained in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Strength. Tempering increases the tensile strength of hardened gray iron. Although the tempering temperature that yields maximum strength depends on chemical composition and increases with higher alloy content, the high-strength tempering range for both unalloyed and alloyed gray irons is approximately 370 to 510 °C (700 to 950 °F).

Other Properties. Tempering temperatures near 370 °C (700 °F) increase the impact resistance of hardened, low-silicon, unalloyed gray iron (Fig. 8). If alloying elements are present, higher tempering temperatures may be necessary.

Although considerable improvement in tensile strength may result from hardening and tempering, proportional improvements in fatigue properties are rarely obtained.

The modulus of elasticity of a low-alloy (1.32% Ni, 0.44% Cr) gray iron was found to be moderately improved by quench hardening and tempering:

Condition	**Modulus of elasticity**	
	GPa	**ksi**
As-cast	122	17,700
Oil quenched	112	16,200

The modulus of rupture increased markedly with the use of higher tempering temperatures. A similar increase was noted for the transverse breaking load and deflection. In an alloy iron containing 4.5% Ni and 1.5% Cr, the transverse breaking load was increased substantially, even with tempering temperatures as low as 200 °C (400 °F).

Austempering

In austempering, the microstructural end-product of the gray iron matrix formed below the pearlite range but above the martensite range is an acicular or bainitic ferrite, plus varying amounts of austenite, depending on the transformation temperature. The iron is quenched from a temperature above the transformation range in a hot quenching bath and is maintained in the bath at constant temperature until the austempering transformation is complete.

In all hot quenching processes, the temperatures to which castings must be heated for austenitizing and the required holding times at temperature prior to quenching in the hot bath correspond to the temperatures and times used in conventional hardening, that is, temperatures between 840 and 900 °C (1550 and 1650 °F). The holding time depends on the size and chemical composition of the casting. A characteristic curve for hardness as related to isothermal transformation temperature is shown in Fig. 11.

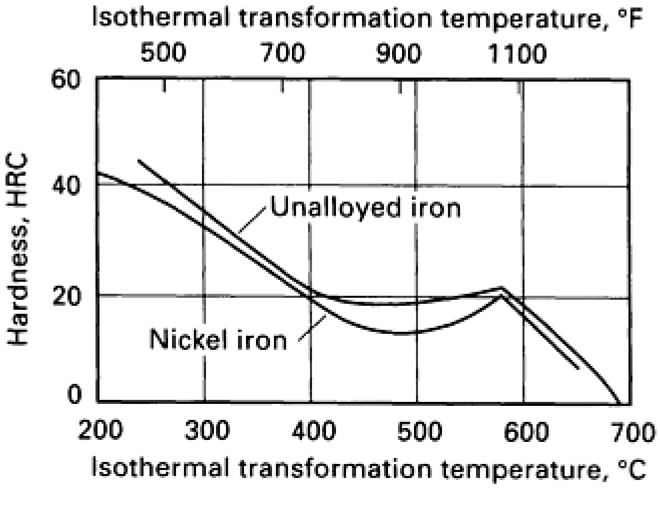

Fig. 11 Effect of isothermal transformation temperature on hardness of austempered gray irons. Holding times were sufficient to complete transformation.

Gray iron is usually quenched in salt, oil, or lead baths at 230 to 425 °C (450 to 800 °F) for austempering. When high hardness and wear resistance are the ultimate aim of this treatment, the temperature of the quench bath is usually held between 230 and 290 °C (450 and 550 °F).

The holding time required for maximum transformation is determined by the temperature of the quenching bath and the composition of the iron. The effect of iron composition on the holding time may be considerable. Alloy additions, such as nickel, chromium, and molybdenum, increase the time required for transformation.

The section thickness and shape of the casting determine the amounts of the added hardenability agents (Ni, Cu, Mo), because cooling must be fast enough to prevent any transformation of austenite until the casting reaches the temperature of the bath. Gray iron cylinder liners containing a minimum of 1.5% total chromium, nickel, molybdenum, and copper have been austempered at about 260 °C (500 °F).

Martempering

Martempering is used to produce martensite without developing the high stresses that usually accompany its formation. It is similar to conventional hardening except that distortion is minimized. Nevertheless, the characteristic brittleness of the martensite remains in a gray iron casting after martempering, and martempered castings are almost always tempered. The casting is quenched from above the transformation range in a salt, oil, or lead bath; held in the bath at a temperature slightly above the range at which martensite forms (200 to 260 °C, or 400 to 500 °F, for unalloyed irons) only until the casting has reached the bath temperature; and then cooled to room temperature.

If a wholly martensitic structure is desired, the casting must be held in the hot quench bath only long enough to permit it to reach the temperature of the bath. Thus, the size and shape of the casting dictate the duration of martempering.

The example below illustrates the use of martempering.

Example 5. Cylinder liners (sleeves) for diesel and heavy-duty gasoline engines, made of gray iron containing 3.25 to 3.50% C, 2.00 to 2.25% Si, 0.25% P (max), 0.12% S (max), 0.55 to 0.80% Mn, and 0.30 to 0.40% Cr, were fully annealed at 870 °C (1600 °F), rough machined, and then austenitized for martempering at 870 °C (1600 °F) in a neutral atmosphere for a total of 1 h (see Table 4 and Fig. 12). They were quenched for 1 min in molten nitrate-nitrite salt at 245 °C (475 °F) and air cooled for 30 min. After being washed to remove adhering salt, the castings were tempered for 2 h at 200 °C (400 °F).

Table 4 Equipment requirements for martempering cast iron cylinder liners

Requirements	Value
Production	
Weight of each piece, kg (lb)	3.8 (8.3)
Number of pieces per push	16
Number of pushes per hour	11
Weight of empty rack, kg (lb)	32 (70)

Total weight of material heated and quenched per hour, kg (lb)	1010 (2231)
Martempering furnace	
Salt pot, 1.83 × 1.98 × 1.83 m (72 × 78 × 72 in.)	Immersion heated, 6.6 m^3 (234 ft^3)[(a)]
Type of salt	Nitrate-nitrite[(b)]
Operating temperature of salt, °C (°F)	245 (475)
Agitation, by 230 mm (9 in.) diam propeller[(c)]	One $7\frac{1}{2}$ hp variable-speed motor
Cooling system	Three $\frac{1}{2}$ hp fans[(d)]

Note: Cylinder liners were austenitized in a radiant tube, gas-fired, single-row pusher furnace containing 27 U-type radiant tubes and accommodating 13 trays per cycle. Each tray measured 610 × 710 mm (24 × 28 in.). Austenitizing temperature was 870 °C (1600 °F). An endothermic atmosphere of 34 m^3/h (1200 ft^3/h) was controlled to 0.2 to 0.4% CO_2 by Orsat analysis.

(a) Pot, containing about 12 Mg (13 tons) of molten salt, was heated by 24 immersion rods, each rated at 5 kW.

(b) Melting point of salt, 145 °C (290 °F). No chloride separation chamber was required because parts were transferred to salt from a controlled-atmosphere hardening furnace.

(c) Propeller was in a 255 mm (10 in.) diam pipe connected to the quench funnel.

(d) Fans force outdoor air through ducts in furnace walls.

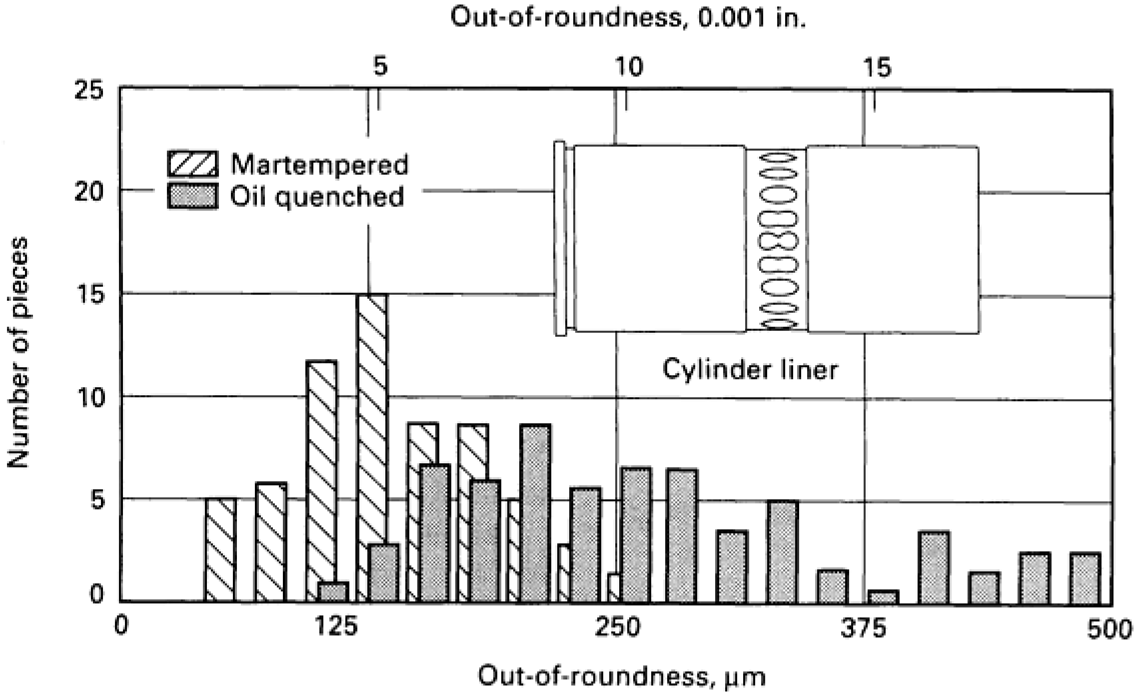

Fig. 12 Distortion in gray iron cylinder liners after martempering and after conventional oil quenching. Before being measured, liners were furnace tempered for 2 h at 200 °C (400 °F).

Austenitizing for martempering was accomplished in a pusher-type continuous furnace. Sixteen sleeves were loaded on each track, which rested on a furnace tray. Upon emerging from the furnace, the rack was pushed from the tray onto a quench elevator that immediately descended into the salt bath; thus, the furnace tray did not come in contact with the molten salt. The sleeves and rack were automatically raised from the salt and remained above the bath for drainage until the next rack was pushed into position, at which point the drained rack was pushed into a slowly moving conveyor for the 30-min cooling cycle. After cooling, the rack and sleeves were moved onto the washer conveyor and, after being washed, were deposited on the tempering-furnace conveyor. Equipment details are summarized in Table 4.

The as-cast sleeves had a graphitic structure predominantly of type A and a graphite flake size of 4 to 6. During the hardening cycle, the matrix dissolved about 0.70% C, and a martensitic structure resulted. The hardness range after hardening was 45 to 50 HRC; the microhardness of the matrix was more than 60 HRC.

Martempering replaced conventional oil quenching, during which each cylinder liner had been placed on a mandrel in order to preserve shape. Despite the use of the mandrel, out-of-roundness after hardening (Fig. 12) and size variations were about twice as great for oil-quenched liners as for those that were martempered. Martempering also eliminated the small percentage of cracked sleeves previously encountered and reduced the amount of grinding stock required for finishing.

Dimensional Accuracy and Distortion. If final dimensional accuracy is important for martempered parts, allowance for growth must be made prior to heat treatment. The uniformity of growth and the allowance required depend on the condition of the iron before hardening. Annealing the cylinder sleeves discussed in Example 5 at 870 °C (1600 °F) and furnace cooling prior to martempering resulted in a linear growth of 0.0010 to 0.0015 mm/mm (0.0010 to 0.0015 in./in.). This was twice as much growth as was encountered when as-cast or normalized pearlitic structures were martempered. A ferritic matrix, which absorbs more carbon during austenitizing than does a pearlitic matrix, causes more expansion (growth).

Some distortion, as differentiated from growth, occurs during martempering. Conditions that may promote excessive distortion are residual stresses from casting, machining, or rapid cooling during previous heat treatments; insufficient time for establishing equilibrium at the austenitizing temperature; and drafts during air cooling after the castings have been removed from the quench bath.

Austempering Versus Martempering. The maximum hardness obtainable by austempering is usually less than that obtainable by martempering, although this difference may be largely canceled during the tempering treatment that is usually necessary following martempering. Both austempering and martempering can result in less distortion and growth than conventional oil quenching and tempering.

Example 6. A high-strength, low-silicon processed iron martempered for 1 min at 260 °C (500 °F) exhibited a hardness of 555 HB, whereas the same iron austempered for 30 min at 275 °C (530 °F) showed a hardness of only 444 HB. After being tempered for 30 min at 390 °C (730 °F), the martempered material had about the same hardness as the austempered material, but its Charpy impact resistance, with a 15 mm (0.6 in.) square specimen and knife edges 70 mm (2.75 in.) apart, was only 14.2 J (10.5 ft · lbf), whereas that of the austempered material was 23.7 J (17.5 ft · lbf). The as-cast material had an impact resistance of 19.7 J (14.5 ft · lbf) and a hardness of 255 HB.

Example 7. When quenched in oil at 95 °C (200 °F) and tempered at 290 °C (550 °F), diesel engine cylinder liners exhibited an average distortion of 0.26 mm (0.0101 in.) and cracked occasionally. When austempered, the same liners had an average distortion of 0.066 mm (0.0026 in.) and when martempered, they displayed an average distortion of 0.06 mm (0.0025 in.). The average maximum growth for these liners was:

Heat treatment	Average maximum growth	
	mm	in.
Oil quenched and tempered	0.71	0.0279
Austempered	0.25	0.0099

The austempering cycle consisted of pre-heating for 5 min at 650 °C (1200 °F), austenitizing for 8 min at 870 °C (1600 °F), quenching to 250 °C (480 °F) and holding for 20 min, and cooling in air. The martempering cycle comprised preheating for 5 min at 650 °C (1200 °F), austenitizing for 8 min at 855 °C (1575 °F), quenching for 1 min in agitated salt at 345 °C (650 °F), cooling in air for a minimum of 1 h, and tempering at 175 °C (350 °F).

Flame Hardening

Flame hardening is the method of surface hardening most commonly applied to gray iron. The mechanics of the process are dealt with in the article "Flame Hardening" in this Volume.

After flame hardening, a gray iron casting consists of a hard, wear-resistant outer layer of martensite and a core of softer gray iron, which during treatment does not reach the A_1 transformation temperature (in fact, the unhardened metal immediately below the hardened case, which has been heated by the flame to some extent, may even be partially annealed during flame hardening if it is unalloyed).

Recommended Composition. Both unalloyed and alloyed gray irons can be successfully flame hardened. However, some compositions yield much better results than do others. One of the most important aspects of composition is the combined carbon content, which should be in the range of 0.50 to 0.70%, although irons with as little as 0.40% combined carbon can be flame hardened. In general, flame hardening is not recommended for irons that contain more than 0.80% combined carbon because such irons (mottled or white irons) may crack in surface hardening.

The stability of the microconstituents from which the carbon precipitates is a factor in determining the hardness of the flame-hardened iron. One user observed that the stability of microconstituents containing combined carbon is indicated by the hardness of test specimens annealed at 845 °C (1550 °F). A test of four pearlitic irons from different sources, containing 3.30% C max, 1.40 to 1.60% Si, 0.80 to 1.10% Mn, and 0.15 to 0.20% Cr, gave the results:

Iron	**Hardness, HB**		**Hardness[(a)], HRC**
	As-cast	**Annealed**	
A	220	200	47-50
B	190	180	47-50
C	200	140	35-38

(a) After flame hardening as-cast iron

For maximum hardness, it is advisable to use an iron containing as small an amount of total carbon as is consistent with the production of sound castings free from any danger of cracking. The coarse graphite flakes typical of high-carbon irons should be avoided because they may be burned out during flame heating, thereby producing a porous and unattractive surface.

Because silicon promotes the formation of graphite and of a low combined carbon content, a relatively low silicon content is also advisable. Several users report that silicon content should not exceed 2% in any iron submitted to a flame-hardening operation, although alloy irons containing 2.4% Si can be hardened successfully. They also recommend that manganese content be held in the range of 0.80 to 1.00% to increase carbon solubility in austenite.

Gray iron to be flame hardened should be as free as possible from porosity and from foreign matter such as sand or slag because porosity and even small inclusions of foreign matter can produce a rough surface or result in cracking after hardening. Rough casting surfaces should be sand or shot blasted prior to heat treatment because skin or scale on the surface acts as a heat insulator and reduces the effectiveness of flame hardening.

Effects of Alloying Elements. In general, alloyed gray irons can be flame hardened with greater ease than can unalloyed irons, partly because alloyed gray irons have increased hardenability. Final hardness also may be increased by alloying additions. The maximum hardness obtainable by flame hardening an unalloyed gray iron containing approximately 3% total carbon, 1.7% Si, and 0.60 to 0.80% Mn ranges from 400 to 500 HB. This is because the Brinell hardness value for gray iron is an average of the hardness of the matrix and that of the relatively soft graphite flakes. Actually, the matrix hardness on which wear resistance depends approximates 600 HB. With the addition of 2.5% Ni and 0.5% Cr, an average surface hardness of 550 HB can be obtained. The same result has been achieved using 1.0 to 1.5% Ni and 0.25% Mo. Small additions of chromium are particularly valuable in preventing softening and ensuring the retention of a high content of combined carbon during austenitizing for hardening. Automotive camshafts containing 1% Cr, 0.50% Mo, and 0.8% Mn are easily flame hardened to 52 HRC to a required depth. These parts are not tempered or stress relieved.

Stress Relieving. Whenever practicable or economically feasible, flame-hardened castings should be stress relieved at 150 to 200 °C (300 to 400 °F) in a furnace, in hot oil, or by passing a flame over the hardened surface. Such a treatment will minimize distortion or cracking and will increase the toughness of the hardened layer.

Stress relieving at 150 °C (300 °F) for 7 h was found to remove 25 to 40% of the residual stresses in a flame-hardened casting, while reducing the hardness of the surface by only 2 to 5 points on the HRA scale. Although stress relieving is desirable, it can often be safely omitted.

Hardness. The surface of flame-hardened gray iron typically has a somewhat lower hardness than the metal immediately below the surface (Fig. 13). This decrease in hardness may be caused by the retention of relatively soft austenite at the surface. Surface hardness often can be raised by heating in the range from 195 to 250 °C (380 to 480 °F).

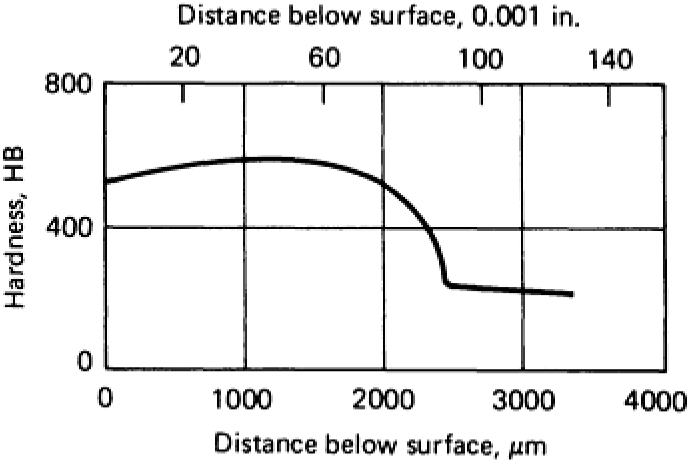

Fig. 13 Typical hardness gradient produced in gray iron by flame hardening

The depth and microstructure of the hardened layer depend on two other factors in addition to temperature: the amount of carbon and alloying elements in solution when the flame-hardened surface is quenched, and the efficiency of quenching. If softness is due to the presence of austenite in the microstructure, subjecting the part to -40 °C (-40 °F) for 1 h will transform the austenite and increase the hardness.

Fatigue strength is usually increased by surface hardening because the treatment induces compressive stresses at the surface. For example, flame or induction heating followed by water quenching induces high compressive stresses (>205 MPa, or 30 ksi) in the fillet areas of crankshafts; however, if self-quenching instead of water quenching is used, undesirable tensile stresses may result at the surface. The degree of improvement in fatigue strength by flame hardening cannot be produced by through hardening.

Quenching. The various methods of flame hardening influence the selection of the quenching medium. In the progressive method, only nonflammable media such as water, soluble-oil mixtures, and solutions of polyvinyl alcohol in water can be employed. Conventional oil cannot be used because of the fire hazard. In spot hardening or spinning methods, in which the flame head is withdrawn from the part before quenching, parts are quenched conventionally by immersion in hot oil.

When quenching is done with water, the water should be at about 30 °C (90 °F) for best results. Lower quenching rates, such as those obtained with 5 to 15% soluble-oil mixtures, compressed air, or compressed air and water at low pressure, are used to prevent cracking. Air quenching is especially suited to highly alloyed cast irons because of their susceptibility to cracking.

Induction Hardening

Gray iron castings can be surface hardened by the induction method when the number of castings to be processed is large enough to warrant the relatively high equipment cost and the need for special induction coils. Considerable variation in

the hardness of the cast irons may be expected because of a variation in the combined carbon content. A minimum combined carbon content of 0.40 to 0.50% C (as pearlite) is recommended for cast iron to be hardened by induction, with the short heating cycles that are characteristic of this process. Heating castings with lower combined carbon content to high hardening temperatures for relatively long periods of time may dissolve some free graphite, but such a procedure is likely to coarsen the grain structure at the surface and will result in undesirably large amounts of retained austenite in the surface layers. The recommended minimum induction hardening temperature for gray iron is 870 to 925 °C (1600 to 1700 °F).

The surface hardness attained from the induction hardening of gray iron is influenced by the carbon equivalent (%C + $\frac{1}{3}$% Si) when this hardness is measured by conventional Rockwell tests. The more graphite that is present in the microstructure, the lower the surface hardness will appear to be after hardening. Table 5 shows the surface hardness of induction-hardened gray iron castings of various carbon equivalents from 3.63 to 4.23. The microstructure of these castings, which were cast in the same manner and cooled at similar rates, contained more and larger graphite flakes as the carbon equivalent increased. This resulted in lower apparent surface hardness after hardening, yet the hardened matrix was consistently 57 to 61 HRC (converted from microhardness).

Table 5 Effect of carbon equivalent on surface hardness of induction-hardened gray irons

Composition, %[(a)]		Carbon equivalent[(b)]	Hardness HRC, converted from		
C	Si		As read	Rockwell 30-N	Microhardness
3.13	1.50	3.63	50	50	61
3.14	1.68	3.70	49	50	57
3.19	1.64	3.74	48	50	61
3.34	1.59	3.87	47	49	58
3.42	1.80	4.02	46	47	61
3.46	2.00	4.13	43	45	59
3.52	2.14	4.23	36	38	61

(a) Each iron also contained 0.50 to 0.90 Mn, 0.35 to 0.55 Ni, 0.08 to 0.15 Cr, and 0.15 to 0.30 Mo.

(b) Carbon equivalent = %C + $\frac{1}{3}$% Si.

Distortion. Induction hardening causes less distortion than would a similar quenching treatment from a furnace. The maximum warpage in a 560 mm (22 in.) length of bar was found to be 0.03 mm (0.0015 in.) after induction hardening, compared with 0.17 to 0.25 mm (0.007 to 0.010 in.) for the same bars quenched from a furnace. For thin-walled cylinders, distortion is not a problem unless the thickness of the induction-hardened layer exceeds 20% of the wall thickness.

For selective hardening, in place or by scanning, to depths up to 3.8 mm (0.150 in.), water quenching can be used safely. However, the hardening of keyways, cross-drilled holes, or extremely thin walls may require the use of oil to prevent excessive distortion or cracking.

Example 8. A cast frame for a baler knotter had a nominal composition of 3.30 to 3.50% C, 0.50 to 0.70% Mn, 0.30 to 0.40% P, 0.15% S max, and about 2.40 to 2.60% Si. A 10.9 mm ($\frac{7}{16}$ in.) section of the frame was heated for 12 s with a 14 kW, 10 kHz unit using a modified hairpin-type inductor. After being water quenched for 4 s, it developed an apparent hardness of approximately 45 HRC (not indicative of the true hardness of the matrix, which can harden to 61 HRC or higher).

Stress Relieving

Gray iron in the as-cast condition contains residual stresses (unless the iron is cooled in the mold, in which case much of the solidification stress is removed)because cooling (and therefore contraction) proceeds at different rates in various sections of a casting. The resultant residual stresses may reduce strength, cause distortion, and in extreme cases even result in failure or cracking. The magnitudes of these stresses depend on the shape and section size of the casting, on the casting technique employed, on the composition and properties of the cast material, and on whether the casting has been stress relieved.

Temperature of stress relieving is usually well below the range for the transformation of pearlite to austenite.

The effects of stress relieving at 650 °C (1200 °F) for 6 h on the tensile strength and hardness of gray irons of classes 25, 35, and 50 are plotted in Fig. 14. As indicated, the properties of the class 25 iron were affected considerably more than were those of the class 35 and class 50 irons. Figure 15 shows the effect of stress-relieving temperature on the hardness of unalloyed and alloyed gray irons.

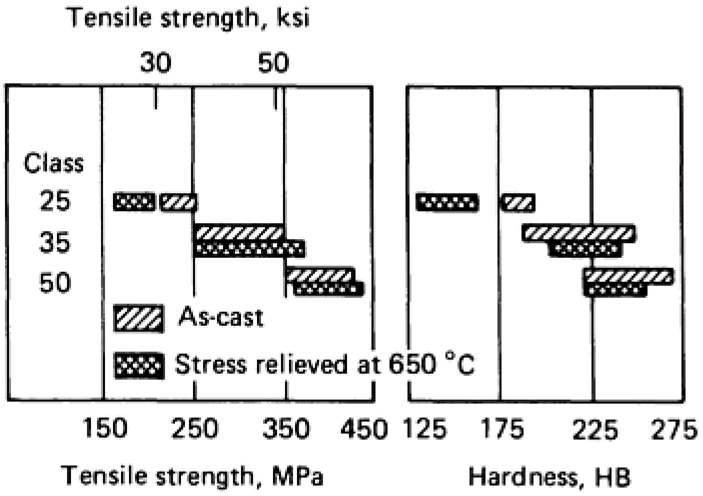

Fig. 14 Effects of stress relieving on tensile strength and hardness of gray iron. Gray iron bars, 30 mm (1.2 in.) in diameter, were stress relieved for 6 h at 650 °C (1200 °F) in a car bottom furnace approximately 13 × 4 × 3 m (42 × 13 × 9 ft); total furnace time was 43$\frac{3}{4}$ h.

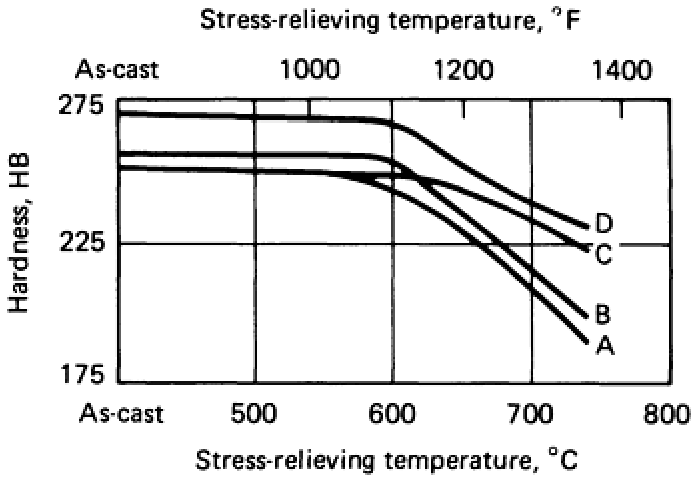

Iron	Composition, %					
	TC[a]	CC[b]	Si	Cr	Ni	Mo
A	3.20	0.80	2.43	0.13	0.05	0.17
B	3.29	0.79	2.58	0.24	0.10	0.55
C	3.23	0.70	2.55	0.58	0.06	0.12

(a) Total carbon.

(b) Combined carbon

Fig. 15 Effect of stress-relieving temperature on hardness of gray irons. Bar specimens 30 mm (1.2 in.) in diameter were held for 1 h at indicated temperatures and then air cooled.

For a maximum relief of stress with a minimum of decomposition of carbide in unalloyed irons, a temperature range of 540 to 565 °C (1000 to 1050 °F) is desirable. Figure 16 indicates that from 75 to 85% of the residual stress can be removed by holding for 1 h in this range. Other investigations (for example, see Fig. 17) indicate that the curves in Fig. 16 are applicable to gray irons over a wide range of compositions.

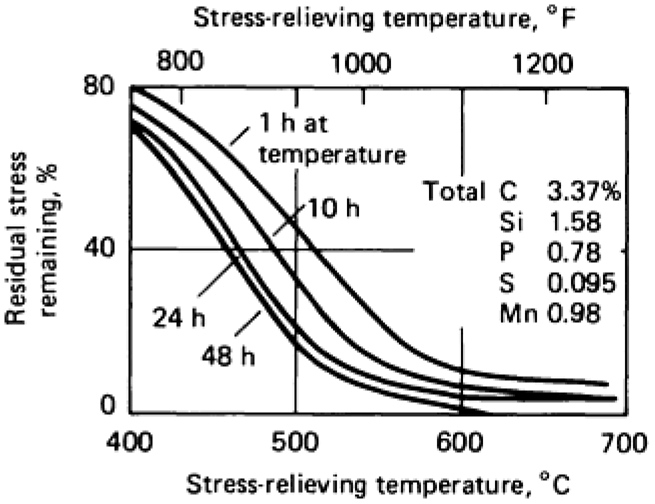

Fig. 16 Effect of stress-relieving temperature on residual stress in gray iron

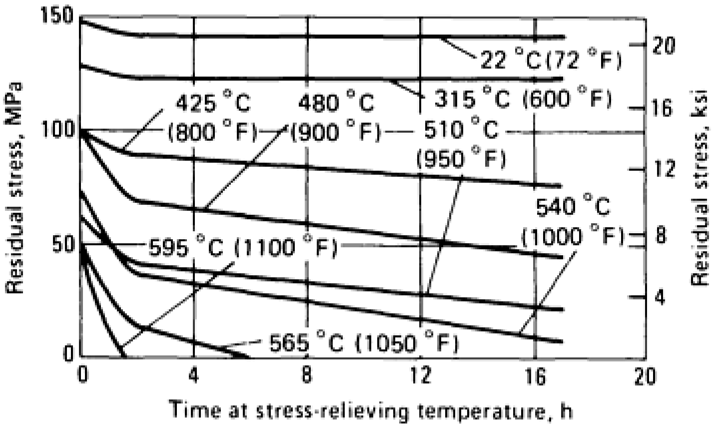

Fig. 17 Effect of stress-relieving temperature and time on residual stress in gray iron. Composition of iron: 2.72% C, 1.97% Si, 0.141% P, 0.080% S, 0.51% Mn

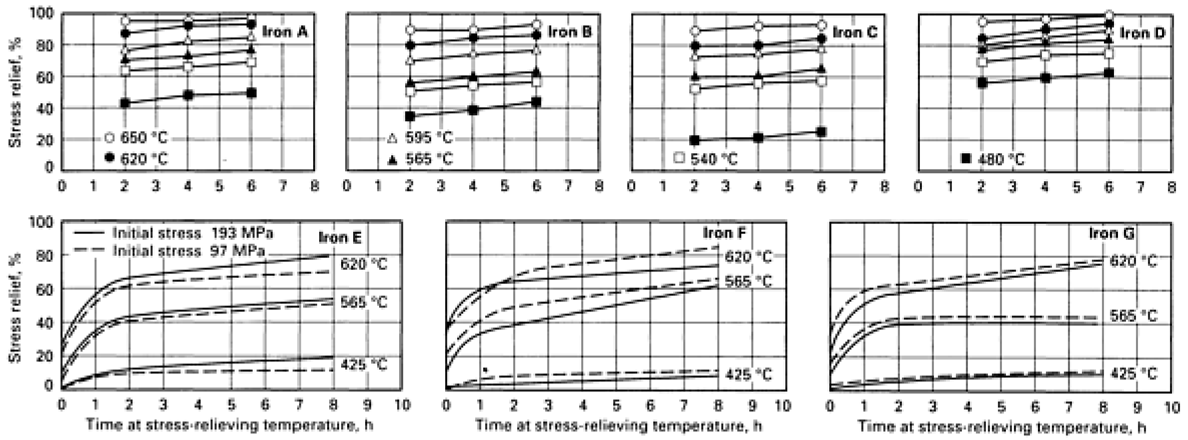
When almost complete stress relief (>85%) is required in unalloyed iron, a minimum temperature of 595 °C (1100 °F) can be employed; however, some sacrifice in strength, hardness, and wear resistance is likely. Fortunately, the soft irons of higher carbon equivalent normally exhibit a lower level of residual stress and comparatively low creep resistance, facilitating stress relief. In fact, irons of high carbon equivalent can be satisfactorily stress relieved at the lower end of the suggested temperature range, that is, at about 510 °C (950 °F). Low-alloy gray irons usually require higher stress-relieving temperatures--on the order of 595 to 650 °C (1100 to 1200 °F), depending on alloy content.

Quantitative data concerning the effects of alloying elements on the optimum stress-relieving temperature are meager. However, it has been reported that in one instance the addition of as little as 0.14% Cr to a 3.20C-2.01Si iron permitted exposure of the iron to a temperature of about 650 °C (1200 °F) for 1 h without sacrifice in room-temperature tensile strength. Figure 18 shows the effect of temperature and time on the relief of stresses for seven low-alloy irons, and the tabulation below the graphs indicates that these irons, depending on shakeout time, can be stress relieved for 8 h at 620 °C (1150 °F) with no adverse effect on hardness.



Iron	Composition, %										Hardness, HRB	
	C	Si	P	S	Mn	Ni	Cr	Mo	Cu	V	Before stress relieving	After stress relieving for 8 h at 620 °C (1150 °F)
A	2.93	2.14	0.110	0.57	0.47	0.35	0.10	. . .	. . .	. . .	98	94
B	3.43	2.12	0.104	0.70	0.81	0.34	0.18	0.23	. . .	. . .	98	94
C	3.24	2.55	0.107	0.62	0.87	0.51	0.20	0.22	. . .	. . .	95	95
D	3.91	1.43	0.54	0.25	0.32	1.56	0.06	. . .	. . .	. . .	82	80
E	3.18	2.13	0.73	0.125	0.70	1.03	0.33	0.65	. . .	. . .	98	98
F	3.12	1.76	0.075	0.097	0.78	1.02	0.41	0.58	. . .	. . .	94	95

Fig. 18 Effect of stress-relieving time and temperature on degree of stress relief obtained in low-alloy gray irons. Table shows compositions and negligible effect of maximum stress-relieving conditions on hardness.

Recommended stress-relieving temperatures, based on normal shakeout times in the foundry, are:

Iron	Temperature	
	°C	°F
Unalloyed, or alloyed without Cr	510-565	950-1050
0.15-0.30% Cr	595-620	1100-1150
>0.30% Cr	620-650	1150-1200

If the service requirements of a casting demand a particularly low residual stress, temperatures about 30 °C (50 °F) above those listed may be used. When these higher temperatures are used, it is advisable to check the hardness of the stress-relieved casting, if hardness and strength are critical, to determine whether an unacceptable decrease in hardness or strength has taken place.

Rate of Heating. The rate at which gray iron castings are heated for stress relief depends on the shape and size of the part but, except for the most complex shapes, is not especially critical. When a batch-type furnace is employed, it is of the utmost importance that furnace temperature not exceed 95 °C (200 °F) at the time of loading. After the furnace is loaded, the heating rate may be fairly high. For example, it is common practice to heat to 620 °C (1150 °F) in about 3 h, hold at temperature for 1 h, and cool to 315 °C (600 °F) in about 4 h before removing castings from the furnace and permitting them to cool in air. These conditions also apply to continuous furnaces in which the various temperature zones can be controlled to avoid introducing additional thermal stress in the castings. It is imperative that flame impingement on castings, which may result in variations in hardness, be avoided.

Rate of Cooling. If a casting is allowed to cool rapidly from the stress-relieving temperature to room temperature, new stresses may be developed and the goal of maximum stress elimination will not be fully achieved. For this reason, slow cooling from the stress-relieving temperature, at least in the upper temperature range, is an essential part of stress relieving.

It is generally recommended that castings be furnace cooled to 315 °C (600 °F) or lower before being allowed to cool in air; for castings of intricate design, it may even be advisable to continue furnace cooling until a temperature of about 95 °C (200 °F) has been reached. Most commercial furnaces cool slowly enough to meet all requirements.

Reduction of Distortion and Elimination of Cracking. The following examples illustrate the use of stress relieving to eliminate distortion and cracking.

Other examples of castings that require stress relief are pump volutes, scrolls, and casings. These parts require two stress-relieving treatments: first, in the as-cast condition, to minimize distortion during machining; and second, after rough machining, to minimize distortion during final machining.

Example 9. A flatness tolerance of 0.1 mm (0.004 in.) could not be maintained after machining as-cast clutch plates. These parts were made of gray iron containing 3.40% C (0.70 to 0.90 combined carbon), 1.30 to 1.80% Si, 0.25 to 0.40% Cr, 0.30 to 0.40% Mo, and nickel and copper as required for a minimum tensile strength of 275 MPa (40 ksi) and a hardness of 207 to 255 HB. After these clutch plates were stress relieved at 620 °C (1150 °F) for 2 h, the tolerance could be held.

Example 10. Necessitated by a rush order, a change in procedure from a slow cool in the mold to a fast shakeout resulted in high residual stress in cast transmission cases. These parts were made of gray iron containing 3.10 to 3.40% C, 2.15 to 2.35% Si, and 0.20 to 0.40% Cr. Some of the first castings produced after the change in procedure developed cracks up to 1.3 mm (0.050 in.) wide during machining; others, although they survived machining without cracking, developed cracks during a final hot washing operation. This problem was eliminated for the remaining pieces from this order by stress relieving them at 620 °C (1150 °F) for 2 h. A return to the original cooling and shakeout practice with subsequent orders eliminated cracking and the need for stress relieving.

Example 11. Hot tears and out-of-roundness occurred in as-cast rings, and additional distortion in the flat plane of these rings occurred during machining. A change in the method of gating these castings equalized temperature differentials and controlled shrinkage distribution, thereby eliminating the hot tears and as-cast distortion. The distortion occurring during machining was eliminated by stress relieving the rings at 370 °C (700 °F) for 2 h.

Example 12. Table 6 shows the results of an evaluation of different cooling methods and stress-relieving treatments on residual stresses in 225 kg (500 lb) diesel engine cylinder blocks. These blocks were made of gray iron containing 3.25% C, 2.20% Si, and 0.30% Cr and having a tensile strength of 240 MPa (35 ksi).

Table 6 Effect of shakeout practice and stress relieving on residual stress in 225 kg (500 lb) diesel engine cylinder blocks

Practice	Close-in		Stress relief, %
	mm	in.	
1. Shakeout after 6 h; cores in place while cooling to 27 °C (80 °F); total time, 16 h	4.1	0.160	Basis for evaluation
2. Practice 1, except cores also shaken out at 6 h	1.9	0.076	52
3. Cooled in mold 16 h before shakeout	1.6	0.064	60
4. Practice 1, followed by stress relieving at 540 °C (1000 °F) for 2 h, furnace cooling to 370 °C (700 °F)	1.5-1.9	0.060-0.076	52-62
5. Practice 1, followed by stress relieving at 620 °C (1150 °F) for 2 h, furnace cooling to 370	0.3-	0.012-	91

Two vertical lines were scribed on one end of each block after shakeout. The distance between these lines was measured before and after vertical saw cuts (parallel to the scribed lines) were made through the end of each block to the first cylinder bore. The amount of close-in between the two vertical lines after sawing was a relative measure of the residual stress.

The results (see Table 6) indicate that the complete shakeout (including cores), allowing inner sections to cool faster, materially reduced stresses, as did the procedure of leaving the casting in the mold to slow the cooling of external sections. This latter procedure is effective if the mass of metal is sufficient to keep the external sections at a high temperature throughout--620 °C (1150 °F) or higher--while equilibrium between outer and inner sections is taking place. As indicated, stress relieving at 540 °C (1000 °F) was substantially less effective than stress relieving at 620 °C (1150 °F).

Heat Treating of Ductile Irons

Karl B. Rundman, Department of Metallurgical and Materials Engineering, Michigan Technological University

Introduction

DUCTILE CAST IRONS (also known as nodular or spheroidal graphite iron), are primarily heat treated to create matrix microstructures and associated mechanical properties not readily obtained in the as-cast condition. As-cast matrix microstructures usually consist of ferrite or pearlite or combinations of both, depending on cast section size and/or alloy composition. These and other factors that affect the casting of ductile irons are discussed in the article "Classification and

Basic Metallurgy of Cast Iron" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.* The purpose of this article is to discuss the heat treatment of ductile irons.

The most important heat treatments and their purposes are:

- Stress relieving, a low-temperature treatment, to reduce or relieve internal stresses remaining after casting
- Annealing, to improve ductility and toughness, to reduce hardness, and to remove carbides
- Normalizing, to improve strength with some ductility
- Hardening and tempering, to increase hardness or to improve strength and raise proof stress ratio
- Austempering, to yield a microstructure of high strength, with some ductility and good wear resistance
- Surface hardening, by induction, flame, or laser, to produce a locally selected wear-resistant hard surface

The normalizing, hardening, and austempering heat treatment, which involve austenitization followed by controlled cooling or isothermal reaction, or a combination of the two, can produce a variety of microstructures and greatly extend the limits on the mechanical properties of ductile cast iron. These microstructures can be separated into two broad classes:

- Those in which the major iron-bearing matrix phase is the thermodynamically stable body-centered cubic (ferrite) structure
- Those with a matrix phase that is a metastable face-centered cubic (austenite) structure

The former are usually generated by the annealing, normalizing, normalizing and tempering, or quenching and tempering processes. The latter are generated by austempering, an isothermal reaction process resulting in a product called austempered ductile iron (ADI).

Other heat treatments in common industrial use include stress-relief annealing and selective surface heat treatment. Stress-relief annealing does not involve major microstructural transformations, whereas selective surface treatment (such as flame and induction surface hardening) does involve microstructural transformations, but only in selectively controlled parts of the casting.

General Characteristics

The basic structural differences between the ferritic and austenitic classes are explained in Fig. 1 and 2. Figure 1 shows a continuous cooling transformation (CCT) diagram and cooling curves for furnace cooling, air cooling, and quenching. It can be seen from Fig. 1 that slow furnace cooling results in a ferritic matrix (the desired product of annealing), whereas the cooling curve for air cooling, or normalizing, results in a pearlitic matrix, and quenching produces a matrix microstructure consisting mostly of martensite with some retained austenite. Tempering softens the normalized and quenched conditions, resulting in microstructures consisting of the matrix ferrite with small particles of iron carbide (or secondary graphite). Examples of furnace-cooled, air-cooled, and water-quenched microstructures are shown in Fig. 3. Actual annealing cycles usually involve more than just furnace cooling, depending on alloy content and prior structure. These processes will be detailed in the next section.

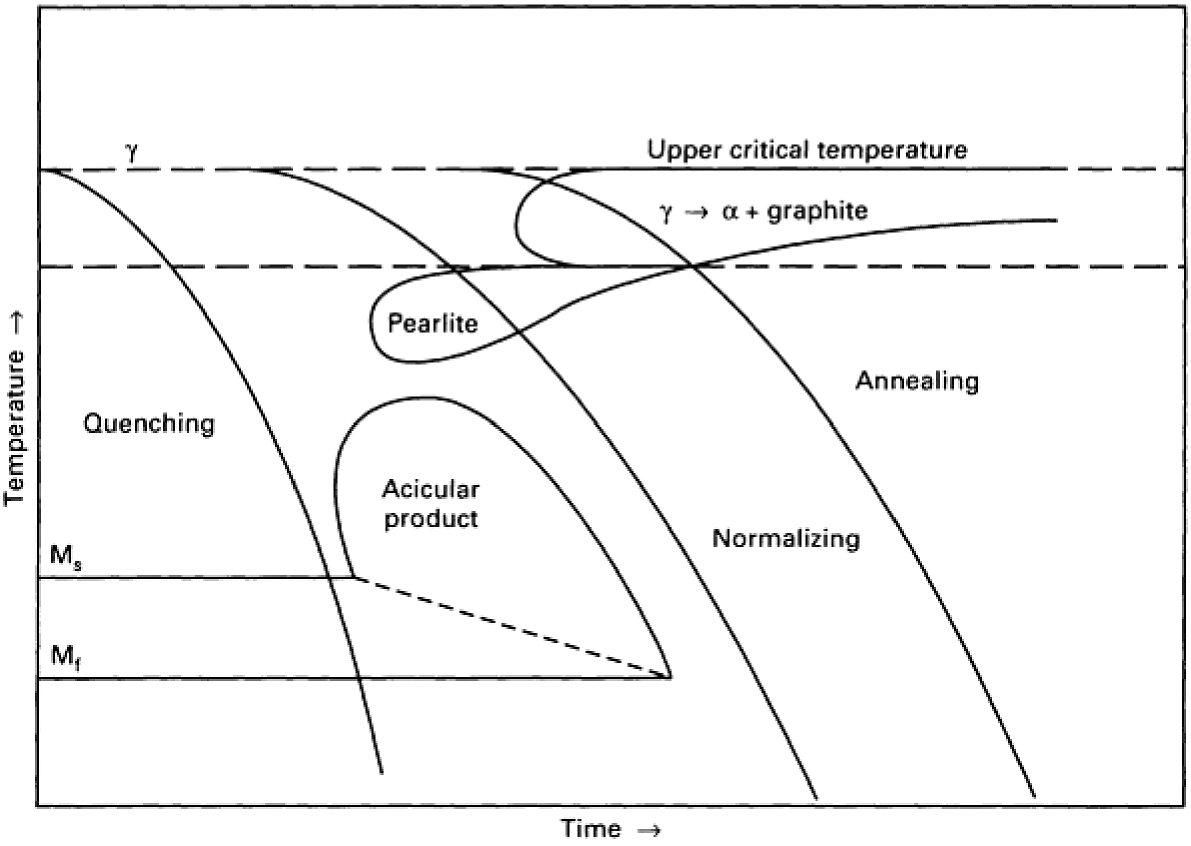


Fig. 1 CCT diagram showing annealing, normalizing, and quenching. M_s, martensite start; M_f, martensite finish

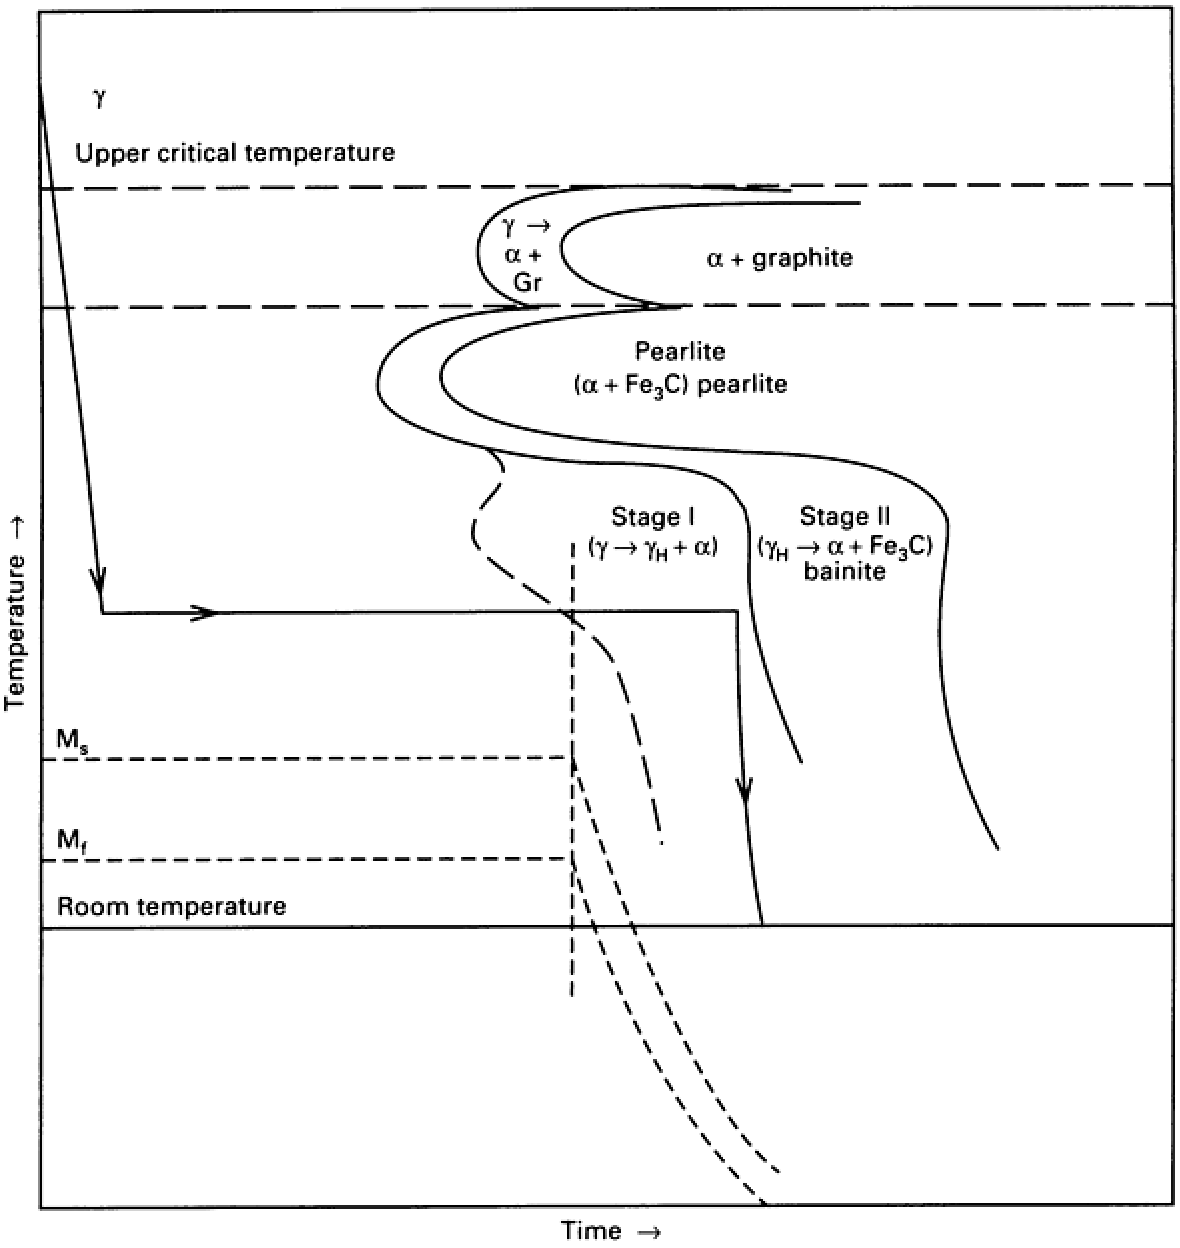

Fig. 2 IT diagram of a processing sequence for austempering, with the M_s and M_f decreasing as the γ is enriched with carbon during stage I

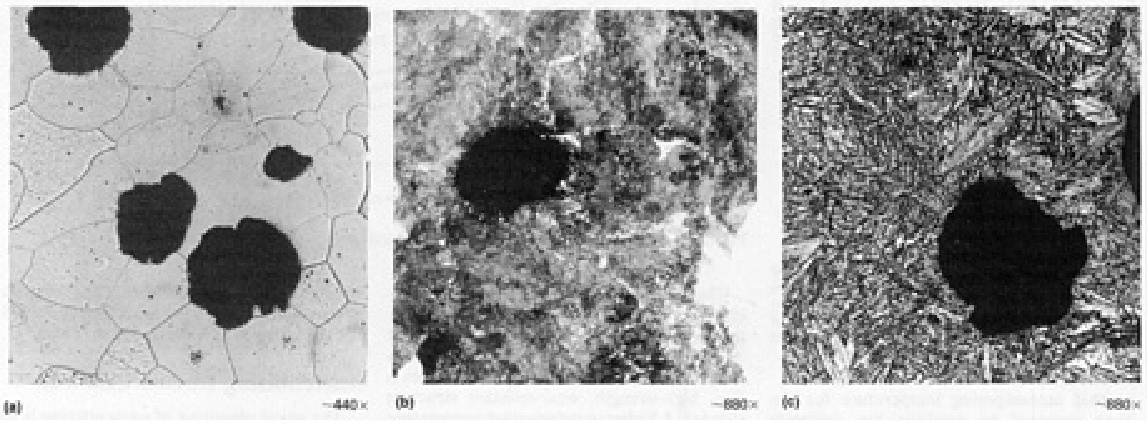

Fig. 3 Optical micrographs of ductile iron with (a) a ferritic matrix in an annealed casting, (b) fine pearlitic matrix in a normalized casting, and (c) a martensitic matrix in a quenched casting. Etched in nital; approximate magnifications shown

Figure 2 shows an isothermal transformation (IT) diagram for a ductile cast iron, together with a processing sequence depicting the production of ADI. In this process, austenitizing is followed by rapid quenching (usually in molten salt) to an intermediate temperature range for a time that allows the unique metastable carbon-rich (~2% C) austenitic matrix (γ_H) to evolve simultaneously with nucleation and growth of a plate-like ferrite (α) or of ferrite plus carbide, depending on the austempering temperature and time at temperature. This austempering reaction progresses to a point at which the entire matrix has been transformed to the metastable product (stage I in Fig. 2), and then that product is "frozen in" by cooling to room temperature *before* the true bainitic ferrite plus carbide phases can appear (stage II in Fig. 2). In ductile cast irons the presence of 2 to 3 wt% Si prevents the rapid formation of iron carbide (Fe_3C). Hence the carbon rejected during ferrite formation in the first stage of the reaction (stage I in Fig. 2) enters the matrix austenite, enriching it and stabilizing it thermally to prevent martensite formation upon subsequent cooling. Thus the processing sequence in Fig. 2 shows that the austempering reaction is terminated before stage II begins and illustrates the decrease in the martensite start (M_s) and martensite finish (M_f) temperatures as γ_H forms in stage I. The kinetics of stage I and stage II have been described in detail in the literature (Ref 1, 2, 3, 4). Typical austempering times range from 1 to 4 h, depending on alloy content and section size. If the part is austempered too long, undesirable bainite will form. Unlike steel, bainite in cast iron microstructures exhibits lower toughness and ductility.

Tensile Properties. Figure 4(a) shows the relationship between minimum specified values for tensile strength and elongation representing the range of values covered by the ISO, ASTM, and SAE specifications. Figure 4(b) shows the difference between minimum values for ASTM grades of austempered and other types of ductile iron. The actual values of properties to be expected from good-quality ductile irons produced to meet any given specified grade will normally cover a range, as shown in Fig. 4(c) and 5.

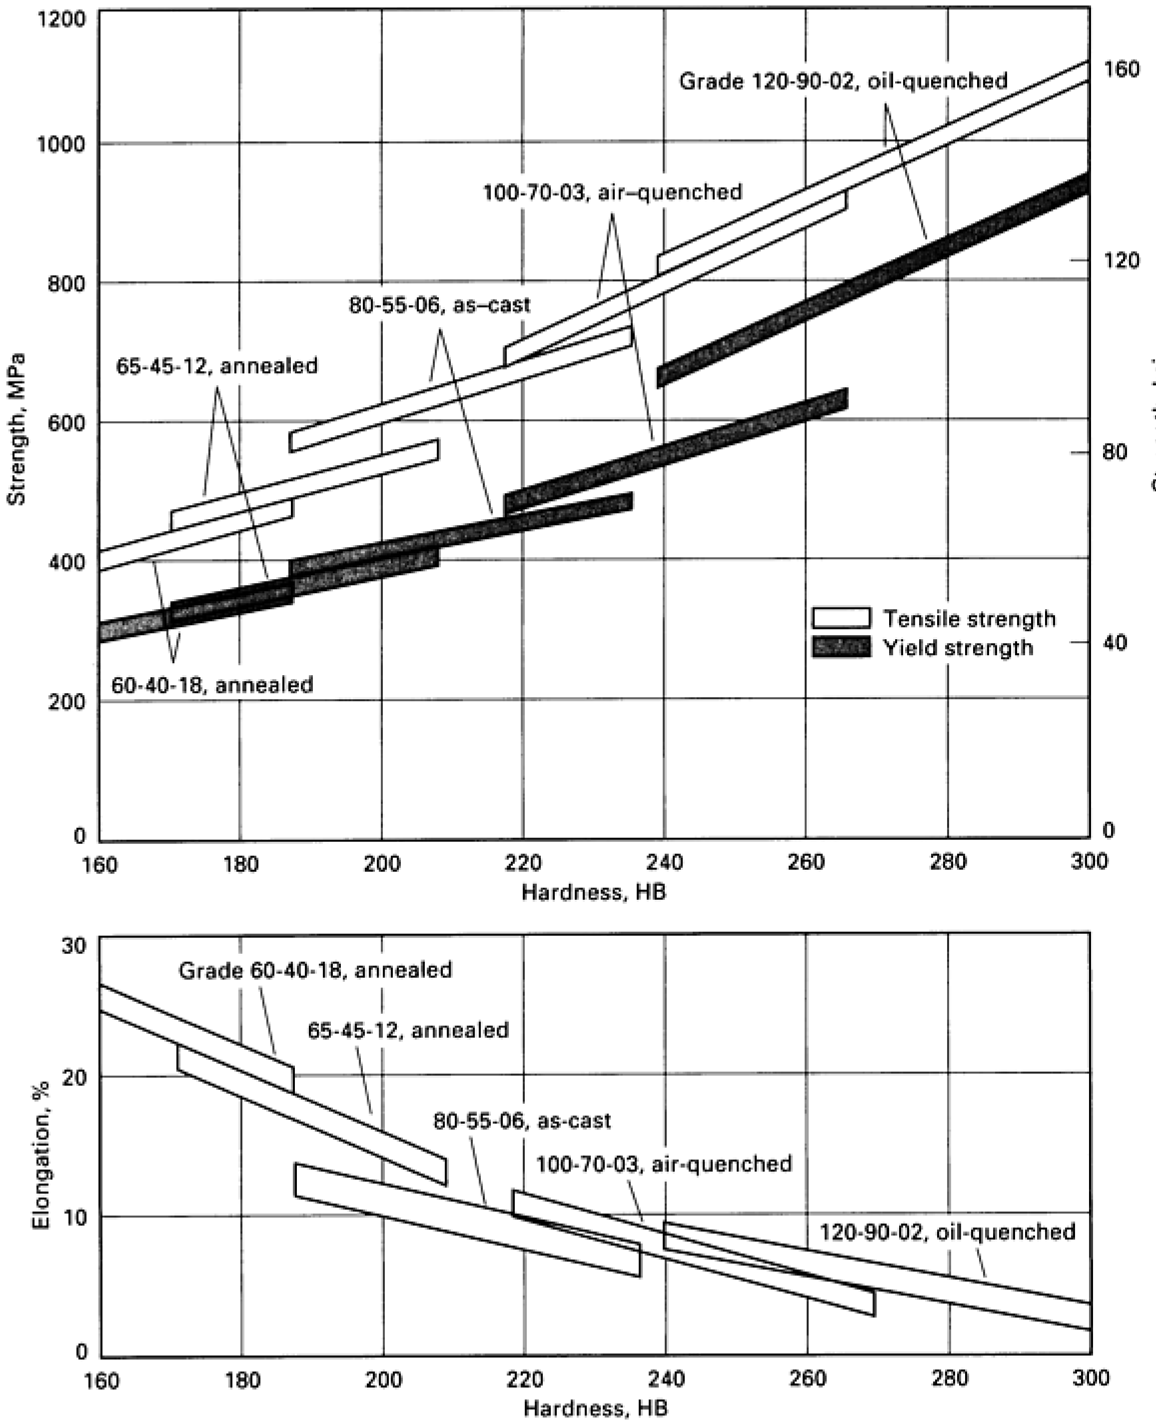

Fig. 5 Strength and ductility versus hardness for ductile iron

Austempered Ductile Iron. It is obvious from Fig. 4(b) and 4(c) that ADI is a unique cast iron material with tensile properties attributable to γ_H. with the fine dispersion of ferrite. As outlined above, austempering is accomplished by heating the casting to a temperature in the austenite-phase range (usually 815 to 925 °C, or 1500 to 1700 °F), holding for the time required to saturate the austenite with carbon, cooling to a temperature above the M_s temperature at a rate

sufficient to avoid the formation of pearlite or other mixed structures, and then holding at that austempering temperature for the time required to produce the optimum structure of acicular ferrite and carbon-enriched austenite.

The properties of ADI can be varied by changing the austempering temperature (see the section "Austempering Temperature and Time" in this article). A lower transformation temperature (260 °C, or 500 °F) produces a fine, high-strength, wear-resistant structure (Fig. 6a). A higher transformation temperature (370 °C, or 700 °F) results in a coarser structure (Fig. 6b) that exhibits high fatigue strength and good ductility. The various grades of ADI have been quantified in ASTM specifications A 897 and A 897M (Table 1).

Table 1 Hardness, toughness, and tensile properties at room temperature for austempered ductile iron grades specified in ASTM A 897 and A 897M (metric)

Grade	Minimum tensile strength		Minimum yield strength		Minimum elongation, %	Unnotched Charpy impact energy		Typical hardness, HB
	MPa	ksi	MPa	ksi		J	ft · lbf	
1	850	125	550	80	10	100	75	269-321
2	1050	150	700	100	7	80	60	302-363
3	1200	175	850	125	4	60	45	341-444
4	1400	200	1100	155	1	35	25	388-477

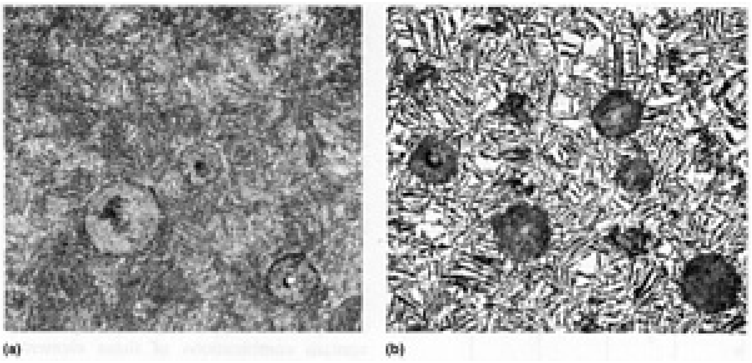

Fig. 6 Micrographs of ductile iron treated at different austempering temperatures. (a) Ductile iron austempered at 260 °C (500 °F) exhibits a fine acicular structure with the following properties: tensile strength, 1585 MPa (230 ksi); yield strength, 1380 MPa (200 ksi); elongation, 3%; unnotched impact, 54 J (40 ft · lbf); hardness, 475 HB. (b) Same iron as in (a) austempered at 370 °C (700 °F) exhibits a coarse acicular structure with the following properties: tensile strength, 1035 MPa (150 ksi); yield strength, 825 MPa (120 ksi); elongation, 11%; unnotched impact, 130 J (95 ft · lbf); hardness, 321 HB. Austenitizing Ductile Cast Iron

The usual objective of austenitizing is to produce an austenitic matrix with as uniform a carbon content as possible prior to thermal processing. Figure 7 is the 2% Si section of the iron-carbon-silicon phase diagram. For a typical hypereutectic ductile cast iron, an upper critical temperature must be exceeded so that the austenitizing temperature is in the two-phase (austenite and graphite) field. This temperature varies with alloy content. It is also clear from Fig. 7 that the "equilibrium" austenite carbon content in equilibrium with graphite increases with an increase in austenitizing temperature. This ability to select (within limits) the matrix austenite carbon content makes austenitizing temperature control important in processes that depend on carbon in the matrix to drive a reaction. This is particularly true in structures to be austempered, in which the hardenability (or austemperability) depends to a significant degree on matrix carbon content. In general, alloy content, the original microstructure, and the section size determine the time required for austenitizing. The sections to follow on annealing, normalizing, quenching and tempering, and austempering discuss austenitizing when it is of concern.

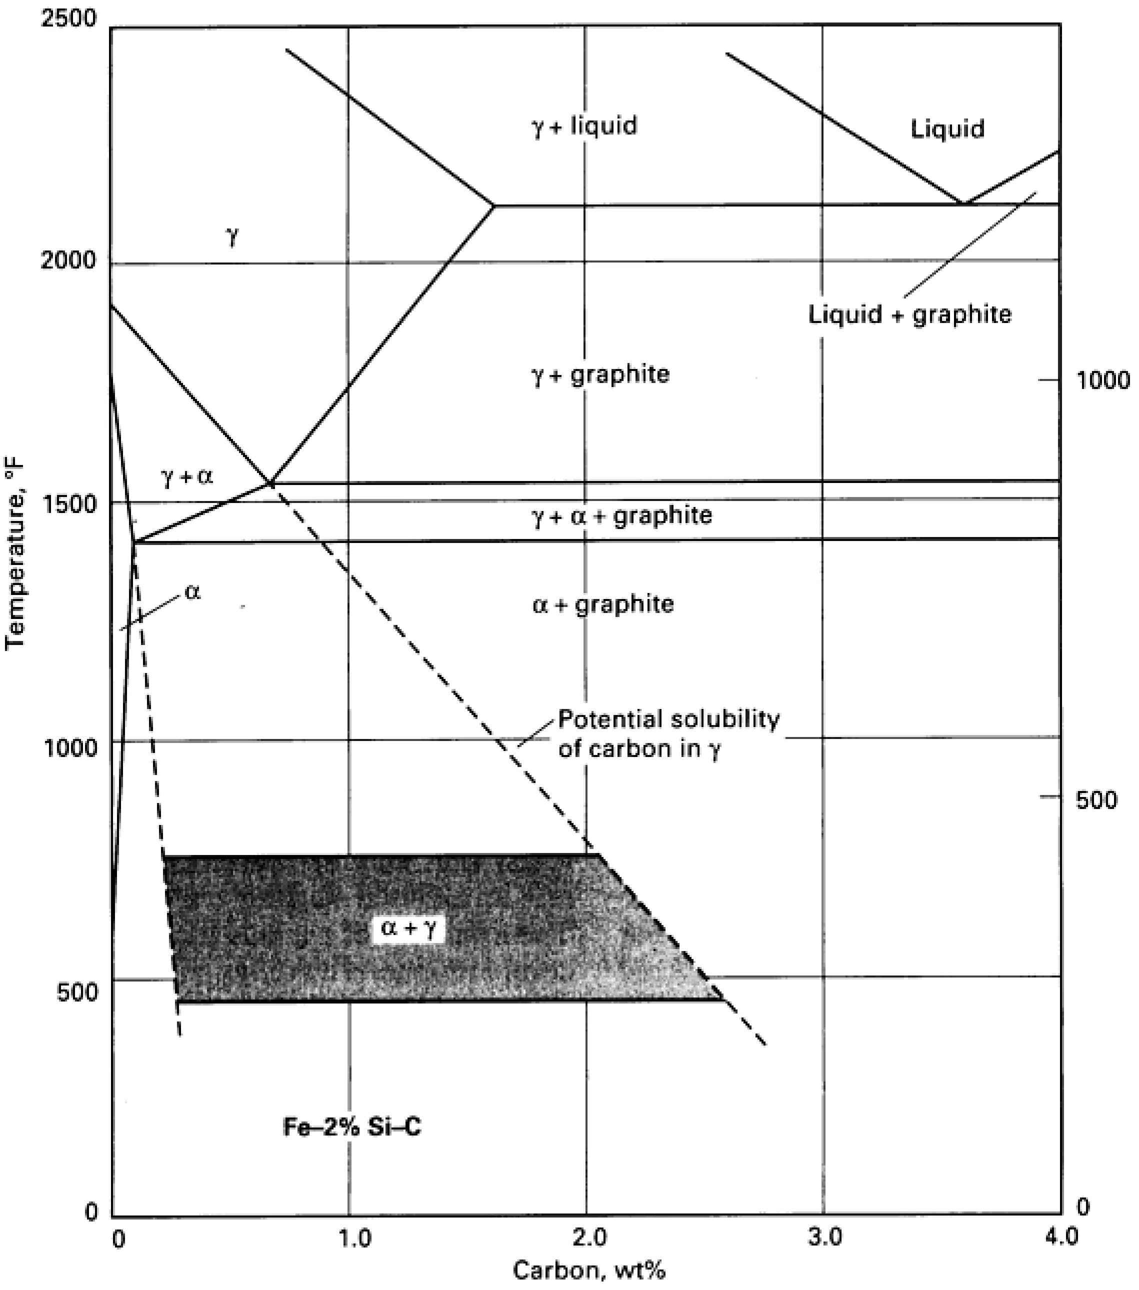

Fig. 7 Section of the Fe-C-2% Si equilibrium phase diagram showing a metastable projection of the α +γ two-phase field into the bainitic transformation temperature range

Annealing Ductile Iron

When maximum ductility and good machinability are desired and high strength is not required, ductile iron castings are generally given a full ferritizing anneal. The microstructure is thus converted to ferrite, and the excess carbon is deposited on the existing nodules (Fig. 3a). This treatment produces ASTM grade 60-40-18. Amounts of manganese, phosphorus, and alloying elements such as chromium and molybdenum should be as low as possible if superior machinability is desired because these elements retard the annealing process.

Recommended practice for annealing ductile iron castings is given below for different alloy contents and for castings with and without eutectic carbides (Ref 5):

- *Full anneal for unalloyed 2 to 3% Si iron with no eutectic carbide:* Heat and hold at 870 to 900 °C (1600 to 1650 °F) for 1 h per inch of section. Furnace cool at 55 °C/h (100 °F/h) to 345 °C (650 °F). Air

cool

- *Full anneal with carbides present:* Heat and hold at 900 to 925 °C (1650 to 1700 °F) for 2 h minimum, longer for heavier sections. Furnace cool at 110 °C/h (200 °F/h) to 700 °C (1300 °F). Hold 2 h at 700 °C (1300 °F). Furnace cool at 55 °C/h (100 °F/h) to 345 °C (650 °F). Air cool
- *Subcritical anneal to convert pearlite to ferrite:* Heat and hold at 705 to 720 °C (1300 to 1330 °F), 1 h per inch of section. Furnace cool at 55 °C/h (100 °F/h) to 345 °C (650 °F). Air cool. Figure 8 shows the influence of subcritical annealing at 705 °C (1300 °F) for various periods of time on the hardness of four ductile irons. When alloys are present, controlled cooling times through the critical temperature range down to 400 °C (750 °F) must be reduced to below 55 °C/h (100 °F/h)

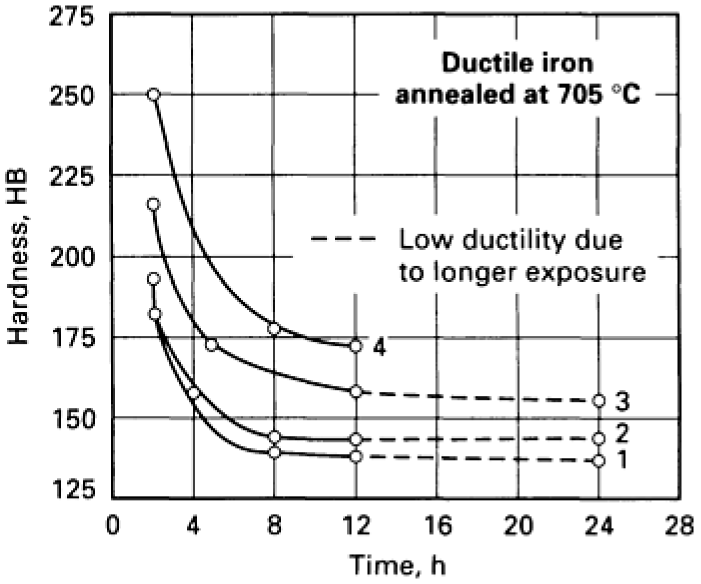

Fig. 8 Influence of time at subcritical annealing temperature on hardness

The effect of time at temperature on the decomposition of primary carbide (Fe_3C) for 6 mm ($\frac{1}{4}$ in.) plate castings is given in Fig. 9. It can be seen from Fig. 9 that these iron carbides break down quite readily; the time required at 900 °C (1650 °F) is approximately 2.5 h. However, certain carbide-forming elements, mainly chromium, form primary carbides that are very difficult, if not impossible, to decompose. For example, the presence of 0.25% Cr results in primary intercellular carbides that cannot be broken down in 2 to 20 h heat treatments at 925 °C (1700 °F). The resulting matrix after pearlite breakdown is carbides in ferrite with only 5% elongation. Other examples of carbide stabilizers are molybdenum contents greater than 0.3%, and vanadium and tungsten contents exceeding 0.05%.

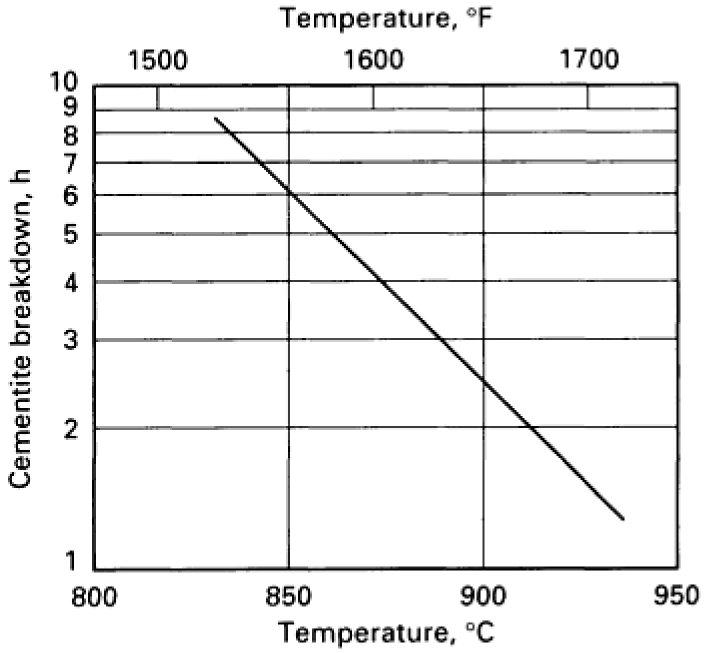

Fig. 9 Effect of time at temperature on decomposition of primary carbide (Fe_3C). Graph is based on an iron with a composition of 3.15% total carbon and 2.66% Si, which is outside the carbon-silicon range for commercial ductile iron.

Hardenability of Ductile Cast Iron

The hardenability of ductile cast iron is an important parameter for determining the response of a specific iron to normalizing, quenching and tempering, or austempering. Hardenability is normally measured by the Jominy test, in which a standard-sized bar (1 in. diam by 4 in. in length) is austenitized and water quenched from one end. The variation in cooling rate results in microstructural variations, giving hardness changes that are measured and recorded. Figure 10 shows Jominy curves from an unalloyed ductile iron (3.9% C, 2.2% Si, 0.04% Mg, and residual Mn, Ni, Cu, Cr, V, Ti) that has been austenitized at 870 and 925 °C (1600 and 1700 °F). The higher matrix carbon content resulting from the higher austenitizing temperature results in an increased hardenability (the Jominy curve is shifted to larger distances from the quenched end) and a greater maximum hardness. The purpose of adding alloy elements to ductile cast irons is to increase hardenability. Figure 11 shows Jominy curves for ductile irons containing variable quantities of manganese, molybdenum, nickel, and copper (Ref 7). It is clear from Fig. 11 that manganese and molybdenum are much more effective in increasing hardenability, per weight percent added, than nickel or copper. However, as is the case with steel, combinations of nickel and molybdenum, or copper and molybdenum, or copper, nickel, and manganese are more effective than the separate elements. The synergistic effects of nickel and molybdenum are shown in the Jominy curves in Fig. 12. Thus heavy-section castings that require through hardening or austempering usually contain combinations of these elements. Silicon, apart from its effect on matrix carbon content, does not have a large effect on hardenability.

Normalizing Ductile Iron

Normalizing (air cooling following austenitizing) can result in a considerable improvement in tensile strength and may be used in the production of ductile iron of ASTM type 100-70-03 (Fig. 5). The microstructure obtained by normalizing depends on the composition of the castings and the cooling rate. The composition of the casting dictates its hardenability, that is, the relative position of the fields in the time-temperature CCT diagram. The cooling rate depends on the mass of the casting, but it also may be influenced by the temperature and movement of the surrounding air during cooling. Normalizing generally produces a homogeneous structure of fine pearlite (Fig. 3b), if the iron is not too high in silicon content and has at least a moderate manganese content (0.3 to 0.5% or higher). Heavier castings that require normalizing usually contain alloying elements such as nickel, molybdenum, and additional manganese, for higher hardenability to ensure the development of a fully pearlitic structure after normalizing. Lighter castings made of alloyed iron may be martensitic or may contain an acicular structure after normalizing. The influence of various nickel contents and combinations of alloying elements on hardnesses after normalizing different section thicknesses is shown in Fig. 13.

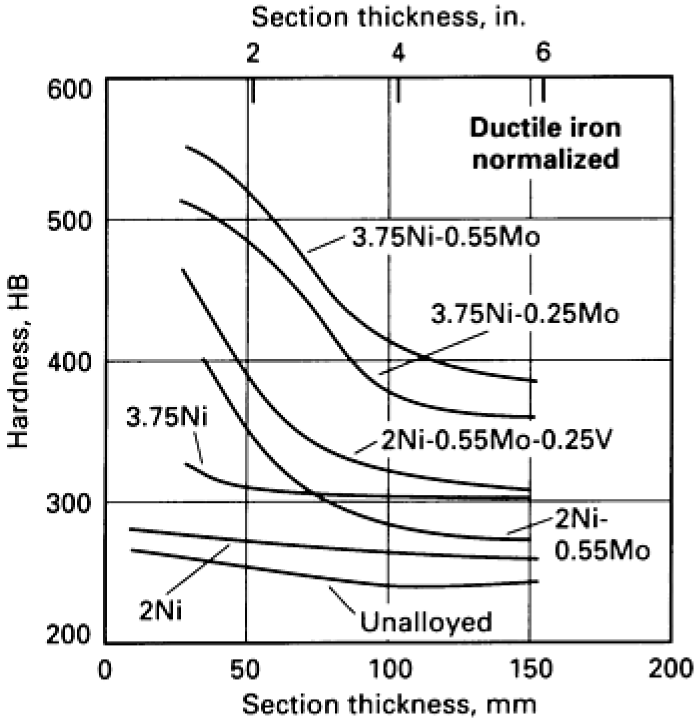

Fig. 13 Effect of alloy content and section thickness on hardness after normalizing

The normalizing temperature is usually between 870 and 940 °C (1600 and 1725 °F). The standard time at temperature of 1 h per inch of section thickness or 1 h minimum is usually satisfactory. Longer times may be required for alloys containing elements that retard carbon diffusion in the austenite. For example, tin and antimony segregate to the nodules, effectively preventing the solution of carbon from the nodule sites (Ref 8).

Normalizing is sometimes followed by tempering to attain the desired hardness and relieve residual stresses that develop upon air cooling when various parts of a casting with different section sizes cool at different rates. Tempering after normalizing is also used to obtain high toughness and impact resistance. The effect of tempering on hardness and tensile properties depends on the composition of the iron and the hardness level obtained in normalizing. Tempering usually consists of reheating to temperatures of 425 to 650 °C (800 to 1200 °F) and holding at the desired temperature for 1 h per

inch of cross section. These temperatures are varied within the above range to meet specification limits. Figure 14 shows the effect of tempering temperature on the hardness of normalized ductile iron.

Quenching and Tempering Ductile Iron

An austenitizing temperature of 845 to 925 °C (1550 to 1700 °F) is normally used for austenitizing commercial castings prior to quenching and tempering. Oil is preferred as a quenching medium to minimize stresses and quench cracking, but water or brine may be used for simple shapes. Complicated castings may have to be oil quenched at 80 to 100 °C (180 to 210 °F) to avoid cracks.

The influence of the austenitizing temperature on the hardness of water-quenched 13 mm ($\frac{1}{2}$ in.) cubes of ductile iron is shown in Fig. 15. These data show that the highest range of hardness (55 to 57 HRC) was obtained with austenitizing temperatures between 845 and 870 °C (1550 and 1600 °F). At temperatures above 870 °C (1600 °F), the higher matrix carbon content resulted in a greater percentage of retained austenite and therefore a lower hardness.

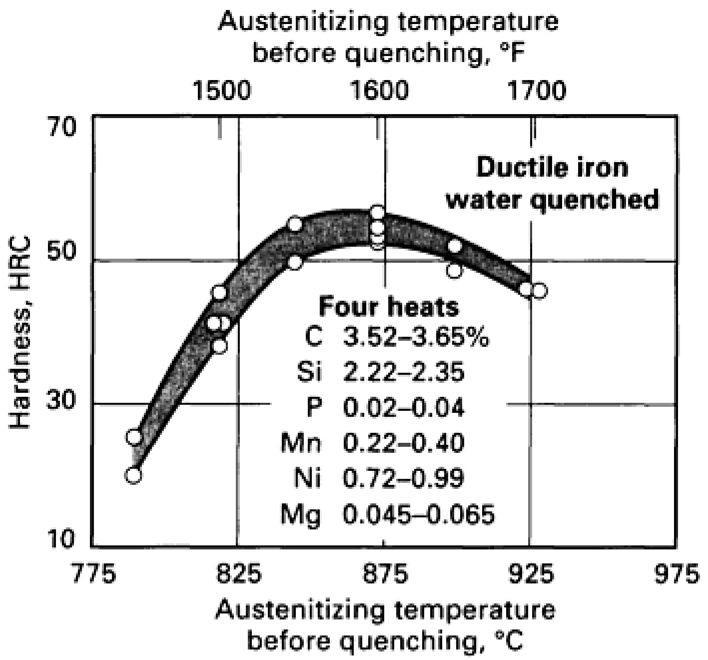

Fig. 15 Influence of austenitizing temperature on hardness of ductile iron. Each value represents the average of three hardness readings. Specimens (13 mm, or $\frac{1}{2}$ in., cubes) were heated in air for 1 h and water quenched.

Castings should be tempered immediately after quenching to relieve quenching stresses. Tempered hardness depends on asquenched hardness level, alloy content, and tempering temperature, as well as time. Tempering in the range from 425 to 600 °C (800 to 1100 °F) results in a decrease in hardness, the magnitude of which depends upon alloy content, initial hardness, and time. Figure 16 shows the change in the Vickers hardness of two quenched ductile iron alloys with tempering temperature and time (Ref 9). Tempering ductile iron in this temperature range is a two-stage process. The first involves the precipitation of carbides similar to the process in steels. The second stage (shown in Fig. 16 by the drop in hardness at longer times) involves nucleation and the growth of small, secondary graphite nodules at the expense of the carbides. The drop in hardness accompanying secondary graphitization produces a corresponding reduction in tensile and fatigue strength as well. Because alloy content affects the rate of secondary graphitization, each alloy will have a unique range of useful tempering temperatures. The influence of tempering temperature between 425 and 700 °C (800 and 1300 °F) for tensile and hardness specimens tempered for 2 h is shown in Fig. 17.

Austempering Ductile Iron

When optimum strength and ductility are required, the heat treater has the opportunity to produce an austempered structure of austenite and ferrite. As shown previously in Fig. 4, the austempered matrix is responsible for a significantly better tensile strength-to-ductility ratio than is possible with any other grade of ductile cast iron. The production of these desirable properties requires careful attention to section size and the time-temperature exposure during austenitizing and austempering.

Section Size and Alloying. As section size increases, the rate of temperature change between the austenitizing temperature and austempering temperature decreases. Quenching and austempering techniques include the hot-oil quench (≤240 °C, or 460 °F, only); nitrate/nitrite salt quenches; fluidizedbed method (for thin, small parts only); and, in tool-type applications, lead baths.

In order to avoid high-temperature reaction products (such as pearlite in larger section sizes), salt bath quench severities can be increased with water additions (Ref 10) or with alloying elements (such as copper, nickel, manganese, or molybdenum) that enhance pearlite hardenability (Ref 3). It is important to understand that these alloying elements tend to segregate during solidification so that a nonuniform distribution exists throughout the matrix. This has a potentially detrimental effect on the austempering reaction and therefore on mechanical properties. Ductility and impact toughness are the most severely affected.

Manganese and molybdenum have the most powerful effect upon pearlite hardenability but will also segregate and freeze into intercellular regions of the casting to promote iron or alloy carbides. While nickel and copper do not affect hardenability nearly as much, they segregate to graphite nodule sites and do not form detrimental carbides. Combinations of these elements, which segregate in opposite fashions, are selected for their synergistic effect on hardenability.

Austenitizing Temperature and Time. The schematic phase diagram of Fig. 7 shows that as austenitizing temperature increases, so does the matrix carbon content; the actual matrix carbon content depends in a complex way on the alloy elements present, their amount, and their location (segregation) within the matrix.

The most important determinant of matrix carbon content in ductile irons is the silicon content; as silicon content increases for a given austenitizing temperature, the carbon content in the matrix decreases. Austenitizing temperatures between 845 and 925 °C (1550 and 1700 °F) are normal, and austenitizing times of approximately 2 h have been shown to be sufficient to recarburize the matrix fully. Figure 10 shows that the austenitizing temperature, through its effect upon matrix carbon, has a significant effect on hardenability. The higher austenitizing temperature with its higher carbon content promotes increased hardenability, which causes a slower rate of isothermal austenite transformation. This reduced rate of austenite reaction to all transformation products is shown in the beginning portions of the IT diagrams in Fig. 18.

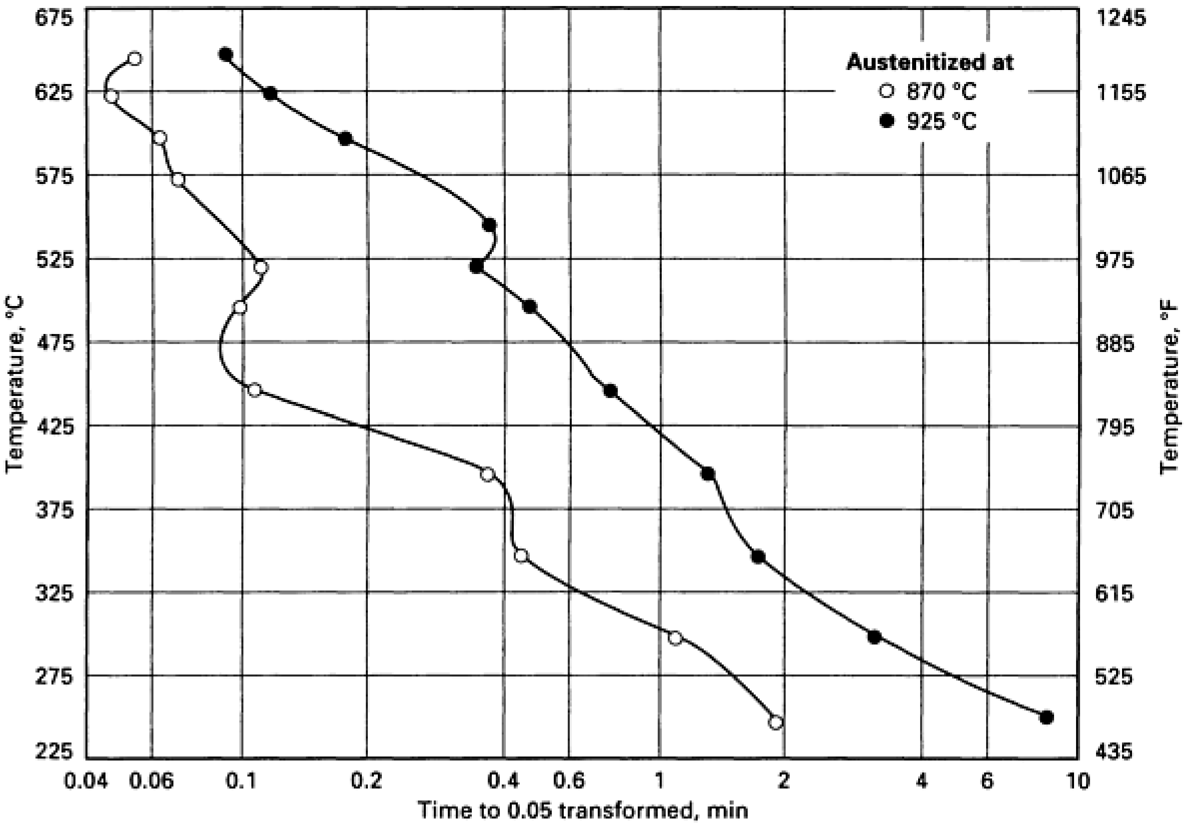

Fig. 18 Time to 5% transformed for a low-alloy ductile iron austenitized at 870 and 925 °C (1600 and 1700 °F). Source: Ref 6

Austempering Temperature and Time. The austempering temperature is the primary determinant of the final microstructure and therefore the hardness and strength of the austempered product. As the austempering temperature increases, the strength and impact toughness vary as shown in Fig. 19 for irons with two levels of manganese. The attainment of maximum ductility at any given austempering temperature is a sensitive function of time, as shown in Fig. 20 for a number of ductile cast iron alloys (Ref 12). The initial increase in elongation occurs as stage I (Fig. 2) and elongation progresses to completion, at which point the fraction of austenite is a maximum. Further austempering merely serves to reduce ductility as the stage II reaction causes decomposition to the equilibrium bainite product. Typical austempering times vary from 1 to 4 h. Micrographs of ASTM ADI grades 5 and 2 (Table 1) are shown in Fig. 6(a) and 6(b), respectively.

Surface Hardening of Ductile Iron

Ductile iron responds readily to surface hardening by flame, induction, or laser heating. Because of the short heating cycle in these processes, the pearlitic types of ductile iron ASTM 80-60-03 and 100-70-03 are preferred. Irons without free ferrite in their microstructure respond almost instantly to flame or induction heating and require very little holding time at the austenitizing temperature in order to be fully hardened.

With a moderate amount of free ferrite, the response may be satisfactory, but an entirely ferritic matrix, typical of the grades with high ductility, requires several minutes at 870 °C (1600 °F) to be fully hardened by subsequent cooling. A

matrix microstructure of fine pearlite, readily obtained by normalizing, has a rapid response to surface hardening and provides excellent core support for the hardened case.

With proper technique and the control of temperature between 845 and 900 °C (1550 and 1650 °F), the ranges of surface hardness for ductile iron with different matrices expected in commercial production are:

- Ductile iron, fully annealed (ferritic), water quenched behind the flame or induction coil, 35 to 45 HRC
- Ductile iron, predominantly ferritic (partly pearlitic), stress relieved prior to heating, self quenched, 40 to 45 HRC
- Ductile iron, predominantly ferritic (partly pearlitic), stress relieved prior to heating, water quenched, 50 to 55 HRC
- Ductile iron, mostly pearlitic, stress relieved before heating, water quenched, 58 to 62 HRC

Heating time and temperature, amount of dissolved carbon, section size, and rate of quench help to determine final hardness values. Often soluble-oil or polymer quench media are used to minimize quench cracking where the casting section changes.

Flame or induction-hardened ductile iron castings have been used for heavy-duty applications such as foils for cold working titanium, ring gears for paper-mill drives, crankshafts, and large sprockets for chain drives. Induction hardening is discussed below; flame hardening is discussed in a separate so-named article in this Volume.

The response of ductile iron to induction hardening is dependent on the amount of pearlite in the matrix of as-cast, normalized, and normalized and tempered prior structures (Ref 13). In quenched and tempered iron, the secondary graphite nodules formed during tempering are close enough together to supply sufficient carbon to the matrix by re-solution during induction heating.

In the as-cast condition, a minimum of 50% pearlite is considered necessary for satisfactory hardening with induction heating cycles of 3.5 s and longer and hardening temperatures of 955 to 980 °C (1750 to 1800 °F). Structures containing less pearlite can be hardened by using higher temperatures, but at the risk of retaining austenite, forming ledeburite, and damaging the surface. With more than 50% pearlite, hardening temperatures may be reduced to within the range of 900 to 925 °C (1650 to 1700 °F).

In the Normalized Condition. For heating cycles of 3.5 s and longer, at temperatures of 955 to 980 °C (1750 to 1800 °F), 50% pearlite in a prior structure would be considered a minimum. Normalized and tempered irons exhibit a poor response with lower pearlite content because of the depletion of the matrix carbon. In the tempering operation, the carbon migrates from the pearlite matrix to the graphite nodules. In the heating cycle, carbon is reabsorbed in the matrix from the nodule; however, there is insufficient time for it to migrate throughout the ferritic areas. Another factor in the response of ductile iron is the graphite nodule count; the greater the number of nodules per unit area, the deeper the hardening for any given heat cycle. This effect is more evident as the percentage of ferrite increases (Fig. 21).

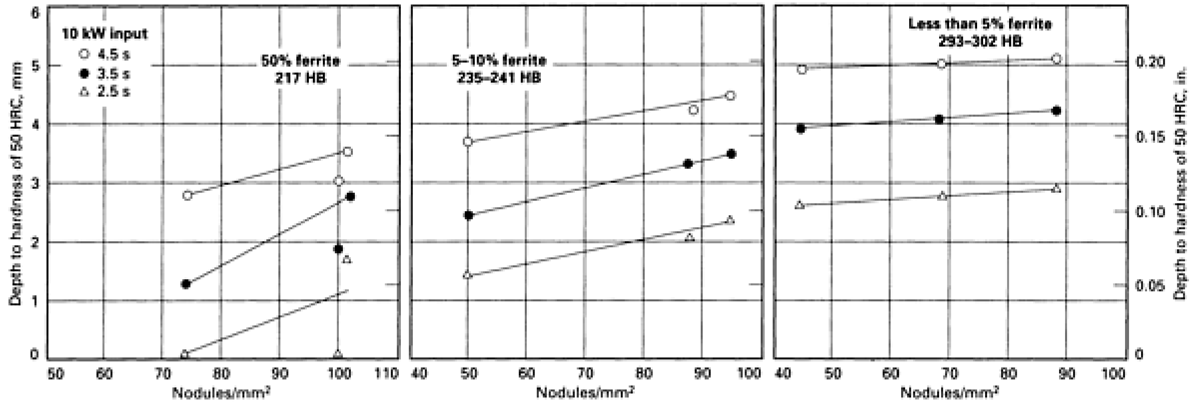

Fig. 21 Relationship between depth of induction hardening to 50 HRC and graphite nodule count in normalized

and tempered ductile (nodular) iron

Quenched and Tempered. The response of quenched and tempered nodular iron to induction hardening is excellent over a wide range of microstructures containing up to 95% ferrite. As a prior treatment, quenching and tempering has the advantage of permitting a lower prior hardness; there is a risk of distortion and quench cracking, however.

Example 1: Response of a Quenched and Tempered Ductile Iron to Induction Surface Hardening.

A quenched and tempered structure that provided good response to induction hardening was obtained by oil quenching from 900 °C (1650 °F) and tempering at 620 °C (1150 °F) for 1 h. This treatment produced a hardness of 262 HB, which could have been lowered, if necessary, by increasing the tempering temperature to 675 °C (1250 °F). By induction heating to a depth of 4.7 mm (0.184 in.), a surface hardness of 54 to 56 HRC was developed, and a depth of hardness to 50 HRC of 4.2 mm (0.164 in.) was obtained.

Nitriding is a case-hardening process that involves the diffusion of nitrogen into the surface at a temperature of about 550 to 600 °C (1020 to 1110 °F). Usually the source of nitrogen is ammonia, and the process produces a surface layer about 0.1 mm (0.004 in.) deep with a surface hardness approaching 1100 HV. The surface layer is typically white and featureless in an etched microstructure, but nitride needles can be found just below it. Alloying elements can be used to increase case hardness, and 0.5 to 1% Al, Ni, and Mo have been reported to achieve useful results. Nitrided cases provide, in addition to very high hardness, increased wear resistance and antiscuffing properties, improved fatigue life, and improved corrosion resistance. Typical applications are for cylinder liners, bearing pins, and small shafts.

Nitriding can also be carried out in liquid salt baths based on cyanide salts. Such processes have lower temperatures of treatment, although case depth may be decreased. More recently, processes for nitriding in a plasma have been developed and applied with success to ductile iron, but the process may be more restricted because of the special equipment and cost likely to be involved.

Remelt Hardening. With the very high local heating achievable with plasma torches or lasers, it is possible to produce a very small melted area on the surface of a ductile iron component. This area then rapidly resolidifies because of the self-quenching effect of the casting mass. The remelted and resolidified region has a structure of white iron that is substantially graphite free and therefore has high hardness and wear resistance. The area that is remelted by a 2 kW laser is very small, typically 1.5 mm (0.06 in.) in diameter and 0.5 to 2 mm (0.02 to 0.08 in.) in depth, and having a hardness of about 900 HV without cracking. By traversing the casting surface, the area hardened by this method can be of useful size and is likely to find application in tappets, cams, and other small components subjected to sliding wear. Figure 22 shows the microstructure of a pearlitic iron traversed by a 1.5 kW laser at 456 mm/s (18.25 in./s).

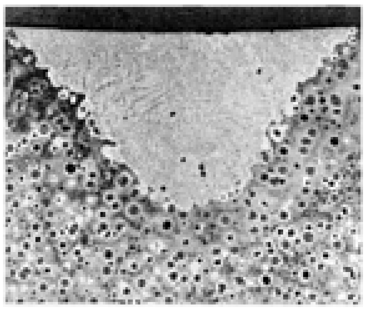

Fig. 22 Remelt-hardened and transition zones in a pearlitic iron after treatment with a 1.6 kW, 1.5 mm (0.06 in.) diam laser beam of 4.56 mm/s (0.18 in./s). Etched in picral. 50×

Stress Relieving of Ductile Iron

When not otherwise heat treated, complex engineering castings of ductile iron may be stress relieved at 510 to 675 °C (950 to 1250 °F). Temperatures at the lower end of this range are satisfactory for many applications; temperatures at the higher end will eliminate virtually all residual stress (Fig. 23) but will also effect some reduction in hardness and tensile strength. Recommended ranges of stress-relieving temperature for various types of ductile iron are as follows:

- *Unalloyed:* 510 to 565 °C (950 to 1050 °F)
- *Low-alloy:* 565 to 595 °C (1050 to 1100 °F)
- *High-alloy:* 595 to 650 °C (1100 to 1200 °F)
- *Austenitic:* 620 to 675 °C (1150 to 1250 °F)

The required time at temperature will depend on the temperature used, the complexity of the casting, and the completeness of stress relief desired (Fig. 22), but 1 h plus 1 h per inch of section thickness is recommended general practice.

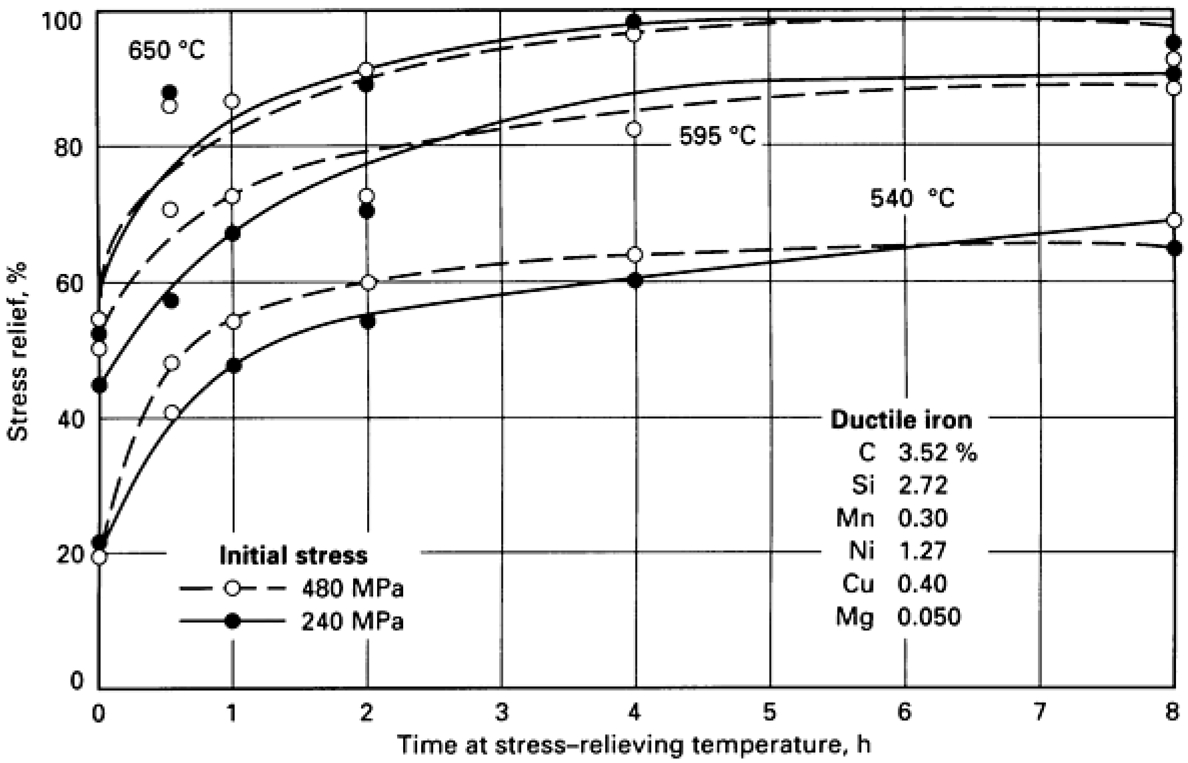

Fig. 23 Stress relief obtained in ductile iron held at three temperatures for $\frac{1}{2}$ to 8 h. Initial hardness was 102 to 103 HRB. Hardness after holding at 540, 595, and 650 °C (1000, 1100, and 1200 °F) for 8 h was 102 to 104, 101 to 103, and 90 to 93 HRB.

Cooling should be uniform to avoid reintroducing stresses. Castings should be furnace cooled to 290 °C (550 °F), after which they can be air cooled. In most instances, however, austenitic iron can be uniformly air cooled from the stress-relieving temperature.

Effect of Heat Treatment on Fatigue Strength

In heat treating to improve fatigue properties, the proper composition and temperature must be selected to ensure the greatest improvement, and it is essential to have an optimum-quality cast microstructure (that is, high nodule count, excellent nodularity, and freedom from defects). For example, one cause of low fatigue strength in quenched and tempered ductile irons results from the precipitation of secondary graphite throughout the matrix upon tempering. The softening that accompanies this event results in reduced fatigue strength as well (see rapid hardness decrease in Fig. 16). The amount of secondary graphite can be controlled by composition (primarily carbon and silicon) and tempering temperature (the incidence of secondary graphite increases with temperature). Naturally as the amount of carbon increases so will the quantity of secondary graphite. An increased silicon content will increase the rate of secondary graphitization (Ref 9).

The fatigue properties of as-cast ductile irons can be improved significantly by heat treatment, but not in the same proportion as can the static tensile properties. Fatigue strength at 20×10^6 cycles (rotary bending) has been shown to increase with matrix hardness as a result of heat treatment (Ref 14), with fatigue strengths ranging from 170 to 200 MPa (25 to 30 ksi) in annealed irons and from 310 to 345 MPa (45 to 50 ksi) in austempered or quenched and tempered irons. Recently rotary bending fatigue strengths (at 20×10^6 cycles) in austempered irons of approximately 480 MPa (70 ksi) have been reported (Ref 15), and fatigue strengths on the order of 690 MPa (100 ksi) can be attained with rolling or peening after austempering. Of course, fatigue strength will be optimal when the matrix structure is homogeneous throughout and no defects are present. The nature of ductile cast iron is such that there are many microstructural sources that can reduce fatigue strength; these include increasing nodule size, microporosity, eutectic carbides in intercellular regions, and slag or other inclusions. All of these problems tend to be exaggerated in heavy-section castings.

Introduction

FERRITIC AND PEARLITIC malleable irons are both produced by annealing white iron of controlled composition. Thus, annealing is an essential part of the manufacturing process for these irons and, as such, is discussed in detail in the article entitled "Malleable Iron" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook*

Malleable irons have largely been replaced by ductile iron in many applications. This is due in part to the necessity of lengthy heat treatments for malleable iron and the difficulty in cooling thick sections rapidly enough to produce white iron. Malleable iron is still often preferred for thin-section castings and parts that require maximum machinability and wear resistance. Figure 1 compares mechanical strengths of nodular and malleable irons.

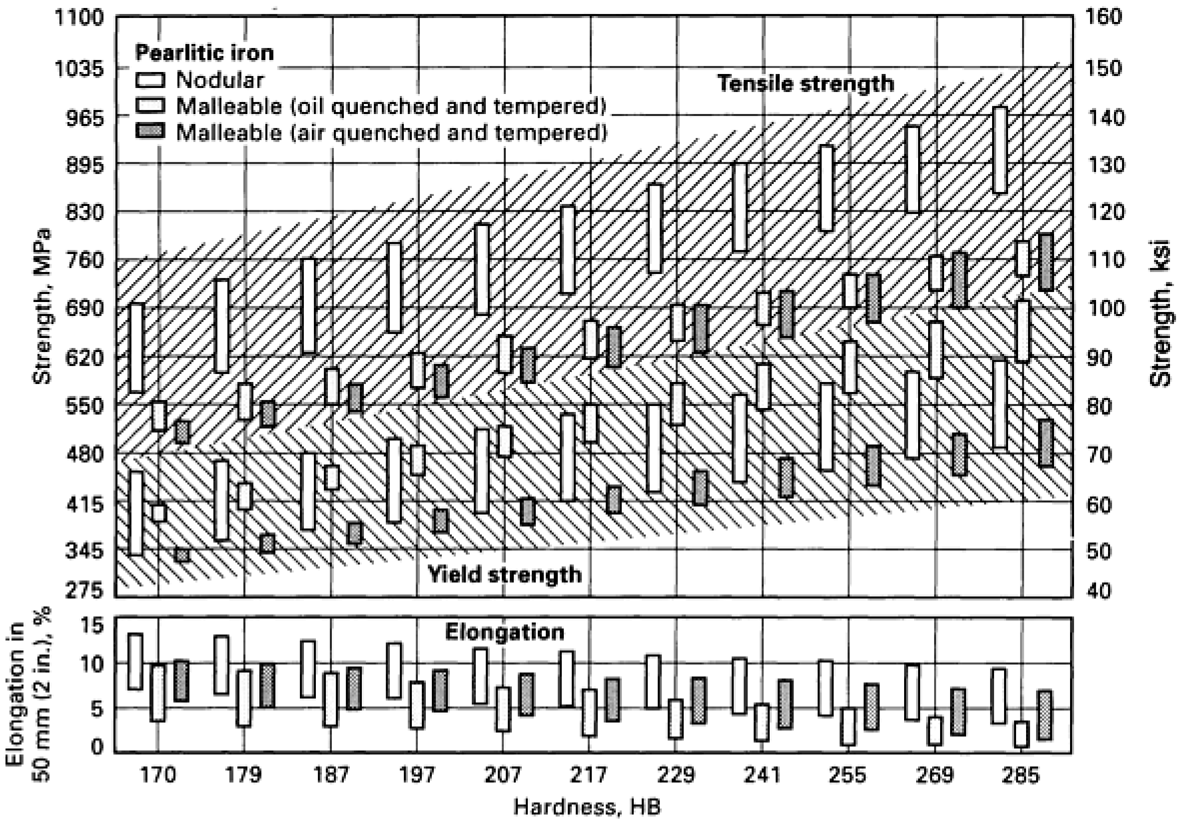

Fig. 1 Tensile properties versus hardness of pearlitic nodular and malleable iron

The annealing of malleable iron should be done in a furnace with a controlled atmosphere of dry nitrogen, hydrogen (1.5%), and carbon monoxide (1.5%). The dew point of this mixture should be between -40 and-7 °C (-40 and -20 °F). These conditions eliminate the possibility of decarburization and loss of temper carbon nodules below the casting surface.

The annealing treatment involves three important steps. The first causes nucleation of temper carbon. It is initiated during heating to a high holding temperature and occurs very early during the holding period.

The second step consists of holding at 900 to 970 °C (1650 to 1780 °F); this step is called first-stage graphitization (FSG). During FSG, massive carbides are eliminated from the iron structure. Long holding periods at 955 °C (1750 °F) will reduce the solubility of nitrogen in iron (which should be kept at 80 to 120 ppm), thereby reducing the mechanical properties of the iron. This occurrence should be kept in mind for long, or "weekend," holding periods. When the carbides are eliminated, the iron is rapidly cooled to 740 °C (1365 °F) prior to entering second-stage graphitization.

The third step in the annealing treatment consists of slow cooling through the allotropic transformation range of the iron; this step is called second-stage graphitization (SSG). During SSG, a completely ferritic matrix free of pearlite and carbides is obtained when the cooling rate is 2 to 28 °C/h (3 to 50 °F/h). Figure 2 shows a ferritic malleable iron. This cooling rate, which depends on the silicon content of the iron and the temper carbon nodule count, may be increased to 85 °C/min (150 °F/min) by air quenching from 900 °C (1650 °F) to form a pearlitic matrix. Oil quenching from 900 °C (1650 °F) will produce a martensitic matrix. However, unless the temperature in the furnace is lowered to 845 °C (1550 °F) for at least 4 h (plus 1 h for each 1 in. of section casting thickness), then raised to 900 °C (1650 °F) for 4 h (plus 1 h for each 1 in. of casting section thickness) prior to uniform quenching in oil, the matrix microstructure will not be uniform in combined carbon. This nonuniformity reduces machinability. If the hardness is reduced by extended tempering, the resulting structure may not have a good response to selective hardening.

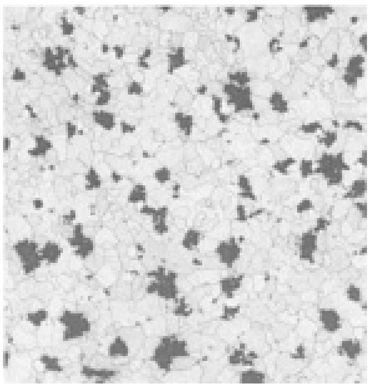

Fig. 2 Ferritic malleable iron etched in 2% nital. 750×

Hardening and Tempering of Malleable Iron

A typical procedure for producing a hardened pearlitic malleable iron consists of, first, air quenching castings after first-stage annealing, which results in retention of about 0.75% combined carbon in the matrix; second, reheating and holding for 1 h at 885 °C (1625 °F) to reaustenitize the matrix and homogenize the combined carbon; and then quenching in heated (50 to 55 °C, or 120 to 130 °F) and agitated oil, thereby developing a matrix consisting of martensite without bainite and having a hardness of 555 to 627 HB. Figure 3 shows the effects of austenitizing temperature and quenching medium on the hardness of ferritic and pearlitic malleable iron. The appropriate austenitizing temperature for pearlitic malleable iron is 885 °C (1625 °F), and for ferritic malleable iron it is 900 °C (1650 °F). If direct oil quenching is used, caution must be exercised to prevent cracking due to high combined carbon.

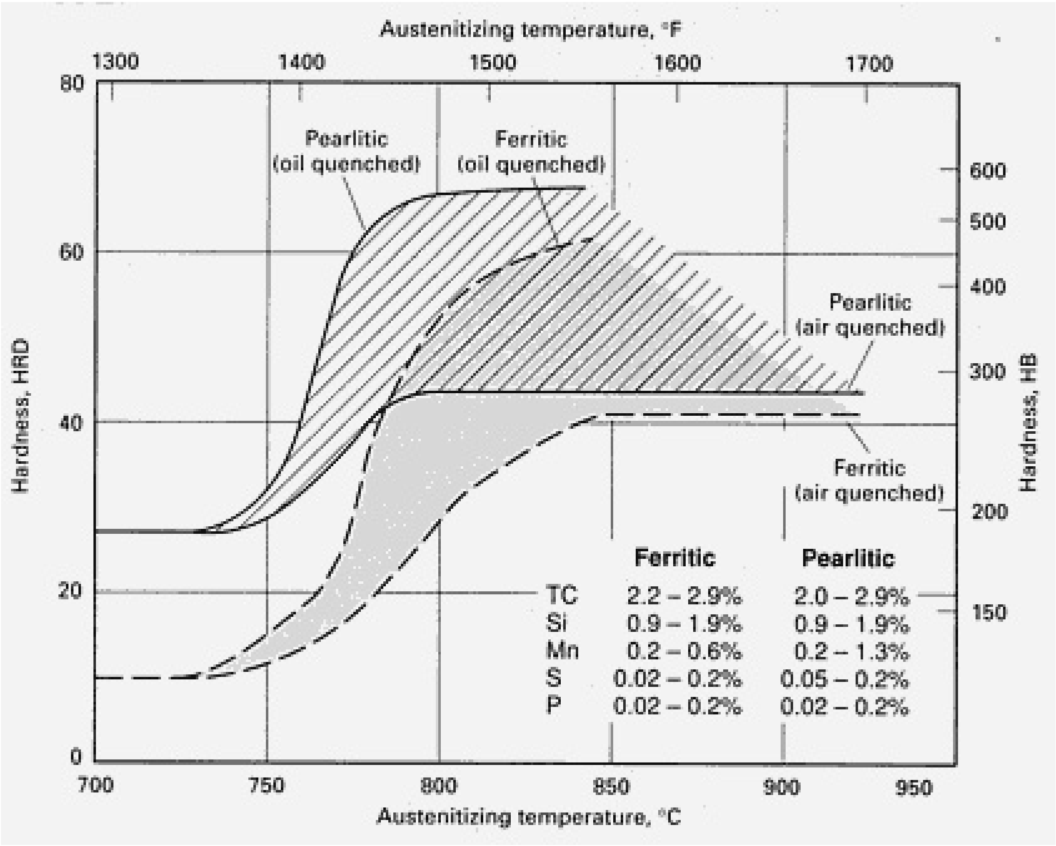

Fig. 3 Effects of austenitizing temperature and quenching medium on hardness of as-quenched malleable iron. The listed composition limits for ferritic and pearlitic malleable iron are general limits given in the *Iron Castings Handbook* (1981). In practice, manganese content is 0.2 to 0.45% Mn for the ferritic class and less than 0.6%

Mn for the pearlitic class.

Figure 4 shows the microstructures of pearlitic malleable iron with various heat treatments. Air-quenched and tempered pearlitic malleable iron has a matrix consisting of a ferrite ring around the tempered carbon (which produces a lower yield strength) and partially broken lamellar pearlite. The remaining lamellar pearlite reduces machinability to a limit of 241 HB. Oil-quenched and tempered pearlitic malleable iron has a matrix of tempered martensite that is totally spheroidizing combined carbon with no ferritic ring around the temper carbon. This produces a higher yield strength and can be machined up to a hardness of 321 HB.

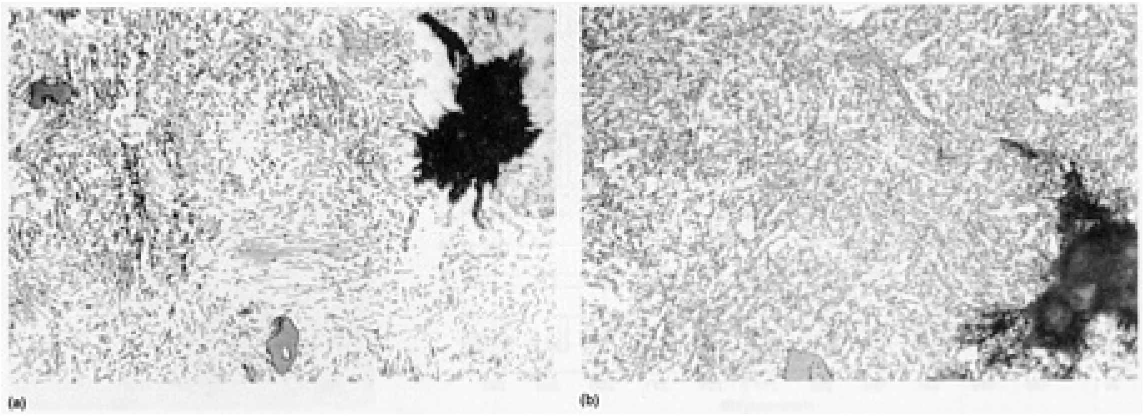

Fig. 4 Pearlitic malleable iron microstructures etched in 2% nital. (a) Arrested anneal (first-stage graphitization), air quenched, and tempered, 212 HB. 750×. (b) Arrested anneal (first-stage graphitization), air quenched, reheated, oil quenched, and tempered, 255 HB. 750×

Increasing the austenitizing time and temperature increases the amount of dissolved carbon, which is measured as combined carbon in the matrix after quenching to room temperature. Austenitizing temperatures in the range of 900 to 930 °C (1650 to 1700 °F) result in a more homogeneous austenite, which is desirable for a more uniform martensite. Higher temperatures can result in a greater tendency toward distortion or cracking. Temperature and time of tempering to attain a specified hardness may be selected from curves such as those shown in Fig. 5. Tempering of pearlite is time and temperature dependent. Tempering of martensite is primarily temperature dependent, with time being secondary.

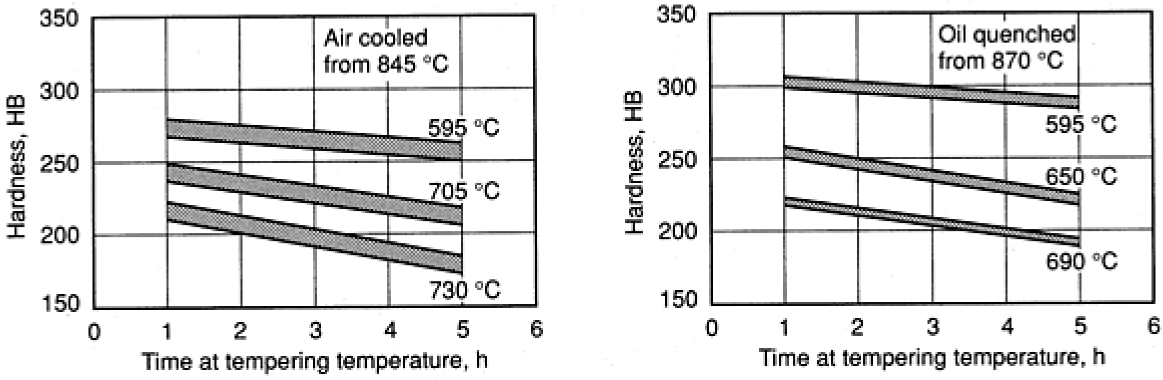

Fig. 5 Influence of time and tempering temperature on room-temperature hardness of pearlitic malleable iron. Composition: 2.35 to 2.45% C, 1.45 to 1.55% Si, 0.03% P, 0.06 to 0.15% S, 0.38 to 0.50% Mn, and less than 0.003% Cr

Hardened and tempered pearlitic malleable iron can also be produced from fully annealed ferritic malleable iron, the matrix of which is essentially carbon-free; graphite can be dissolved in austenite by holding at 900 to 930 °C (1650 to

1700 °F) for a time sufficiently long for the production of an austenite matrix of uniform carbon content. In general, the combined carbon content of the matrix produced by this procedure is slightly lower than that of a pearlitic malleable iron made by air quenching directly from 900 °C (1650 °F), and therefore the final tempering temperatures required for the development of specific hardnesses are lower (Fig. 6).

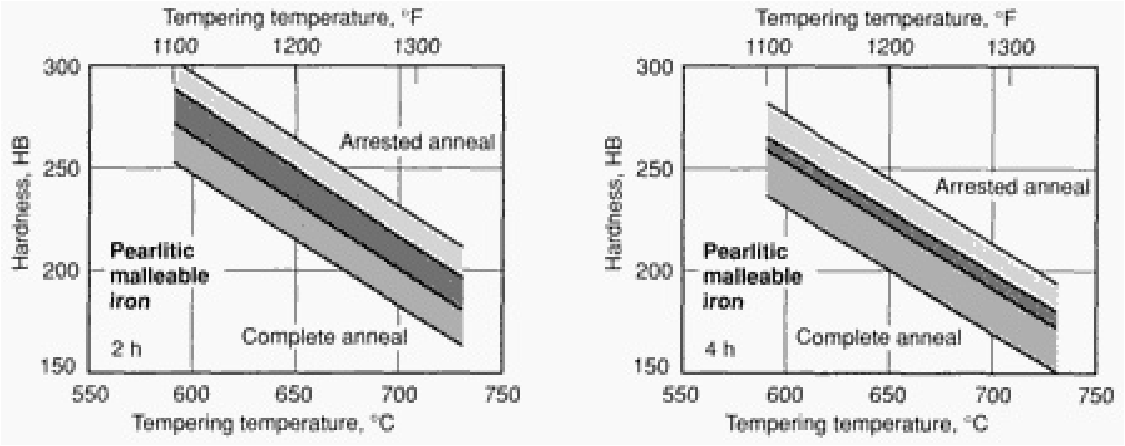

Fig. 6 Room-temperature hardness of tempered pearlitic malleable iron produced by arrested annealing and by complete-ferritize or ferritic annealing and rehardening

Tempering treatments consist of cycles of no less than 2 h at temperature to ensure uniformity of product. Tempering times must also be adjusted for section thickness and quenched microstructures. Fine pearlite and bainite require longer tempering times than that for martensite. In general, final hardness is controlled with process controls approximately the same as those encountered in the heat treatment of medium-carbon and higher-carbon steels. This is particularly true when the specification requires final hardnesses in the range from 241 to 321 HB.

Figure 7 shows the control of hardness attained by one foundry producing quenched and tempered sleeve yokes of grade 80002 pearlitic malleable iron. These yokes were heated at 870 °C (1600 °F) for 30 min, quenched in oil at 65 °C (150 °F), and tempered at 650 °C (1200 °F) for 2 h.

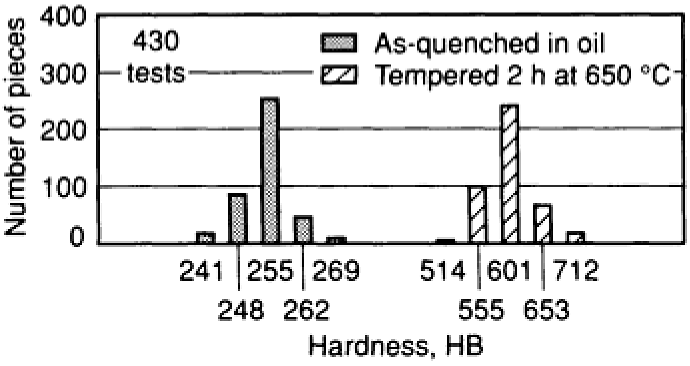

Fig. 7 Room-temperature hardness distribution for quenched and tempered pearlitic malleable iron sleeve yokes. Desired hardness range after tempering was 241 to 269 HB.

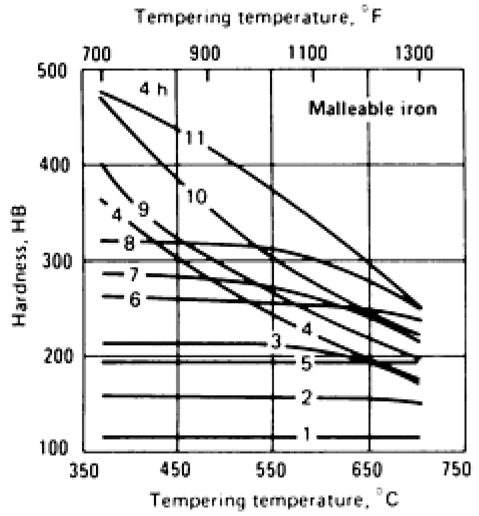
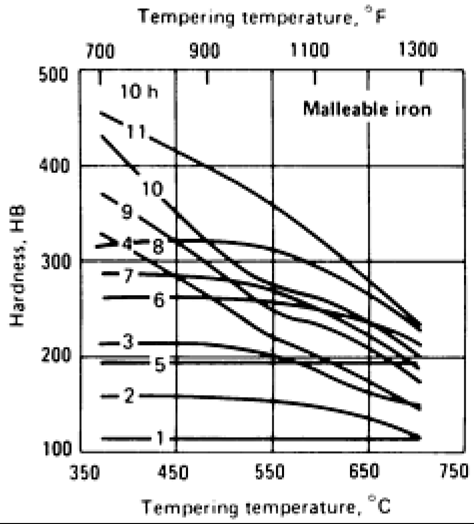
The effects of tempering on the hardness of alloyed and unalloyed malleable irons are shown in Table 1; these data illustrate the beneficial effects of alloying on asquenched hardness and stability at elevated temperatures. During all tempering treatments, carbide has a tendency to decompose, with resulting deposition of graphite on existing temper carbon nodules. This tendency is least at the lower tempering temperatures or in suitably alloyed pearlitic malleable irons.

Table 1 Effect of tempering temperature and time on the hardness of ferritic and pearlitic malleable irons in the as-received and reheated-and-quenched conditions





Iron	Material	Composition, %					Alloying and prior heat treatment	Hardness, HB
		TC	Si	S	Mn	Mo		
1	Standard (ferritic) grade 32510	2.40	1.80	0.072	0.30	. . .	Unalloyed; fully malleablized	116
2	Pearlitic malleable iron, grade 45007	2.40	1.80	0.072	0.30	. . .	Unalloyed; air quenched from 925 °C (1700 °F), tempered 8 h at 695 °C (1280 °F)	156
3	Pearlitic malleable iron, grade 60003	2.40	1.80	0.072	0.30	. . .	Unalloyed; oil quenched from 870 °C (1600 °F), tempered 3 h at 650 °C (1200 F)	212
4	Oil-quenched malleable iron	2.40	1.80	0.072	0.30	. . .	Unalloyed; oil quenched from 870 °C (1600 °F), not tempered	444
5	Pearlitic malleable iron, grade 45010	2.40	1.80	0.076	0.90	. . .	Alloyed (Mn); air quenched from 940 °C (1720 °F), tempered 34 h at 715 °C (1320 °F)	192
6	Pearlitic malleable iron, grade 80002	2.40	1.80	0.072	0.90	0.45	Alloyed (Mn and Mo); air quenched from 940 °C (1720 °F), tempered 12 h at 620 °C (1150 °F)	262
7	Air-quenched alloyed malleable iron	2.40	1.80	0.079	0.90	. . .	Alloyed (Mn); air quenched from 925 °C (1700 °F), not tempered	285
8	Air-quenched alloyed malleable iron	2.40	1.80	0.076	1.10	. . .	Alloyed (Mn); air quenched from 925 °C (1700 °F), not tempered	321
9	Oil-quenched alloyed malleable iron	2.40	1.80	0.079	0.90	. . .	Alloyed (Mn); oil quenched from 830 °C (1525 °F), not tempered	514
10	Oil-quenched alloyed	2.40	1.80	0.076	1.10	. . .	Alloyed (Mn); oil quenched from 830 °C (1525 °F),	578

	malleable iron						not tempered	
11	Air-quenched alloyed malleable iron	2.40	1.80	0.072	0.90	0.45	Alloyed (Mn and Mo); air quenched from 940 °C (1720 °F), not tempered	514

Martempering and tempering develops mechanical properties similar to those resulting from conventional oil quenching and tempering: typical tensile strength, 860 MPa (125 ksi); yield strength, 760 MPa (110 ksi); and hardness, 300 HB. Pearlitic malleable iron castings that are susceptible to cracking when quenched in warm oil (40 to 95 °C, or 100 to 200 °F) from the austenitizing temperature may be safely quenched in salt or oil at about 200 °C (400 °F). Elevator camshafts varying in length from 0.3 to 0.45 m (12 to 18 in.) and various sizes of wearchain components are examples of martempered pearlitic malleable iron.

Bainitic Heat Treatment of Pearlitic Malleable Iron

Both upper and lower bainite can be formed in pearlitic malleable iron with a marked increase in tensile strength and hardness but with a decrease in ductility. A pearlitic malleable iron (2.6C-1.4Si-0.5Mn-0.11S), annealed at 930 °C (1700 °F) for 16 h, air quenched, and tempered at 680 °C (1250 °F) for 4 h, developed an ultimate tensile strength of 650 MPa (94.2 ksi), a yield strength of 460 MPa (66.5 ksi), and a 3.4% elongation at 217 HB. This same iron austenitized at 900 °C (1650 °F) in molten salt for 1 h, quenched in molten salt at 295 °C (560 °F) for 3 h, and air cooled gave an ultimate strength of 995 MPa (144.2 ksi), a yield strength of 920 MPa (133.4 ksi), and a 1% elongation at 388 HB.

Surface Hardening of Pearlitic Malleable Iron

Fully pearlitic malleable iron may be surface hardened by either induction heating and quenching or flame heating and quenching. Laser and electron beam techniques also have been used for hardening selected areas on the surface of pearlitic and ferritic malleable iron castings that are free from decarburization. Generally, hardness in the range from 55 to 60 HRC is attainable, with the depth of penetration being controlled by the rate of heating and by the temperature developed at the surface of the part being hardened. In induction hardening, this is accomplished by the close regulation of power output, operating frequency, heating time, and alloy content of the iron.

The maximum hardness obtainable in the matrix of a properly hardened part is 67 HRC; however, conventional hardness measurements show less than the true matrix hardness because of the temper carbon nodules that are averaged into the hardness. Generally, a casting with a matrix micro-hardness of 67 HRC will have about 62 HRC average hardness, as measured with the standard Rockwell tester.

Rocker arms and clutch hubs are examples of automotive production parts that are surface hardened by induction. Flame hardening requires close control for these applications in order to avoid distortion that would interfere with their operation. The two examples that follow describe the successful application of induction and flame hardening to other production parts.

Example 1: Selective Hardening of Crimping Tool Jaws Made of Pearlitic Malleable Iron.

Grade 45010 pearlitic malleable iron was used for tools for crimping electrical connectors. The jaws of these tools as originally designed were inserts made of hardened tool steel. Shell mold casting these jaws and heat treating them to pearlitic malleable iron made it possible for the jaws to be cast integrally to the desired intricate contour and to be hardened by induction heating and water quenching in order to provide required wear resistance. Hardening was thus restricted to the jaws, and the strength and toughness inherent in grade 45010 were maintained in the arms of the handles.

Example 2: Flame Hardening of Malleable Iron Pinion Spacers.

Flame hardening has been used effectively on pearlitic malleable iron pinion spacers that support the cups of roller bearings. The ends of the pinion spacers were flame hardened to file hard (58 HRC or more) to a depth of about 2.4 mm ($\frac{3}{32}$ in.). This treatment eliminated service failures.

Introduction

HIGH-ALLOY CAST IRONS are an important group of materials whose production should be considered separately from that of the ordinary types of cast irons. In these cast iron alloys, alloy content is well above 4% and, consequently, they cannot be produced by ladle additions to irons of otherwise standard compositions. They are usually produced in foundries specially equipped to produce highly alloyed irons. These iron alloys are most often melted in electric furnaces, where precise control of composition and temperature can be achieved. The producing foundries usually have the equipment needed to handle the heat treatment and other thermal processing unique to the production of these alloys.

The cast iron alloys discussed in this article are alloyed for increased abrasion resistance, for strength and oxidation resistance at elevated temperatures, and for improved corrosion resistance. They include the high-alloy graphitic irons and the high-alloy white irons. The heat treatment practices for the following alloys are described:

High-alloy graphitic irons

- Austenitic gray and ductile irons
- High-silicon irons for heat resisting applications
- High-silicon irons for corrosion resisting applications

High-alloy white irons

- Nickel-chromium white irons
- High-chromium white irons

High-Alloy Graphitic Cast Irons

The high-alloy graphitic cast irons have found special use primarily in applications requiring (1) corrosion resistance or (2) strength and oxidation resistance in high-temperature service. They are commonly produced in both flake graphite and nodular graphite versions. Those alloys used in applications requiring corrosion resistance comprise the nickel-alloyed (13 to 36% Ni) gray and ductile irons (also called Ni-Resist irons), and the high-silicon (14.5% Si) gray irons. The alloyed irons produced for high-temperature service comprise the austenitic, nickel-alloyed gray and nodular irons, the high-silicon (4 to 6% Si) gray and nodular irons and the aluminum-alloyed gray and nodular irons. Two groups of aluminum-alloyed irons are recognized: the 1 to 7% Al irons and the 18 to 25% Al irons. Neither the high-silicon (4 to 6% Si) irons or the Al-alloyed irons are covered by ASTM Standards. Although oxidation resistance of the Al-alloyed irons is exceptional, problems in melting and casting the alloys are great; commercial production of the alloys is uncommon, and information on the heat treatment of the alloys is very limited.

The higher alloy contents affect the constitution of the irons, creating conditions for the formation of third phases, and/or secondary eutectics, during solidification; therefore, many of the alloys commonly contain interdendritic carbides or silico-carbides in the as-cast structure. These constituents often remain after heat treatment and are an accepted part of the microstructure.

Austenitic Nickel-Alloyed Graphitic Irons

The nickel-alloyed austenitic irons are produced in both gray and nodular cast iron versions primarily for corrosion resistance and for high-temperature service. Austenitic gray irons date back to the 1930s, at which time they were specialized materials of minor importance. After the invention of ductile iron, austenitic grades with nodular graphite were also developed. These nickel-alloyed austenitic irons have found usefulness in applications requiring corrosion resistance, wear resistance, and high-temperature stability and strength. Additional properties of benefit are low thermal expansion coefficients, nonmagnetic properties, and cast iron materials having good toughness at low temperatures. The procedures and temperatures of the heat treatments for these ductile irons with nodular graphite are similar to those for gray (flake-graphite), corrosion-resistant austenitic cast irons. Heat treatment is discussed in the next section "Heat Treatment of Austenitic Ductile Irons."

Austenitic Gray Irons. These cast irons exhibit properties that include:

- Resistance to corrosion by alkalis, acids, salts, oils, and foods
- High-temperature oxidation resistance
- High electrical resistivity
- Nonmagnetic characteristics
- Abrasive wear resistance
- Uniform thermal expansion
- Moderate strength and toughness

Many of the irons combine several of these properties, which result from the high-temperature austenite phase; this phase is stabilized at room temperature by the high alloy content and contains a uniform dispersion of carbides. The compositions of flake-graphite corrosion-resistant austenitic cast irons are given in Table 1; typical mechanical properties of these irons are presented in Table 2.

Table 1 Compositions of flake-graphite austenitic cast irons per ASTM A 436-84

Type	UNS number	Composition, %					
		TC[(a)]	Si	Mn	Ni	Cu	Cr
1[(b)]	F41000	3.00 max	1.00-2.80	0.50-1.50	13.50-17.50	5.50-7.50	1.50-2.50
1b	F41001	3.00 max	1.00-2.80	0.50-1.50	13.50-17.50	5.50-7.50	2.50-3.50
2[(c)]	F41002	3.00 max	1.00-2.80	0.50-1.50	18.00-22.00	0.50 max	1.50-2.50
2b	F41003	3.00 max	1.00-2.80	0.50-1.50	18.00-22.00	0.50 max	3.00-6.00[(d)]

5	F41006	2.40 max	1.00-2.00	0.50-1.50	34.00-36.00	0.50 max	0.10 max[(e)]

(a) Total carbon.

(b) Type 1 is recommended for applications in which the presence of copper offers corrosion-resistance advantages.

(c) Type 2 is recommended for applications in which copper contamination cannot be tolerated, such as handling of foods or caustics.

(d) Where some machining is required, 3.0 to 4.0 Cr is recommended.

(e) Where increased hardness, strength; and heat resistance are desired, and where increased expansivity can be tolerated, Cr may be increased to 2.5 to 3.0%.

(f) Type 6 also contains 1.0% Mo.

Table 2 Typical mechanical properties of flake-graphite austenitic cast irons per ASTM 436-84

Type	Tensile strength[(a)]		Hardness, HB[(b)]
	MPa	ksi	
1	170	25	131-183
1b	205	30	149-212
2	170	25	118-174
2b	205	30	171-248
3	170	25	118-159
4	170	25	149-212
5	140	20	99-124

(a) Minimum.

(b) 3000-kg load

These alloys are susceptible to work hardening during machining and require careful cooling from the casting operation and/or subsequent heat-treating operations to minimize the initial stresses and the rate of work hardening during metal-removal operations. Castings that have not been heat treated may cause "chattering" during machining.

ASTM Specification A 436 defines eight grades of austenitic gray iron alloys, four of which are designed to be used in elevated-temperature applications (2, 2b, 3, and 5 in Table 1) and four types are used in applications requiring corrosion resistance (1, lb, 4, and 6 in Table 1). The nickel produces a stable austenitic microstructure with good corrosion resistance and strength at elevated temperatures. The nickel-alloyed irons are additionally alloyed with chromium and silicon for wear resistance and oxidation resistance at elevated temperatures. Types 1 and 1b, which are designed exclusively for corrosion-resistant applications, are alloyed with 13.5 to 17.5% Ni and 6.5% Cu. Types 2b, 3, and 5, which are principally used for high-temperature service, contain from 18 to 36% Ni and varying levels of silicon from 1 to 2.8% and chromium from 0 to 6%. Type 4 is alloyed with 29 to 32% Ni, 5 to 6% Si, and 4.5 to 5.5% Cr and is recommended for stain resistance.

Austenitic Ductile Irons. The ASTM Specification A 439 defines the group of austenitic ductile irons (see Table 3). There are nine alloys listed in the specification. The austenitic ductile iron alloys have similar compositions to the austenitic gray iron alloys but have been treated with magnesium to produce nodular graphite. The ductile family of alloys is available in every type but Type 1, due to its high copper content which is not compatible with production of spheroidal graphite. The ductile iron alloys have high strength and ductility combined with the same desirable properties of the gray iron alloys. They provide resistance to frictional wear, corrosion resistance, strength and oxidation resistance at high temperatures, non-magnetic characteristics and, in some alloys, low thermal expansivity at ambient temperatures. The mechanical properties of several of these ductile austenitic irons are listed in Table 4. Figure 1 illustrates the microstructure typical of austenitic ductile iron.

Table 3 Compositions of nodular-graphite austenitic cast irons per ASTM A 439-83

Applications. The nickel-alloyed irons, or Ni-Resist irons, have found wide application in chemical process-related equipment such as compressors and blowers, condenser parts, phosphate furnace parts, pipe, valves and fittings, pots and retorts, and pump casings and impellers. Likewise in food handling equipment the various alloy components include bottling and brewing equipment, canning machinery, distillery equipment, feed screws, meat grinders, and salt filters. In high-temperature applications they are used as cylinder liners, exhaust manifolds, valve guides, gas turbine housings, turbocharger housings, nozzle rings, and piston ring carriers in aluminum pistons.

Heat Treatment of Austenitic Ductile Irons

Heat treatment of the nickel-alloyed austenitic irons serves to reduce residual stresses and to stabilize the microstructure for increased durability. Heat treatments are similar with the graphite in nodular form (ductile iron) or flake form (gray iron).

Stress Relieving. For most applications, it is recommended that austenitic cast irons be stress relieved at 620 to 675 °C (1150 to 1250 °F), for 1 h per 25 mm (1 in.) of section, to remove residual stresses resulting from casting or machining, or both. Stress relieving should follow rough machining, particularly for castings that must conform to close dimensional tolerances, that have been extensively welded, or that are to be exposed to high stresses in service.

Holding of castings at 480 °C (900 °F) for 1 h per 25 mm (1 in.) of thickness will remove about 60% of the stress; stress relieving at 675 °C (1250 °F) will remove almost 95%. It is usually acceptable to cool castings in air at a rate of 1 to 2 h per inch (25 mm) of section thickness, although furnace cooling produces maximum stress relief. Stress relieving does not affect tensile strength, hardness, or ductility.

For large, relatively thin-section castings, mold-cooling to below 315 °C (600 °F) is recommended rather than stress relief heat treatment.

Spheroidize Annealing. Castings with hardnesses above 190 HB may be softened by heating to 980 to 1040 °C (1800 to 1900 °F) for $\frac{1}{2}$ to 5 h except those alloys containing 4% or more chromium. Excessive carbides cause this high hardness and may occur in rapidly cooled castings and thin sections. Annealing dissolves or spheroidizes carbides. Although it lowers hardness, spheroidize annealing does not adversely affect strength.

High-Temperature Stabilization. Except for castings of alloy type 1 (Table 1), which are not recommended for service above 430 °C (800 °F), castings used for either static or cyclic service at 480 °C (900 °F) or above should be given a stabilization heat treatment. This treatment consists of holding at 760 °C (1400 °F) for 4 h minimum or at 870 °C (1600 °F) for 2 h minimum, furnace cooling to 540 °C (1000 °F), and then cooling in air. This treatment stabilizes the microstructure and minimizes growth and warpage in service. The treatment is designed to reduce carbon levels in the matrix and some growth and distortion often accompanies heat treatment. Thus, it is usually advisable to stabilize castings prior to final machining.

Dimensional Stabilization. This treatment normally is limited to castings that require true dimensional stability, such as those used in precision machinery or scientific instruments. The treatment is not applicable to castings of type 1 alloys. Other alloys may be dimensionally stabilized by the following treatment:

- Heat to 870 °C (1600 °F), and hold for 2 h minimum plus 1 h per 25 mm (1 in.) of section
- Furnace cool, at a maximum rate of 50 °C/h (100 °F/h), to 540 °C (1000 °F)
- Hold at 540 °C (1000 °F) for 1 h per 25 mm (1 in.) of section, and then cool uniformly in air
- After rough machining, reheat to 455 to 480 °C (850 to 900 °F) and hold for 1 h per 25 mm (1 in.) of section, and cool uniformly in air
- Finish machine and reheat to 260 to 315 °C (500 to 600 °F), and cool uniformly in air

Solution Treating. Although this treatment is seldom used, quenching from high temperatures is capable of producing higher-than-normal strength levels and slightly higher hardnesses by dissolving some carbon in austenite at elevated temperatures and by preventing precipitation of the carbon by rapid cooling. This treatment consists of heating to 925 to 1010 °C (1700 to 1850 °F) and quenching in oil or water. Because no metallurgical phase change occurs, the possibility of cracking is lessened.

Refrigeration and reaustenitization heat treatments are applied to Type D2 (Table 3) to increase yield strength. Solution heat treatment at 925 °C (1700 °F), followed by refrigeration at -195 °C (-320 °F), followed by reheating between 650 and 760 °C (1200 and 1400 °F) will increase yield strength considerably without materially affecting magnetic properties or corrosion resistance in sea water or dilute sulfuric acid.

High-Silicon Irons for High-Temperature Service

Graphitic irons alloyed with from 4 to 6% Si have provided good service, and low cost, in many elevated-temperature applications. These irons, whether gray or nodular, provide good oxidation resistance and stable ferritic matrix structures that will not go through a phase change at temperatures up to 815 °C (1500 °F). The elevated silicon content of these otherwise normal cast iron alloys reduces the rate of oxidation at elevated temperatures, because it promotes the formation of a dense, adherent film at the surface, which consists of iron silicate rather than iron oxide. This layer is much more resistant to oxygen penetration and its effectiveness improves with increasing silicon content.

The high-silicon gray irons were developed in the 1930s at the British Cast Iron Research Institute and are commonly called "Silal". In Silal, the advantages of a high critical (A_1) temperature, a stable ferritic matrix, and a fine undercooled, type D graphite structure are combined to provide good resistance to growth and oxidation. Oxidation resistance is further improved with additions of chromium, which in these grades can approach levels of 2% Cr. An austenitic grade called "Nicrosilal" was also developed, but the Ni-Resist irons have replaced this alloy. Structural and dimensional stability improve with subcritical annealing heat treatments.

High-Silicon Nodular Irons. The advent of ductile iron led to the development of high-silicon nodular irons, which currently represent the greatest tonnage of these types of irons being produced. Converting the eutectic flake graphite network to isolated graphite nodules further improved resistance to oxidation and growth. The higher strength and ductility of the nodular iron versions of these alloys qualifies them for more rigorous service.

The high-silicon nodular iron alloys are designed to extend the upper end of the range of service temperatures viable for ferritic nodular irons. These irons are used to temperatures of 900 °C (1650 °F). Raising the silicon content to 4% raises the A_1 temperature to 815 °C (1500 °F), and at 5% Si the A_1 temperature is above 871 °C (1600 °F). The mechanical properties of these alloyed irons at the lower end of the range (4 to 4.5% Si) are similar to those of standard ferritic nodular irons. At 5 to 6% Si, oxidation resistance is improved and critical temperature is increased, but the iron can be very brittle at room temperature. At higher silicon levels impact transition temperature rises well above room temperature and upper shelf energy is reduced. Ductility improves when temperatures exceed 430 °C (800 °F).

For most applications alloying with 0.5 to 1% Mo provides adequate elevated-temperature strength and creep resistance. Higher molybdenum additions are used when maximum elevated-temperature strength is needed. High molybdenum additions (>1%) tend to generate interdendritic carbides of the M_2C type, which persist even through annealing, and tend to reduce toughness and ductility at room temperature.

Silicon lowers the eutectic carbon content and the latter must be controlled to avoid graphite flotation. For 4% Si irons, carbon content should range from 3.2 to 3.5% C, depending on section size; and at 5% Si, it should be around 2.9% C.

Applications. While quite brittle at room temperature, the high-silicon gray irons are reasonably tough at temperatures above 260 °C (500 °F) and have been used successfully for furnace and stoker parts, burner nozzles, and for heat treatment trays.

The high-silicon and Si-Mo nodular irons are currently produced as manifolds and turbocharger housings for trucks and some automotive applications. They are also used in heat treating racks.

Heat Treatment of High-Silicon Irons for High-Temperature Service. The high-silicon gray and nodular irons are predominantly ferritic as-cast, but the presence of carbide-stabilizing elements will result in a certain amount of pearlite and often intercellular carbides. These alloys are inherently more brittle than standard grades of iron and usually have higher levels of internal stress due to lower thermal conductivity and higher elevated-temperature strength. These factors should be taken into account when deciding on heat treatment requirements.

For the high-silicon nodular irons, high-temperature heat treatment is advised in all cases to anneal any pearlite and stabilize the casting against growth in service. A normal graphitizing (full) anneal in the austenitic temperature range is recommended when undesirable amounts of carbide are present. For the 4 to 5% Si irons this will require heating to at least 900 °C (1650 °F) for several hours, followed by slow cooling to below 700 °C (1300 °F). At higher silicon contents (>5%), in which carbides readily break down, and in castings relatively carbide-free, subcritical annealing in the temperature range 720 to 790 °C (1325 to 1450 °F) for 4 h is effective in ferritizing the matrix. Compared to full annealing, the subcritically annealed material will have somewhat higher strength, but ductility and toughness will be reduced. Figure 2 illustrates the full-annealed microstructure in a 4Si-Mo ductile iron casting.

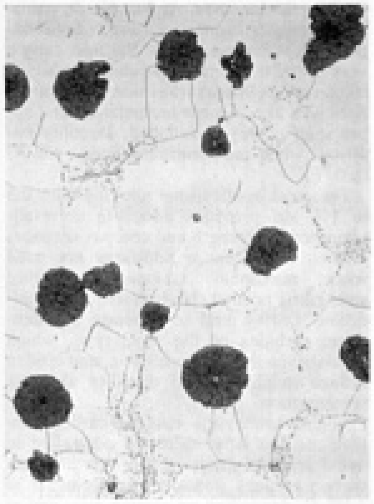

Fig. 2 Photomicrograph of subcritically annealed 4% Si-Mo ductile iron casting showing nodular graphite structure. 400×

High-Silicon Irons for Corrosion Resistance

Irons with high silicon content (14.5% Si) comprise a unique corrosion-resistant ferritic cast iron group. These alloys are widely used in the chemical industry for processing and for transporting highly corrosive liquids. They are particularly good for handling sulfuric and nitric acids. The most common of the high-silicon iron alloys are covered in ASTM Specification A 518M (see Table 5). Three alloys are defined in the specification, all containing 14.2 to 14.75% Si and from 0.7 to 1.15% C. Grades 2 and 3 are additionally alloyed with 3.25 to 5% Cr, and grade 2 also calls for 0.4 to 0.6% Mo. Other compositions are also commercially produced with up to 17% Si. The high-silicon iron castings usually require stress relief heat treatments prior to going into service.

Table 5 Compositions of corrosion-resistant high-silicon cast iron alloys

Alloy	Composition, %					
	C	Mn	Si	Cr	Mo	Cu
Grade 1	0.70-1.10	1.50 max	14.20-14.75	0.50 max	0.50 max	0.50 max
Grade 2	0.75-1.15	1.50 max	14.20-14.75	3.25-5.00	0.40-0.60	0.50 max
Grade 3	0.70-1.10	1.50 max	14.20-14.75	3.25-5.00	0.20 max	0.50 max

Applications. High-silicon irons are extensively used in equipment for the production of sulfuric and nitric acids, for sewage disposal and water treatment, for handling mineral acids in petroleum refining, and in the manufacture of fertilizer, textiles, and explosives. Specific components include pump rotors, agitators, crucibles, and pipe fittings in chemical laboratories.

Heat Treatment of High-Silicon Irons for Corrosion Resistance. Because of the very brittle nature of high-silicon cast iron, castings are usually shaken out only after mold cooling to ambient temperature. However, some casting geometries demand hot shake-out so that the castings can be immediately stress-relieved and furnace cooled to prevent cracking.

Castings are stress relieved by heating in the range of 870 to 900 °C (1600 to 1650 °F) followed by slow cooling to ambient temperatures to minimize the likelihood of cracking. Heat treatments have no significant effect on corrosion resistance.

High-Alloy White Cast Irons

The high-alloy white irons are primarily used for abrasion-resistant applications and are readily cast in the shapes needed in machinery used for crushing, grinding, and general handling of abrasive materials. The large volume of eutectic carbides in their microstructures provide the high hardness needed for crushing and grinding other materials. The metallic matrix supporting the carbide phase in these irons can be adjusted by alloy content and heat treatment to develop the proper balance between resistance to abrasion and the toughness needed to withstand repeated impact.

All high-alloy white irons contain chromium to prevent formation of graphite on solidification and to ensure the stability of the carbide phase. Most also contain nickel, molybdenum, copper, or combinations of these alloying elements to prevent the formation of pearlite in the microstructure. While low-alloyed pearlitic white iron castings develop hardness in the range 350 to 550 HB, the high-alloyed white irons range from 450 to 800 HB. In addition, several grades contain alloy eutectic carbides (M_7C_3 chromium carbides) which are substantially harder than the iron carbide in low-alloy irons. For many applications, the increased abrasion resistance of the more expensive high-alloy white irons adds significantly to wear life, causing them to provide the most cost-effective performance.

ASTM Specification A 532 covers the composition and hardness of white iron grades used for abrasion-resistant applications (see Table 6). Many castings are ordered according to these specifications; however, a large number of castings are produced with modifications to composition for specific applications. It is most desirable that the designer, metallurgist, and foundryman work together to specify the composition, heat treatment, and foundry practice to develop the most suitable alloy and casting design for a specific application.

Table 6 Composition and mechanical requirements of abrasion-resistant cast irons per ASTM A 532-82

Class	Type	UNS number	Designation	Composition, wt%					
				C	Mn	Si	Ni	Cr	Mo

ASTM A 532-87 data have slight variations.

(a) Maximum: 0.30% P, 0.15% S.

(b) Maximum: 0.10% P, 0.15% S.

(c) Maximum: 0.10% P, 0.06% S, 1.2% Cu

The high-alloy white cast irons fall into three major groups:

- The Ni-Cr white irons, which are low-chromium alloys containing 3 to 5% Ni and 1 to 4% Cr, with one alloy modification which contains 7 to 11% Cr. The Ni-Cr irons are also commonly identified by the tradename Ni-Hard types 1 to 4

- The chromium-molybdenum irons containing 11 to 23% Cr, up to 3% Mo, and often additionally alloyed with nickel or copper
- The 25% Cr or 28% Cr white irons, which may contain other alloying additions of molybdenum and/or nickel up to 1.5%

Mechanical properties for three white irons representing each of these three general groups are shown as bar graphs in Fig. 3. The properties for the austenitic matrix were obtained with as-cast irons; the martensitic properties were obtained by heat treatment. In all irons, heat treating to achieve a martensitic matrix resulted in improved properties.

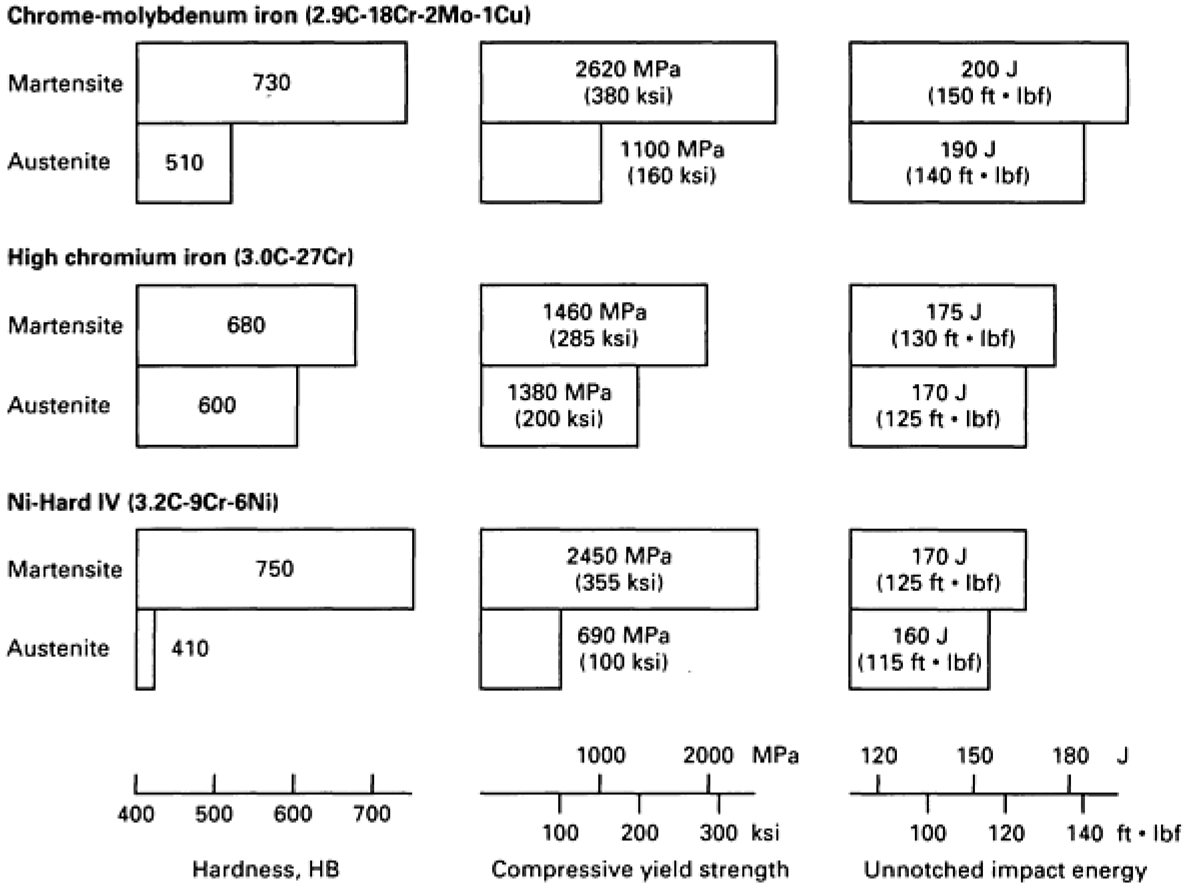

Fig. 3 Typical mechanical properties of white cast irons

In alkali environments, the corrosion-resistant properties of the high-alloyed white irons used in abrasion-resistant applications increase as the pH exceeds 7. In acidic environments, the nickel-chromium white irons are recommended for use in very dilute acid sulfate conditions while high-chromium white irons are recommended for use in very dilute acid chloride conditions.

Nickel-Chromium White Irons

One of the oldest groups of high-alloy irons of industrial importance, the Ni-Cr white irons, or Ni-Hard irons, have been produced for more than 50 years and are very cost-effective materials for crushing and grinding. In these martensitic white irons, nickel is the primary alloying element because at levels of 3 to 5% it is effective in suppressing the transformation of the austenite matrix to pearlite, and thus ensuring that a hard, martensitic structure (usually containing significant amounts of retained austenite) will develop on cooling in the mold. Chromium is included in these alloys, at levels from 1.4 to 4%, to ensure that the irons will solidify with carbides to counteract the graphitizing effect of nickel. A typical microstructure is shown in Fig. 4.

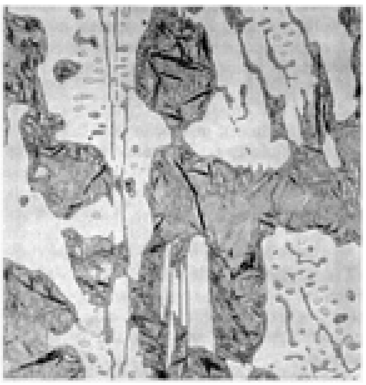

Fig. 4 Typical microstructure of class I type A nickel-chromium white cast iron. 340×

Composition Selection and Control. The optimum composition of the Ni-Cr white iron alloy depends on the properties required for the service conditions and the dimensions and weight of the casting. Abrasion resistance is generally a function of the bulk hardness and the volume of carbide in the microstructure. When abrasion resistance is the principal requirement and resistance to impact loading is secondary, alloys having high carbon contents, ASTM A 532 class I type A (Ni-Hard 1), are recommended. Where conditions of repeated impact are anticipated, the lower carbon alloys, class I type B (Ni-Hard 2), are recommended because they have less carbide and, therefore, greater toughness. A special grade, class I type C, has been developed for producing grinding balls and slugs. Here, the Ni-Cr alloy composition has been adapted for chill casting and specialized sand casting processes.

The class I type D (Ni-Hard 4) alloy is a modified Ni-Cr iron which contains higher levels of chromium ranging from 7 to 11%, and increased levels of nickel ranging from 5 to 7%. Whereas the eutectic carbide phase in the lower-alloyed Ni-Cr irons is M_3C (iron carbide) which forms as a continuous network in these irons, the higher chromium in the type D alloy promotes M_7C_3 chromium carbides which form a relatively discontinuous eutectic carbide distribution (Fig. 5). This modification in eutectic carbide pattern provides an appreciable improvement in resistance to fracture by impact. The higher alloy content of this iron grade also results in improved corrosion resistance, which has proved useful in the handling of corrosive slurries.

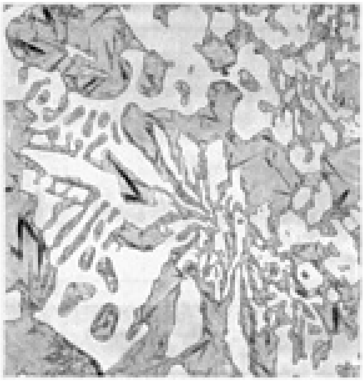

Fig. 5 Typical microstructure of class I type D nickel-chromium white cast iron. 340×

Carbon is varied according to properties needed for the intended service. Carbon contents in the range of 3.2 to 3.6% are prescribed when maximum abrasion resistance is desired. Where impact loading is present, carbon content should be held in the range of 2.7 to 3.2%.

Nickel content is increased with section size or cooling time of the casting to inhibit pearlitic transformation. For castings of 1.5 to 2 in. thick, nickel contents of 3.4 to 4.2% are sufficient to suppress pearlite formation on mold cooling. Heavier

sections may require nickel levels up to 5.5% to avoid the formation of pearlite. It is important to limit nickel content to the level needed for control of pearlite; excess nickel increases the amount of retained austenite and lowers hardness.

Silicon is needed for two reasons. A minimum amount of silicon is necessary to improve fluidity and produce a fluid slag. But of equal importance is its effect on as-cast hardness. Increased levels of silicon, in the range of 1 to 1.5%, have been found to increase the amount of martensite and the resulting hardness. Late additions of ferrosilicon (0.2% as 75% Si FeSi) have been reported to increase toughness. Note that higher silicon contents can promote pearlite and may increase the nickel requirement.

Chromium is primarily added to offset the graphitizing effects of nickel and silicon in the class I types A, B, and C alloys (see Table 6) and ranges from 1.1 to 4.0%. Chromium content must increase with increasing section size. In the type D alloy, chromium levels range from 7 to 11% (typically 9%) for the purpose of producing eutectic carbides of the M_7C_3 chromium carbide type, which are harder and less deleterious to toughness.

Manganese is usually held to 0.8% max. While it provides increased hardenability to avoid pearlite formation, it is also a potent austenite stabilizer, more so than nickel, and will promote increased amounts of retained austenite and lower as-cast hardness. For this reason higher manganese levels are undesirable. In considering the nickel content required to avoid pearlite in a given casting, the level of manganese present should be a factor.

Copper increases hardenability and the retention of austenite and, therefore, must be controlled for the same reason manganese is limited. Copper should be treated as a nickel substitute and, when properly included in the calculation of the amount of nickel required to inhibit pearlite in a given casting, it reduces the nickel requirement.

Molybdenum is a potent hardenability agent in these alloys and is used in heavy section castings to augment hardenability and inhibit pearlite.

Heat Treatment of Nickel-Chromium White Irons. All nickel-chromium white iron castings are given a stress-relief heat treatment because, properly made, they have a martensitic matrix structure, as-cast. Tempering is performed between 205 to 260 °C (400 to 450 °F) for at least 4 h. This tempers the martensite, relieves some of the transformation stresses, and increases the strength and impact toughness by 50 to 80%. Some additional martensite may form on cooling from the tempering temperature. This heat treatment does not reduce hardness or abrasion resistance.

In the heat treatment of any white cast iron, care must be taken to avoid cracking by thermal shock; never place the castings in a hot furnace or otherwise subject them to rapid heating or cooling. The risk of cracking increases with the complexity of the casting shape and section thickness.

High-Temperature Heat Treatment. In the past, hardening of the class I type D, Ni-Hard 4, was performed by supercritical heat treatment when as-cast hardness was insufficient. An austenitizing heat treatment usually comprised heating at temperatures between 750 and 790 °C (1380 and 1450 °F) with a soak time of 8 h. Air or furnace cooling, not over 30 °C/h (50 °F/h), was conducted followed by a tempering/stress-relief heat treatment. Refrigeration heat treatment is the more commonly practiced remedy for low hardness today.

Refrigeration Treatments. To achieve a hardness of 550 HB, it is necessary that the as-cast austenite-martensite microstructure have at least 60% martensite present. When martensite content is increased to 80 to 90%, however, hardness values exceed 650 HB. To reduce the amount of retained austenite (form more martensite), deep freeze treatments are commonly applied. Refrigeration to temperatures between -70 and -180 °C (-100 and -300 °F) for $\frac{1}{2}$ to 1 h will usually raise the hardness level 100 HB units. A subsequent tempering/stress-relief heat treatment usually follows. The typical refrigerated Ni-Cr iron microstructure is shown in Fig. 6.

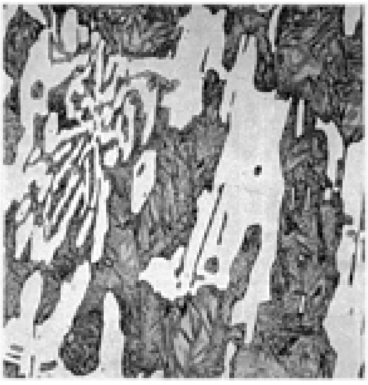

Fig. 6 Microstructure of class I type D nickel-chromium white cast iron after refrigeration. 340×

Special Ni-Cr White Iron Alloys. Certain proprietary grades of the type A alloy have been developed by the rolling mill roll industry. The compositions of these alloys have been modified to produce mottled structures, containing some graphite. The graphite inclusions are reported to improve resistance to thermal cracking. These "indefinite chill" rolls are cast in thick-walled gray iron chiller molds in roll diameters up to 1000 mm (40 in.) or more. The silicon-to-chromium ratios and inoculation with ferrosilicon are carefully regulated to control the amount and distribution of the graphite particles. The rolls can be double-poured with a gray iron core. With molybdenum modification, the matrix of the chill cast shell will be martensitic. Some roll alloys are designed to be heat treated, a modified normalizing heat treatment, to obtain a bainitic microstructure.

High-Chromium White Irons

The oldest high-alloy white irons produced commercially were the high-chromium (28% Cr) white irons. The high-chromium white irons have excellent abrasion resistance and are used effectively in slurry pumps, brick molds, coal-grinding mills, rolling mill rolls, shot blasting equipment, and components for quarrying, hard-rock mining and milling. In some applications they must also be able to withstand heavy impact loading. These alloyed white irons are recognized as providing the best combination of toughness and abrasion resistance attainable among the white cast irons.

In the high-chromium irons, as with most abrasion-resistant materials, there is a trade-off between wear resistance and toughness. Through variations in composition and heat treatment these properties can be adjusted to meet the needs of most abrasive applications.

As a class of alloyed irons, the high-chromium irons are distinguished by the hard, relatively discontinuous, M_7C_3 eutectic carbides present in the microstructure, as opposed to the softer, more continuous M_3C eutectic carbides present in the alloyed irons containing less chromium. With few exceptions, these alloys are usually produced as hypoeutectic compositions.

Classes of High-Chromium Irons. Specification ASTM A 532 covers the compositions and hardnesses of two general classes of the high-chromium irons (see Table 6). The chromium-molybdenum irons (class II of ASTM A 532) contain 11 to 23% Cr and up to 3% Mo and can be supplied either as-cast with an austenitic or austenitic-martensitic matrix, or heat treated with a martensitic matrix microstructure for maximum abrasion resistance and toughness. They are usually considered the hardest of all grades of white cast irons. Compared to the lower alloy Ni-Cr white irons, the eutectic carbides are harder and these alloys can be heat treated to achieve castings of higher hardness. Molybdenum (and nickel and copper when needed) is added to prevent pearlite and assure maximum hardness is obtained.

The high-chromium irons (class III of ASTM A 532) represent the oldest grade of high-chromium irons, with the earliest patents dating back to 1917. These general purpose irons, also called 25% Cr and 28% Cr irons, contain 23 to 28% Cr with up to 1.5% Mo. To prevent pearlite and attain maximum hardness, molybdenum is added in all but the lightest cast sections. Other alloying with nickel and copper up to 1% is also practiced. Although the maximum attainable hardness is not as high as in the class II Cr-Mo white irons, these alloys are selected when resistance to corrosion is also desired.

Special High-Chromium Iron Alloys for Corrosion Resistance. Alloys with improved resistance to corrosion, for applications such as pumps handling fly ash, are produced with high chromium contents (26 to 28% Cr) and low carbon contents (1.6 to 2.0% C). These high-chromium, low-carbon irons will provide the maximum chromium content in the matrix. Addition of 2% Mo is recommended for improving resistance to chloride-containing environments. For this application, fully austenitic matrix structures provide the best resistance to corrosion, but some reduction in abrasion resistance must be expected. Castings are normally supplied in the as-cast condition.

Special High-Chromium Irons for High-Temperature Service. Because of castability and cost, high-chromium white iron castings can often be used for complex and intricate parts in high-temperature applications at considerable savings compared to stainless steel. These cast iron grades are alloyed with 12 to 39% Cr. Chromium causes the formation of an adherent, complex, chromium-rich oxide film providing resistance to scaling at temperatures up to 1040 °C (1900 °F). The high-chromium irons designated for use at elevated temperatures fall into one of three categories, depending upon the matrix structure:

- The martensitic irons alloyed with 12 to 28% Cr
- The ferritic irons alloyed with 30 to 34% Cr
- The austenitic irons which in addition to containing 15 to 30% Cr, also contain 10 to 15% Ni to stabilize the austenite phase

Carbon contents of these alloys range from 1 to 2%. The choice of the exact composition is critical to prevent sigma (σ) phase formation at intermediate temperatures, while at the same time avoiding ferrite-to-austenite transformation during thermal cycling, which leads to distortion and cracking. Typical applications include recuperator tubes, breaker bars and trays in sinter furnaces, grates, burner nozzles and other furnace parts, glass bottle molds and valve seats for combustion engines.

Hardness in High-Chromium Iron Castings. The hardness ranges which can be expected in high-chromium irons with different matrix microstructures are shown in Table 7. The hardness values of microconstituents in abrasion-resistant irons, as well as the hardness of minerals being crushed, are shown in Table 8. It is evident that carbides and martensite are needed to resist abrasion by the common minerals associated with mining and oil drilling.

Table 7 Typical hardness range for castings

Matrix structure	Hardness, HB
Pearlite	320-500
Austenite	420-500
Martensite (as-cast)	550-650
Martensite (heat treated)	650-850

Table 8 Hardness of minerals and microconstituents

Mineral	Hardness		Material or microconstituents	Hardness	
	Knoop	HV		Knoop[(a)]	HV
Talc	20		Ferrite	235	70-200

Carbon	35		Pearlite, unalloyed		250-320
Gypsum	40	36	Pearlite, alloyed		300-460
Calcite	130	140	Austenite, 12% Mn	305	170-230
Fluorite	175	190	Austenite, low alloy		250-350
Apatite	335	540	Austenite, high Cr iron		300-600
Glass	455	500	Martensite	500-800	500-1010
Feldspar	550	600-750	Cementite (Fe_3C)	1025	840-1100
Magnetite	575		Chromium carbide $(Fe,Cr)_7C_3$	1735	1200-1600

(a) Typical values.

Figure 7 shows the relation between hardness and abrasive wear loss (in a laboratory pin test which has been shown to correlate with abrasion in mining service), for one composition of high-chromium iron subjected to a wide range of heat treatments to provide matrix structures which are either predominantly austenitic or martensitic (Ref 2). Best resistance to abrasion (low-volume losses in the test) was achieved with martensitic structures using heat treatments with an air-quench

from high austenitizing temperatures (such as data points 9, 11, 15, and 43 in Fig. 7). Subsequent treatments, such as refrigerating or low-temperature tempering, did not improve the abrasion resistance significantly.

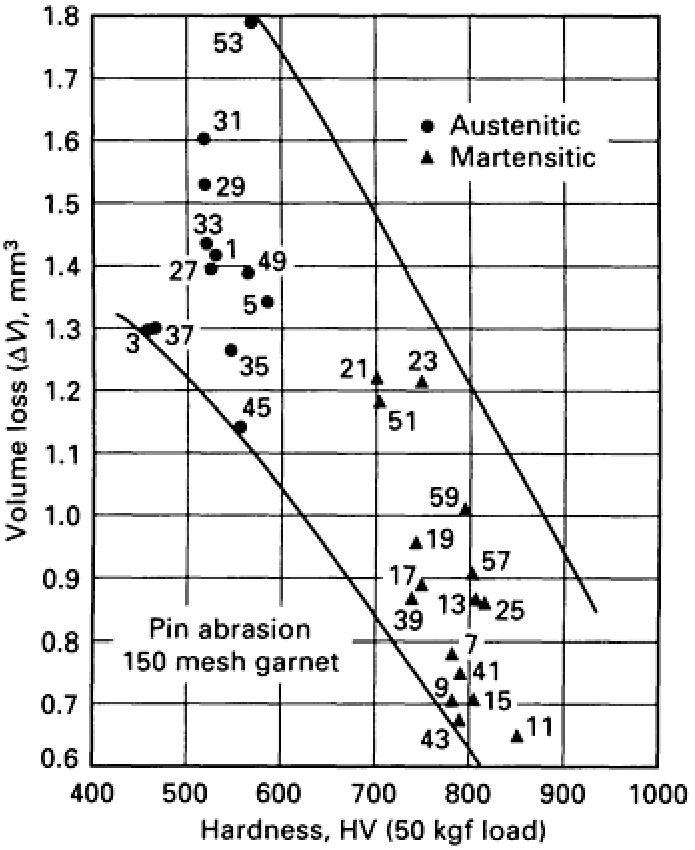

Fig. 7 Volume loss in pin abrasion test as a function of hardness for 2.9% C-19% Cr-2.4% Mo-0.9% Cu iron subjected to various heat treatments. Source: Ref 2

Typical mechanical properties for three white irons of widely varying compositions are shown as bar graphs in Fig. 3. The properties for the austenitic matrix were obtained with as-cast irons; the martensitic properties were obtained by heat treatment. In all irons, heat treating to achieve a martensitic matrix resulted in improved properties.

Optimizing Fracture Toughness and Abrasion Resistance. Abrasion resistance and fracture toughness were determined for a series of high-alloy white irons with varying carbide content and matrix microstructures (Ref 2). Results were correlated for one such iron in Fig. 8 to show the effect of structure and heat treatment. Austenitic matrix structures could provide higher fracture toughness, and martensitic matrix structures could provide better resistance to abrasion. But careful selection of heat treatments (for example data points 17 and 51) provided good wear resistance and reasonable fracture toughness. These heat treatments involved air quenching from high temperatures, followed by tempering at 200 °C (390 °F).

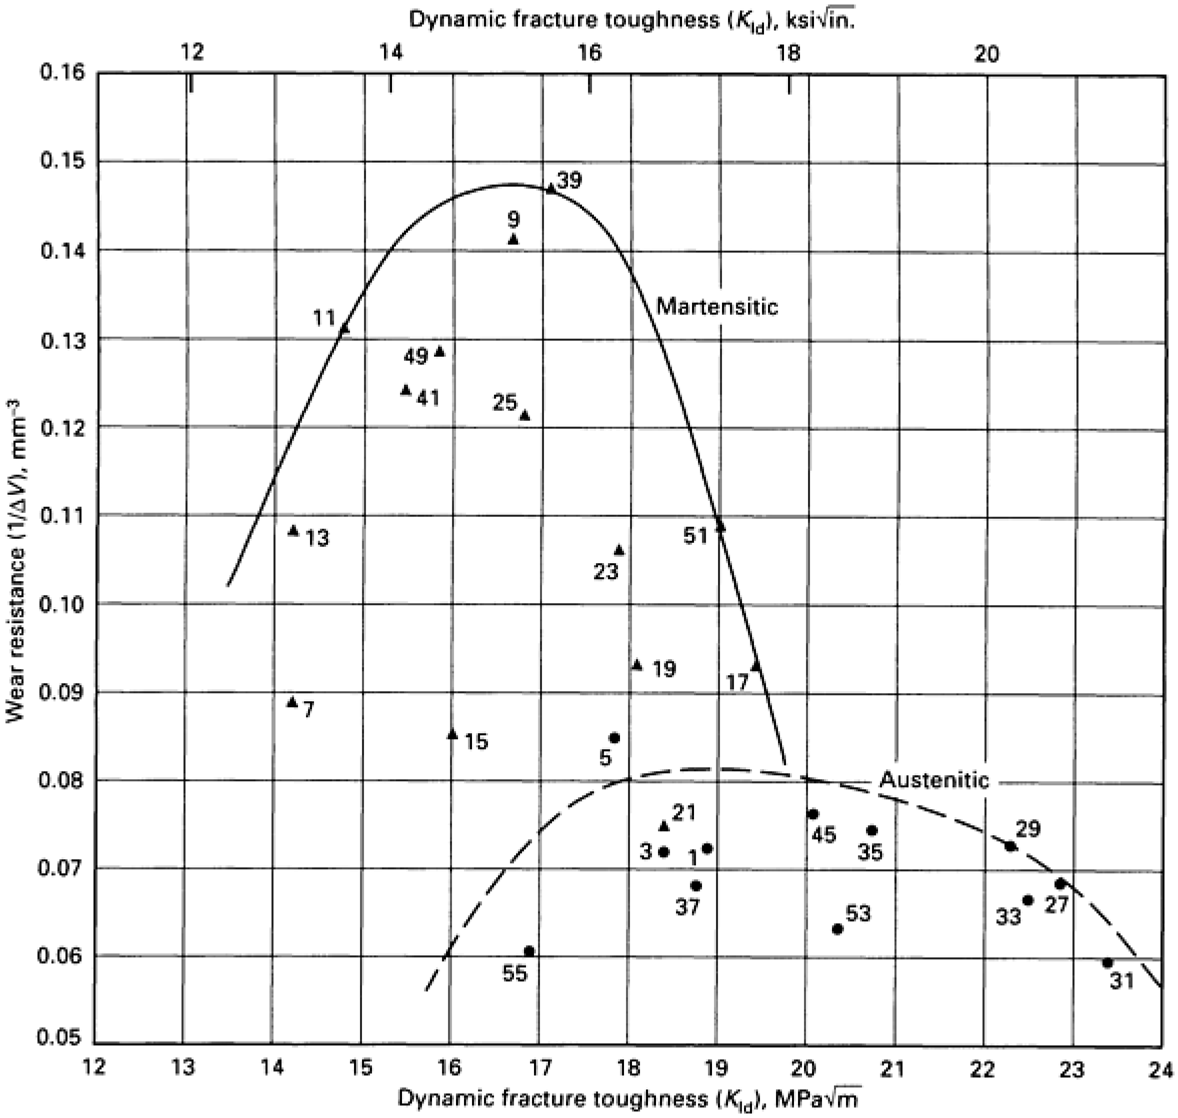

Fig. 8 Abrasive wear resistance versus fracture toughness for a 2.9% C-19% Cr-2.4% Mo-0.9% Cu iron subjected to various heat treatments. Wear resistance expressed as the reciprocal of volume loss (Δ*V*). Source: Ref 2

A study of spalling of high-chromium white cast irons provided data showing the advantage of careful control of heat treatment (Ref 3). Spalling resistance could be maximized by either high-temperature tempering or austenitizing and tempering.

Microstructure of High-Chromium White Irons

Optimum Metallic Matrix. To a large extent the metal matrix in high-chromium irons has characteristics of tool steel. It can be made tough to increase the tolerance to impact loading, or hardened to reduce wear, though generally at the expense of toughness. Matrix structures can be pearlite, austenite, or martensite, or some combination of these.

Detailed studies of microstructures are described in work by Maratray and Poulalion (Ref 4). A summary of this work and of other studies of structures in high-chromium irons was made by Dodd and Parks (Ref 5). As with steels, maximum abrasion resistance is achieved with a fully martensitic matrix structure. As-cast austenitic irons, though relatively soft, can give satisfactory performance in many abrasive wear applications due to pronounced work hardening in service. Resistance to crack propagation is greatest in irons having a fully austenitic matrix. Under conditions of repeated impact, however, martensitic irons, which have been tempered to minimize retained austenite, have the maximum resistance to spalling.

Pearlitic matrix structures have modest abrasion resistance and low toughness and, therefore, are not generally desirable. Pearlite will always occur when alloying is insufficient to inhibit its formation. Most of the chromium is tied up in the chromium carbides and, therefore, other alloying elements are needed to provide adequate hardenability.

The carbides in high-chromium irons are very hard and wear resistant but are also brittle. In general wear resistance is improved by increasing the amount of carbide (increasing the carbon content), while toughness is improved by increasing the proportion of metallic matrix (reducing the carbon content). The influence of carbon content on the shape and distribution of the carbide phase in these alloys is shown in Fig. 9.

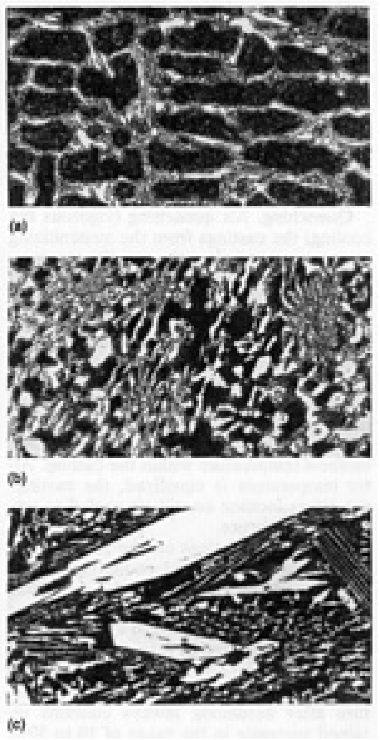

Fig. 9 Microstructures of high-chromium white iron compositions. (a) Low-carbon (hypoeutectic). (b) Eutectic. (c) High-carbon (hypereutectic). All 75×. Courtesy of Climax Molybdenum Company

Large hexagonal carbide rods occur when carbon contents exceed the eutectic carbon content (Fig. 9c). These primary chromium carbides, which precipitate from the melt ahead of eutectic solidification, are quite deleterious to impact toughness and should be avoided in castings subjected to any impact in service. The eutectic carbon content varies inversely with chromium content in these alloys. The relationship between eutectic carbon content and chromium content is shown in Fig. 10.

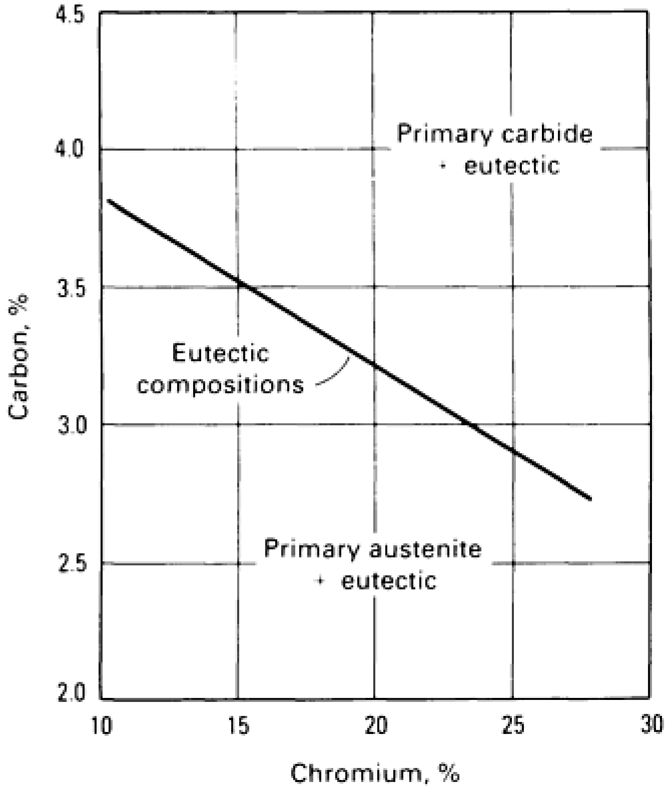

Fig. 10 Relationship between the chromium and carbon contents and the eutectic composition in high-chromium white irons

As-Cast Austenitic Microstructures. Solidification in the hypoeutectic alloys occurs by the formation of austenite dendrites followed by the eutectic formation of austenite and M_7C_3 chromium carbides. Under equilibrium conditions, additional chromium carbide will precipitate from the austenite matrix on cooling from the eutectic to the critical temperature, about 760 °C (1400 °F), and transformation to ferrite and carbide occurs on subsequent cooling. However, when cooling under nonequilibrium conditions such as encountered in most commercial castings, the austenite becomes super-saturated in carbon and chromium. Due to elevated carbon and chromium contents, a metastable austenitic cast iron normally develops, provided pearlitic and bainitic transformations have been inhibited (Fig. 11). With sufficient alloying with molybdenum, manganese, nickel, and copper, pearlitic transformation can be avoided in virtually any cast section.

Fig. 11 High-chromium iron with an as-cast austenitic matrix microstructure. 500×. Courtesy of Climax Molybdenum Company

As-Cast Martensitic Microstructures. Martensitic structures can be obtained as-cast in heavy section castings which cool slowly in the mold. With slow cooling rates, austenite stabilization is incomplete and partial transformation to martensite occurs. But in these castings, martensite is mixed with large amounts of retained austenite (Fig. 12a), and therefore hardness levels are lower than can be achieved in heat treated martensitic castings. These castings must contain sufficient alloy to suppress pearlite on cooling. Some compositions (higher silicon) have been developed to assist martensite formation in refrigeration treatments. Subcritical annealing has been employed to reduce austenite content and, at the same time, increase hardness and toughness.

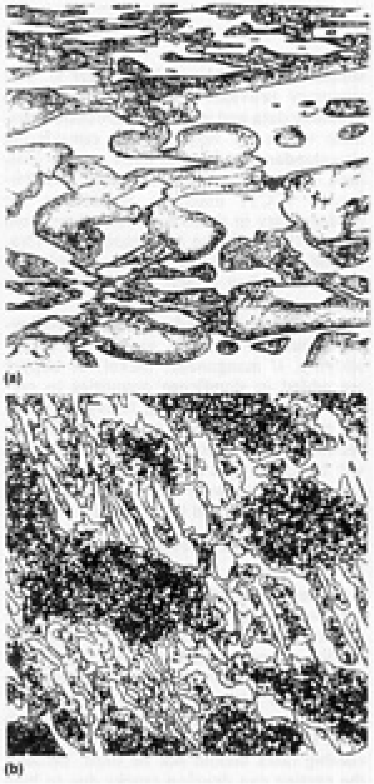

Fig. 12 High-chromium iron microstructures. (a) As-cast austenitic-martensitic matrix microstructure. (b) Heat-treated martensitic microstructure. Both at 500×. Courtesy of Climax Molybdenum Company

Heat Treated Martensitic Microstructures. To obtain maximum hardness and abrasion resistance, martensitic matrix structures must be produced by full heat treatment (Fig. 12b). The casting must contain sufficient alloy to avoid pearlite formation on cooling from the heat treatment temperature.

As-Cast Pearlitic Microstructures. For castings which will be heat treated, the desired mold-cooled structure is often pearlite. This softer structure will facilitate removal of gates and risers and minimize the transformational and thermal stresses that cause cracking. The pearlitic structure will also shorten the response to heat treatment. Careful design of alloy composition will assure that a substantially pearlitic structure develops in the casting after mold-cooling, but will provide enough hardenability to prevent pearlite formation during subsequent heat treatment. Heavy section castings made pearlitic by such an alloy content, can oftentimes be removed from the mold once the castings have reached black heat.

Selecting Compositions to Obtain Desired Structures. Many complex sections, such as slurry pump components, are often used in the as-cast austenitic/martensitic condition to avoid the possibility of cracking and distortion on heat treatment. To avoid forming pearlite during mold cooling, alloying additions are usually required. As the carbon content is increased, more chromium is consumed to form additional carbide, and therefore, larger alloying additions are required.

Table 9 presents a guide to appropriate alloying to prevent pearlite in the various classes of as-cast irons. Table 10 is offered as a guide to alloying for air quenching heat-treated castings of various sections.

Table 9 Minimum alloy content to avoid pearlite in mold-cooled castings for indicated effective section size (plate thickness or radius of rounds)

ASTM A 532 class	Cr[(a)], %	C[(a)], %	Plate thickness or radius of rounds		
			25 mm (1 in.)	**50 mm (2 in.)**	**100 mm (4 in.)**

(a) In base irons containing 0.6% Si and 0.8% Mn

Table 10 Minimum alloy content to avoid pearlite in heat treatment for indicated effective section size (plate thickness or radius of rounds)

ASTM A 532 class	Cr[(a)], %	C[(a)], %	Plate thickness or radius of rounds		
			50 mm (2 in.)	**125 mm (5 in.)**	**150-255 mm (6-10 in.)**
IIB, C	14-18	2.0	1.5 Mo	1.5 Mo + 0.5 (Ni + Cu)	2.0 Mo + 1.0 (Ni + Cu)
		3.5	3.0 Mo	2.0 Mo + 1.0 (Ni + Cu)	2.5 Mo + 1.2 (Ni + Cu)[(b)]
IID, E	18-23	2.0	1.0 Mo	2.0 Mo	2.0 Mo + 0.5 (Ni + Cu)
		3.2	1.5 Mo	2.0 Mo + 0.7 (Ni + Cu)	2.0 Mo + 1.2 (Ni + Cu)[(b)]
IIIA	23-28	2.0	0.5 Mo	1.5 Mo	1.5 Mo + 0.5 (Ni + Cu)
		3.0	1.5 Mo	1.5 Mo + 0.6 (Ni + Cu)	1.5 Mo + 1.2 (Ni + Cu)[(b)]

(a) In base irons containing 0.6% Si and 0.8% Mn.

(b) Nickel and copper promote retained austenite and should be restricted to combined levels of 1.2% maximum; manganese behaves similarly and should be restricted to 1.0% maximum.

These recommendations for alloying specific ASTM grades are based on studies of continuous-cooling transformation of high-chromium irons, and are cited in a useful summary by Dodd and Parks (Ref 5). The summary provides specific references to available data and includes regression equations which are helpful when considering non-standard grades and thick section castings. Typical continuous-cooling transformation (CCT) diagrams illustrating the hardenability in three common alloys from classes II and III are presented in Fig. 13(a, b, and c). More information on such diagrams and alloy effects in high-chromium irons are given by Cias (Ref 6).

It should be pointed out that over-alloying should be avoided, as well as under-alloying. If manganese, nickel, or copper are added in significant quantities to prevent pearlite formation in heavy sections, too much austenite will be retained in light sections. As a result, air-cooled hardness will be lower than desired in the light sections, and both wear resistance and resistance to spalling will be reduced.

Heat Treatment of High-Chromium White Irons

Optimum performance is usually achieved with heat treated martensitic structures. As described in the previous section, alloying must be sufficient to ensure that a pearlite-free microstructure is obtained in heat treatment. Of necessity, the heat treatment requires an air quench from the austenitizing temperature. Faster cooling rates should not be used, because the casting can develop cracks due to high thermal and/or transformation stresses. Thus the alloy must have sufficient hardenability to allow air hardening. Over-alloying with manganese, nickel, and copper will promote retained austenite, which detracts from resistance to abrasion and spalling.

Toughness and abrasion resistance are improved by heat treatment to a martensitic microstructure. Figure 14, which illustrates the process, emphasizes the importance of slow heating *in a cold furnace* to 650 °C (1200 °F) to avoid cracking. For complex shapes a maximum rate of 30 °C/h (50 °F/h) is recommended. Simple shapes and fully pearlitic castings can be heated at faster rates. The heating rate can be accelerated above red heat.

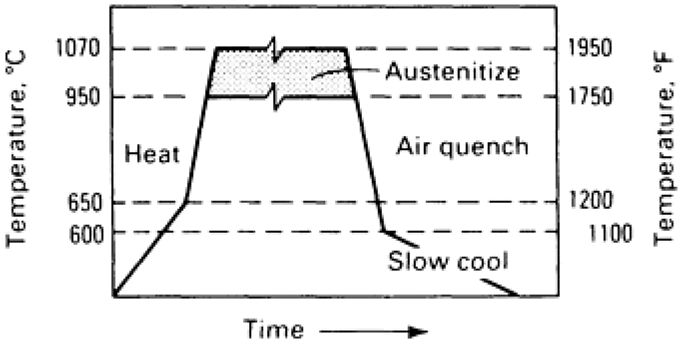

Fig. 14 Heat treatment schedule for hardening high-chromium irons

Austenitization. There is an optimum austenitizing temperature to achieve maximum hardness (Fig. 15), which varies for each composition. The austenitizing temperature determines the amount of carbon that remains in solution in the austenite matrix. Too high a temperature increases the stability of the austenite, and the higher retained austenite content reduces hardness. Low temperatures result in low-carbon martensite reducing both hardness and abrasion resistance. Because of this sensitivity to temperature, furnaces which can produce accurate and uniform temperatures are most desirable. The successful heat treatment produces austenite destabilization by precipitation of fine secondary M_7C_3 carbides within the austenite matrix, as illustrated in Fig. 16.

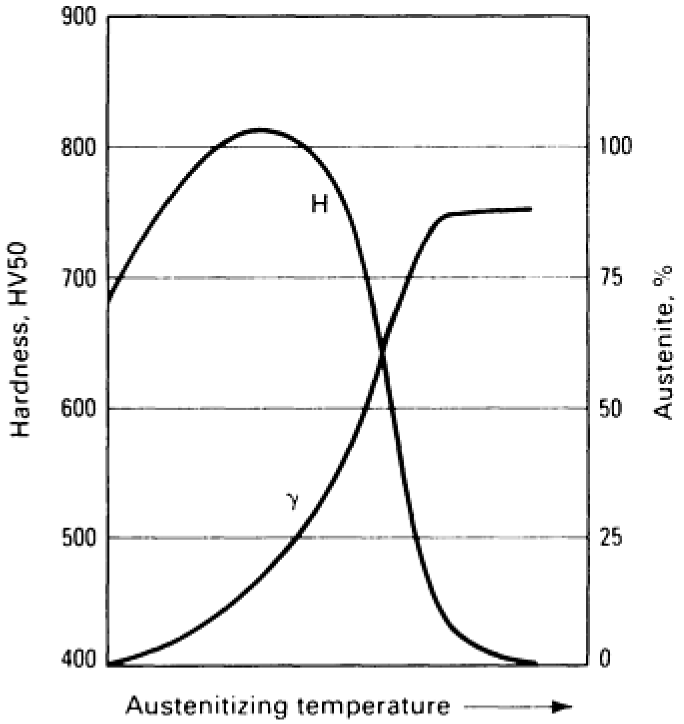

Fig. 15 Influence of austenitizing temperature on hardness (H) and retained austenite (γ) in high-chromium irons

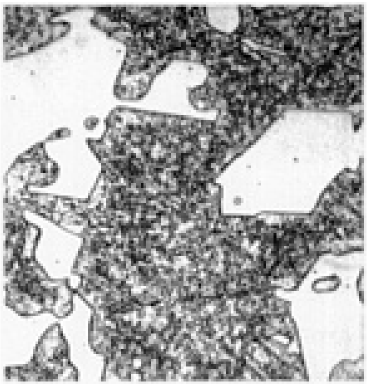

Fig. 16 Microstructure of heat-treated martensitic high-chromium iron illustrating fine secondary M_7C_3 carbides. 680×

Class II irons containing 12 to 20% Cr are austenitized in the temperature range 950 to 1010 °C (1750 to 1850 °F). Class III irons containing 23 to 28% Cr are austenitized in the temperature range 1010 to 1090 °C (1850 to 2000 °F). Heavy sections usually require higher temperatures within the range.

Castings should be held at temperature long enough to accomplish equilibrium dissolution of chromium carbides to ensure proper hardening response. A minimum of 4 h at temperature is necessary. For heavy sections the rule of 1 hour per 25 mm (1 in.) of section thickness is usually adequate. For castings which are fully pearlitic prior to heat treatment, the holding time at temperature can be reduced.

Quenching. Air quenching (vigorous fan cooling) the castings from the austenitizing temperature to below the pearlite temperature range (that is, between 550 and 600 °C, or 1020 and 1110 °F) is highly recommended. The subsequent cooling rate should be substantially reduced to minimize stresses; still-air or even furnace cooling to ambient is common.

Complex and heavy section castings are often placed back into the furnace, which is at 550 to 600 °C (1020 to 1110 °F), and allowed sufficient time to reach uniform temperature within the casting. After temperature is equalized, the castings are either furnace or still-air cooled to ambient temperature.

Tempering. Castings can be put into service in the hardened (as cooled) condition without further tempering or subcritical heat treatments; however, tempering in the range of 200 to 230 °C (400 to 450 °F) for 2 to 4 h is recommended to restore some toughness in the martensitic matrix and to further relieve residual stresses. The microstructure after hardening always contains retained austenite in the range of 10 to 30%. Some retained austenite will be transformed following tempering at low temperatures; but if spalling is a problem, higher subcritical temperature tempering can be used to further reduce austenite contents.

Subcritical Heat Treatment. Subcritical heat treatment (tempering) is sometimes performed, particularly in large heat-treated martensitic castings, to reduce retained austenite contents and increase resistance to spalling. The tempering parameters necessary to eliminate retained austenite are very sensitive to time and temperature and vary depending on the casting's composition and prior thermal history. Typical tempering temperatures range from 480 to 540 °C (900 to 1000 °F) and times range from 8 to 12 h. Excess time or temperature results in softening and a drastic reduction in abrasion resistance. Insufficient tempering results in incomplete elimination of austenite. The amount of retained austenite present cannot be determined metallographically; those experienced with this heat treatment practice have developed techniques, using specialized magnetic instruments, to determine the level of retained austenite after tempering.

Annealing. Castings can be annealed to make them more machinable, either by subcritical annealing or a full anneal. Subcritical annealing is accomplished by pearlitizing, via soaking in the narrow range between 690 and 705 °C (1280 and 1300 °F) for from 4 to 12 h, which will produce hardness in the range 400 to 450 HB. Lower hardness can often be achieved with full annealing, whereby castings are heated in the range 955 to 1010 °C (1750 to 1850 °F) followed by slow cooling to 760 °C (1400 °F) and holding at this temperature for 10 to 50 h depending on composition. Annealing does not affect the primary carbides nor the potential for subsequent hardening; guidelines for hardening as-cast castings also apply to annealed castings.

Stress-Relieving. Very little information is available on the amount of stress relief that occurs with tempering. The predominant stresses present in heat-treated castings develop as a result of the volume change accompanying austenite to martensite transformation. Low-temperature tempering, in the range of 200 to 230 °C (400 to 450 °F), is particularly desirable because a substantial improvement (20%) in fracture toughness occurs when tempering the martensite phase. Tempering at temperatures sufficient to significantly relieve stresses (that is, above 540 °C, or 1000 °F), will substantially reduce abrasion resistance. Therefore, it is much more desirable to minimize the development of transformational stresses via controlled cooling through the martensitic transformation temperature range ($\leq$260 °C, or 500 °F). This is accomplished by slow, controlled cooling to minimize temperature gradients and differential transformation in the casting.

Introduction to Heat Treating of Tool Steels

Revised by Bruce A. Becherer and Thomas J. Witheford, Teledyne Vasco

Introduction

TOOL STEELS are high-quality steels made to close compositional and physical tolerances; they are used to make tools for cutting, forming, or shaping a material into a part or component adapted to a definite use. The earliest tool steels were simple, plain carbon steels, but beginning in 1868, and to a greater extent early in the 20th century, many complex, highly alloyed tool steels were developed. These complex alloy tool steels, which contain, among other elements, relatively large amounts of tungsten, molybdenum, vanadium, and chromium, make it possible to meet increasingly severe service demands and to provide greater dimensional control and freedom from cracking during heat treating. Many alloy tool steels also are widely used for machinery components and structural applications where particularly severe requirements must be met, such as high-temperature springs, ultrahigh-strength fasteners, special-purpose valves, punches and dies, wear-resistant liners, and bearings of various types for elevated-temperature service. This article discusses procedures and process control requirements for heat treating the principal types of tool steels. It also provides a review of heat-treating processes that are applied to tool steels and the specific applicability of these processes to the various types of tool steels.

In service, most tools are subjected to extremely high loads that are applied rapidly. They must withstand these loads a great number of times without breaking and without undergoing excessive wear or deformation. In many applications, tool steels must provide this capability under conditions that develop high temperatures in the tool. No single tool material combines maximum wear resistance, toughness, and resistance to softening at elevated temperatures. Consequently, selection of the proper tool material for a given application often requires a trade-off to achieve the optimum combination of properties. Table 1 gives the classifications and nominal compositions of various tool steels.

(a) These steels were not included in the March 1978 AISI Steel Products Manual, *Tool Steels*, in the main table of compositions nor in tables of heat-treating practice, because of their less common use.

(b) Available with various carbon contents, in increments of 0.10% within this range.

(c) Optional.

(d) Intermediate high-speed steels M50 and M52, which are lower in alloy content than standard high-speed steels, have been employed successfully in applications requiring greater abrasion resistance than plain carbon steels, but less red hardness than high-speed steels. Typical uses include woodworking tools and hack saw blades. M50 and M52 steels meet the criteria promulgated by the American Society for Testing and Materials for intermediate high-speed steels but do not meet the more stringent criteria for standard high-speed steels.

Most tool steels are wrought products, but precision castings can be used to advantage in some applications (additional information is available in the article "Wrought Tool Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*). The powder metallurgy (P/M) process also is used in making tool steels; this process provides more uniform carbide size and distribution in large sections and special compositions that are difficult or impossible to produce by melting and casting and then mechanically working the cast product (additional information is available in the article "P/M Tool Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*).

For typical wrought tool steels, raw materials (including scrap) are carefully selected, not only for alloy content but also for qualities that ensure cleanliness and homogeneity in the finished product. Tool steels are generally melted in small-tonnage electric-arc furnaces to achieve composition tolerances economically, cleanliness and precise control of melting conditions. Special refining and secondary remelting processes such as argon oxygen decarburization (AOD), electroslag remelting (ESR), and vacuum arc remelting (VAR) (see the articles "Vacuum Melting and Remelting Processes" and "Degassing Processes (Converter Metallurgy)" in Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*), have been introduced to satisfy particularly difficult demands on tool steel quality and performance. The medium-to-high alloy contents of many tool steels require careful control of forging and rolling, which often results in a large amount of process scrap. Semifinished and finished bars are given rigorous in-process and final inspection. This inspection can be so extensive that both ends of each bar may be inspected for macrostructure (etch quality), cleanliness, hardness, grain size, annealed structure, and hardenability. The inspection may require that the entire bar be subjected to magnetic, particle, eddy current, and ultrasonic inspections for surface and internal discontinuities. It is important that finished tool steel bars have limited decarburization, which requires that annealing be done by special procedures under closely controlled

conditions. Controlled atmosphere continuous annealing furnaces, vacuum furnaces, and protective coatings are often used to minimize decarburization during annealing.

Such precise production practices and stringent quality controls contribute to the high cost of tool steels, as do the expensive alloying elements they contain. Insistence on quality in the manufacture of these specialty steels is justified, however, because tool steel bars generally are made into complicated cutting and forming tools worth many times the cost of the steel itself. Although some standard constructional alloy steels resemble tool steels in composition, they are seldom used for expensive tooling because, in general, they are not manufactured to the same rigorous quality standards as are tool steels.

The performance of a tool in service depends on:

- Proper tool design
- Accuracy with which the tool is made
- Selection of the proper tool steel
- Application of the proper heat treatment

A tool can perform successfully in service only when all four of these requirements have been fulfilled.

With few exceptions, all tool steels must be heat treated to develop specific combinations of wear resistance, resistance to deformation or breaking under high loads, and resistance to softening at elevated temperatures. A few simple shapes may be obtained directly from tool steel producers in correctly heat-treated condition. However, most tool steels first are formed or machined to produce the required shape and then heat treated as required. Figure 1 shows typical processing and heat-treatment sequences for tool steels as a function of time, temperature, and phase transformation. Improper finishing after heat treatment--principally grinding--can damage tool steels through the development of surface residual stresses and cracks. Some tools are heat treated (hardened) in a blank or semifinished state and subsequently ground, turned, or electrical discharge machined to create the final tool. Although these manufacturing techniques have progressed in recent years, metallurgical damage and surface stresses are still a major concern.

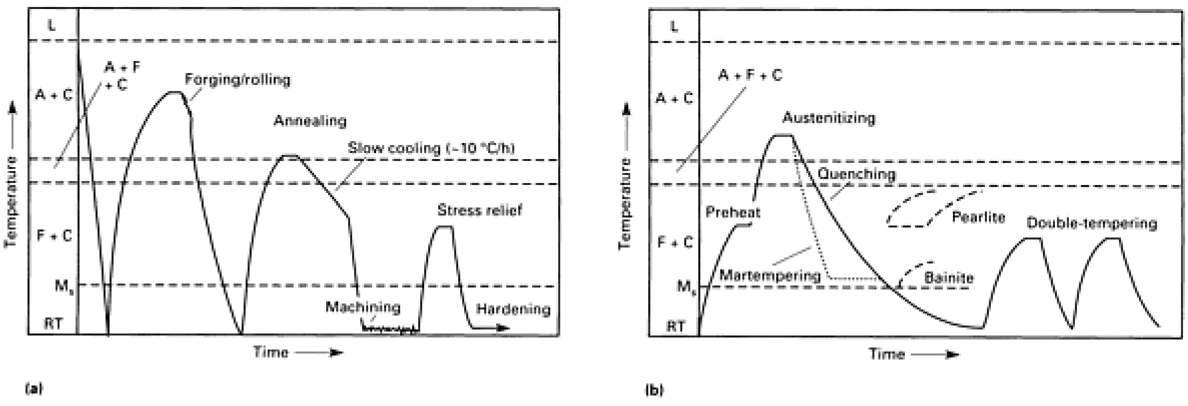

Fig. 1 Plots of temperature versus time showing sequence of operations required to produce tool steels. (a) Thermomechanical processing. (b) Hardening heat treatment. L, liquid; A, austenite; C, cementite; F, ferrite; M_s, temperature at which martensite starts to form on cooling; RT, room temperature. Source: Ref 1

Processing information and service characteristics of tool steels are presented in Tables 2, 3, 4. This information is essential in understanding the problems involved in selection, processing, and application of tool steels. Tool steel suppliers provide more specific information on the properties developed by specific heat treatments in the steels produced by their companies. They should be consulted as to the type of steel and heat treatment best suited to meet all service requirements at the least over-all cost.

(a) Time held at temperature varies from 15 min for small sections to 1 h for large sizes. Cooling is done in still air. Normalizing should not be confused with low-temperature annealing.

(b) The upper limit of ranges should be used for large sections and the lower limit for smaller sections. Time held at temperature varies from 1 h for light sections to 4 h for heavy sections and large furnace charges of high-alloy steel.

(c) For 0.25 Si type, 183 to 207 HB; for 1.00 Si type, 207 to 229 HB.

(d) Temperature varies with carbon content: 0.60 to 0.75 C, 815 °C (1500 °F); 0.75 to 0.90 C, 790 °C (1450 °F); 0.90 to 1.10 C, 870 °C (1600 °F); 1.10 to 1.40 C, 870 to 925 °C (1600 to 1700 °F).

(e) Temperature varies with carbon content: 0.60 to 0.90 C, 740 to 790 °C (1360 to 1450 °F); 0.90 to 1.40 C, 760 to 790 °C (1400 to 1450 °F).

Table 3 Hardening and tempering of tool steels

(a) O, oil quench; A, air cool; S, salt bath quench; W, water quench; B, brine quench.

(b) When the high-temperature heating is carried out in a salt bath, the range of temperatures should be about 15 °C (25 °F) lower than given in this line.

(c) Double tempering recommended for not less than 1 h at temperature each time.

(d) Triple tempering recommended for not less than 1 h at temperature each time.

(e) Times apply to open-furnace heat treatment. For pack hardening, a common rule is to heat 1.2 min/mm (30 min/in.) of cross section of the pack.

(f) Preferable for large tools to minimize decarburization.

(g) Carburizing temperature.

(h) After carburizing.

(i) Carburized case hardness.

(j) P21 is a precipitation-hardening steel having a thermal treatment that involves solution treating and aging rather than hardening and tempering.

(k) Recommended for large tools and tools with intricate sections

Table 4 Processing and service characteristics of tool steels

Normalizing

Normalizing requires slow and uniform heating above the transformation range to dissolve excess constituents, then cooling in still air (see the article "Normalizing of Steel" in this Volume). Normalizing breaks up nonuniform structures, relieves residual stresses, and produces greater uniformity in grain size--thus counteracting undesirable results of unequal reductions for different sections during forging, differences in temperature between varying thicknesses of sections, and the subsequent irregular cooling rates. Normalizing also conditions the steel for subsequent spheroidizing, annealing, or hardening.

Applicability. Many tool steels harden even when cooled in still air; normalizing these steels for the purpose of refining a structure is not recommended. Tool steels that should not be normalized include all high-speed steels, all shock-resisting steels, all hot work steels, cold work steels of types A and D (except A10), and the mold steel P4.

For other types of tool steel, normalizing is most commonly applied after forging and before annealing. Normalizing also may be used before full annealing for parts that are being hardened for a second time.

Standard practice consists of heating to the normalizing temperature, soaking for a suitable time to allow the bar to reach a uniform temperature, and then cooling in still air. No special equipment is required, but the work should be protected against decarburization during heating.

Annealing

Tool steels usually are received from the supplier in the annealed condition. This condition allows the steel to be easily machined and heat treated. However, if they are subjected to hot or cold forming, often they must be fully annealed again before subsequent operations. If a tool is to be rehardened, it should first be thoroughly annealed. This procedure is important with the steels of higher alloy content; otherwise, irregular grain growth occurs and a mixed grain size (sometimes called fish scale or duplex grains) will result.

Full annealing involves heating the steel slowly and uniformly to a temperature above the transformation range, holding it at the temperature for from 1 to 4 h (which is generally long enough for complete heat penetration), and cooling slowly at a controlled rate followed by air cooling.

Atmosphere furnaces, salt baths, vacuum furnaces, or lead pots may be used for annealing. Requirements of the heating equipment include reasonably accurate temperature control and a means of preventing decarburization. In box or roller-hearth furnaces, surface protection often is accomplished through proprietary decarb-resistant coating or by packing the workpieces in pipes, in which they are then surrounded by nondecarburizing material, such as spent charcoal and mica, or cast iron chips. Furnaces with prepared atmospheres frequently are used for the annealing of tool steels.

These packing materials may carburize, decarburize, or be neutral to steel, depending on the heating temperature, the carbon content of the steel, and the density of the packing (also the particle size of the packing material). The principal aim of such materials is to exclude the decarburizing gases from contact with the steel. If oxygen is to be excluded, the packing must be very tight and the sealing of the container perfect, for most gases can diffuse through ordinary seals at a surprisingly rapid rate at elevated temperatures. Materials that contain carbonaceous substances are, therefore, somewhat better where this is the case. In the annealing operation, where scale is present on the bars as charged in the furnace, decarburization may occur unless a carbonaceous material is present. Needless to say, the presence of moisture in the packing material is not tolerable as decarburization will take place very readily.

Figure 2 shows the range of usefulness of each of the packing compounds. This should be used only as a guide, as the presence of scale, the age of the packing compound, the moisture content, and the carbon content of the steel will appreciably alter the range. Furthermore, the temperature at which one material will change from neutral to decarburizing is not necessarily as definite as that indicated. It is to be noted that the effect of carbon content is not included. The chart applies particularly to high-carbon steels.

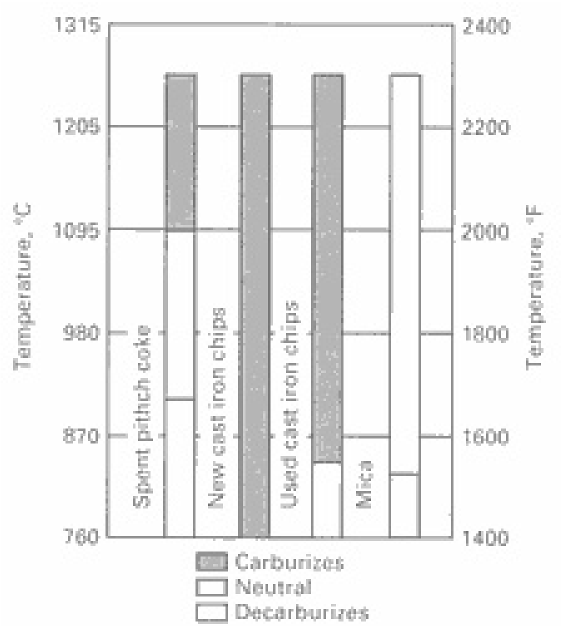

Fig. 2 Approximate range of usefulness of selected packing compounds used in the annealing of tool steels. Temperatures of change from one behavior to another are actually not sharp. For cast iron chips, the temperature below which decarburization will take place depends on the carbon content of the chip. Source: Ref 2

Cracking from thermal shock can be minimized by loading the furnace at a relatively low temperature (room temperature or a few hundred degrees Fahrenheit) to permit the furnace load to heat up slowly with the furnace. Following the soak at annealing temperature, the workpieces (and container, if used) should be cooled in the furnace at 8 to 22 °C/h (15 to 40 °F/h) to 540 °C (1000 °F) or lower. Below about 540 °C (1000 °F), the cooling rate for most tool steels is no longer critical, and the work may then be cooled in air. Typical annealed hardness values for the various tool steels are given in Table 1.

Additional information is available in the articles "Annealing of Steel" and "Continuous Annealing of Steel" in this Volume.

Isothermal annealing is an alternative method of cooling that consists of rapidly cooling the workload in the furnace from the annealing temperature to a temperature just below the transformation range and holding the load and furnace at this temperature for one or more hours. Following this period of soaking at just below the transformation range, the load may be safely air cooled. This process, known as isothermal annealing, is best suited for applications in which full advantage can be taken of the rapid cooling to the transformation temperature, and from this temperature to room temperature. Thus, for small parts that can be handled in salt or lead baths, or for light loads in batch furnaces, isothermal annealing makes possible large savings in time, as compared with the conventional slow furnace cooling. It can also be adapted conveniently to continuous annealing cycles where adequate equipment is available.

Isothermal annealing offers no particular advantage for applications (such as the batch annealing of large furnace loads) in which the rate of cooling at the center of the load may be so slow as to preclude any rapid cooling to the transformation temperature. For such applications, conventional full annealing usually offers a better assurance of obtaining the desired properties.

Stress Relieving

Stress relieving removes or reduces residual stress induced in tools by heavy machining or forming, and thereby decreases the probability of distortion or cracking during hardening of the tool (see the article "Stress-Relief Heat Treating of Steel" in this Volume).

The ground surface of a hardened tool may be highly stressed after grinding but not cracked. The high stress may, however, cause cracks to develop immediately after grinding, before use, or during use. Ground tools with high residual stress can often be salvaged by stress relieving, immediately after grinding, at or just below the tempering temperature in order to maintain the specified tool hardness.

Tools also develop high residual stress in use. It is sometimes advantageous to relieve this stress at each redressing of the tool by retempering at an appropriate temperature. This temperature should not exceed the tempering temperature; otherwise, undesirable softening will occur.

Procedure. Stress relieving is most commonly performed in air furnaces or salt baths used for tempering. Neither the heating nor the cooling rate is critical, although cooling should be slow enough to prevent the introduction of new stress. Protection against scaling or decarburization is seldom required, unless the stress-relieving temperature is above 650 °C (1200 °F). Under some conditions, vacuum or inert atmosphere furnaces may be required to prevent scaling or discoloration.

After stress relieving, it may be necessary to correct certain dimensions before hardening, because the relief of stress causes some dimensional change. Precision tools usually are stress relieved after machining and before hardening; it is often desirable to stress relieve after rough machining but before finish machining. Stress relieving after electrical discharge machining (EDM) work will reduce some of the residual stress but will not remove all of the effects of this machining method.

Austenitizing

Austenitizing is the most critical of all heating operations performed on tool steels. Excessively high austenitizing temperatures or abnormally long holding times may result in excessive distortion, abnormal grain growth, loss of ductility, and low strength; this is especially true for high-speed steels, which are frequently austenitized at a temperature close to that at which melting begins. Underheating may result in low hardness and low wear resistance. At the time of quenching, if the center of a tool is cooler than the exterior, spalling or fracturing of the corners may result, particularly with water-hardening steels. Prior to heat treatment, all tool surfaces must be free of decarburization. Typically, steel is supplied decarb free of centerless ground bar or precision ground flats. If hot rolled material is purchased, sufficient stock must be removed.

Austenitizing is the heat treatment where the final alloy element partitioning between the austenitic matrix (that will transform to martensite) and the retained carbides occurs. This partitioning fixes the chemistry, volume fraction, and dispersion of the retained carbides. The retained alloy carbides not only contribute to wear resistance, but also control austenitic grain size. The finer the carbides and the larger the volume fraction of carbides, the more effectively austenitic grain growth is controlled. Thus if austenitizing is performed at too high a temperature, undesirable grain growth may occur as the alloy carbides increasingly coarsen or dissolve into the austenite.

The alloying elements not tied up in retained carbides are in solution in the austenite, and thus the carbides provide an important mechanism by which austenite composition is fixed. The austenite composition then sets the hardenability, M_s temperature, retained austenite content, and secondary hardening potential of a tool steel.

Figure 3 shows the effect of increasing austenitizing temperature on the as-quenched, quenched and subzero cooled, and tempered hardness of an A2 tool steel. The highest as-quenched hardness is produced by austenitizing at 950 °C (1740 °F), the recommended austenitizing temperature for A2. In this condition after quenching, the retained austenite content is finely dispersed and at a minimum and therefore subzero cooling has little effect on hardness. With increasing austenitizing temperature, more alloying elements go into solution, the M_s temperature drops, and more austenite is retained at room temperature. As a result, the as-quenched room temperature hardness decreases and subzero cooling has a greater effect as more of the large volume fraction of retained austenite transforms to martensite on subzero cooling. Figure 4 shows that eventually tempering, by a combination of retained austenite transformation and secondary hardening, will also raise the hardness of as-quenched structures with large amounts of retained austenite. Not shown is the deleterious increase in austenite grain size which develops as more and more carbides dissolve at the higher austenitizing temperatures.

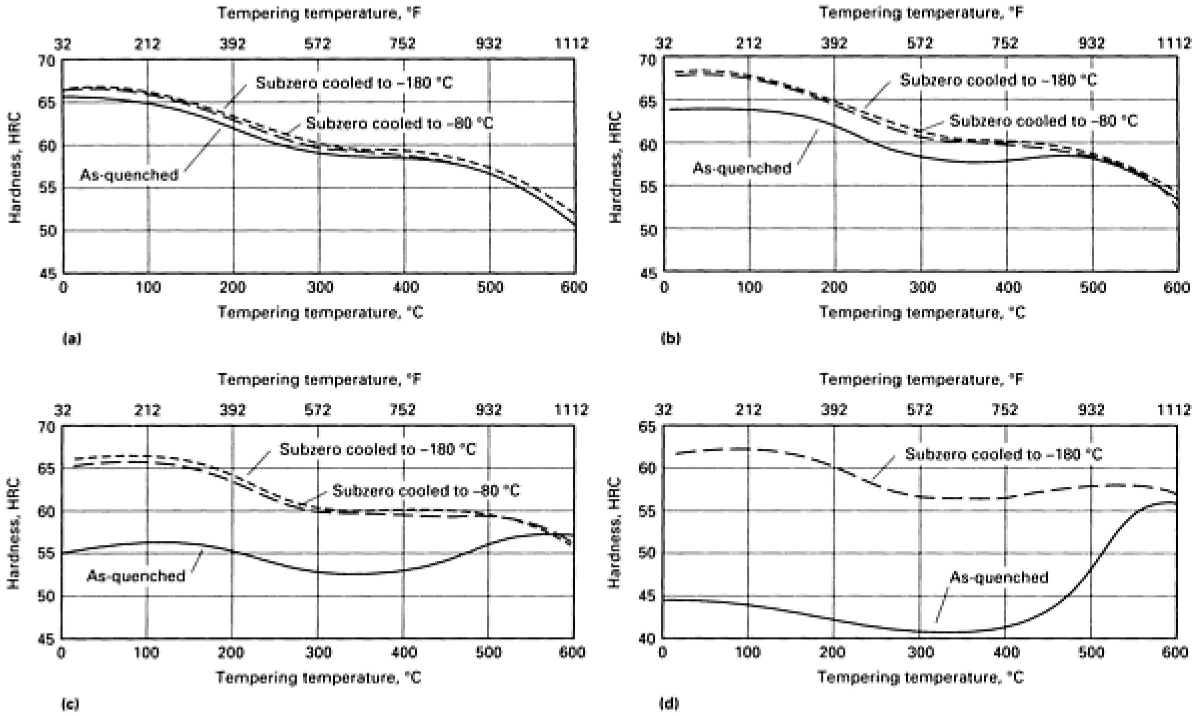

Fig. 3 Plots of hardness versus tempering temperatures of as-quenched, quenched, and subzero cooled to -80 °C (-110 °F), and quenched and subzero cooled to -180 °C (-290 °F) A2 tool steels to show effect of increasing austenitizing temperatures. (a) 950 °C (1740 °F). (b) 1000 °C (1830 °F). (c) 1050 °C (1920 °F). (d) 1100 °C (2010 °F). Source: Ref 3

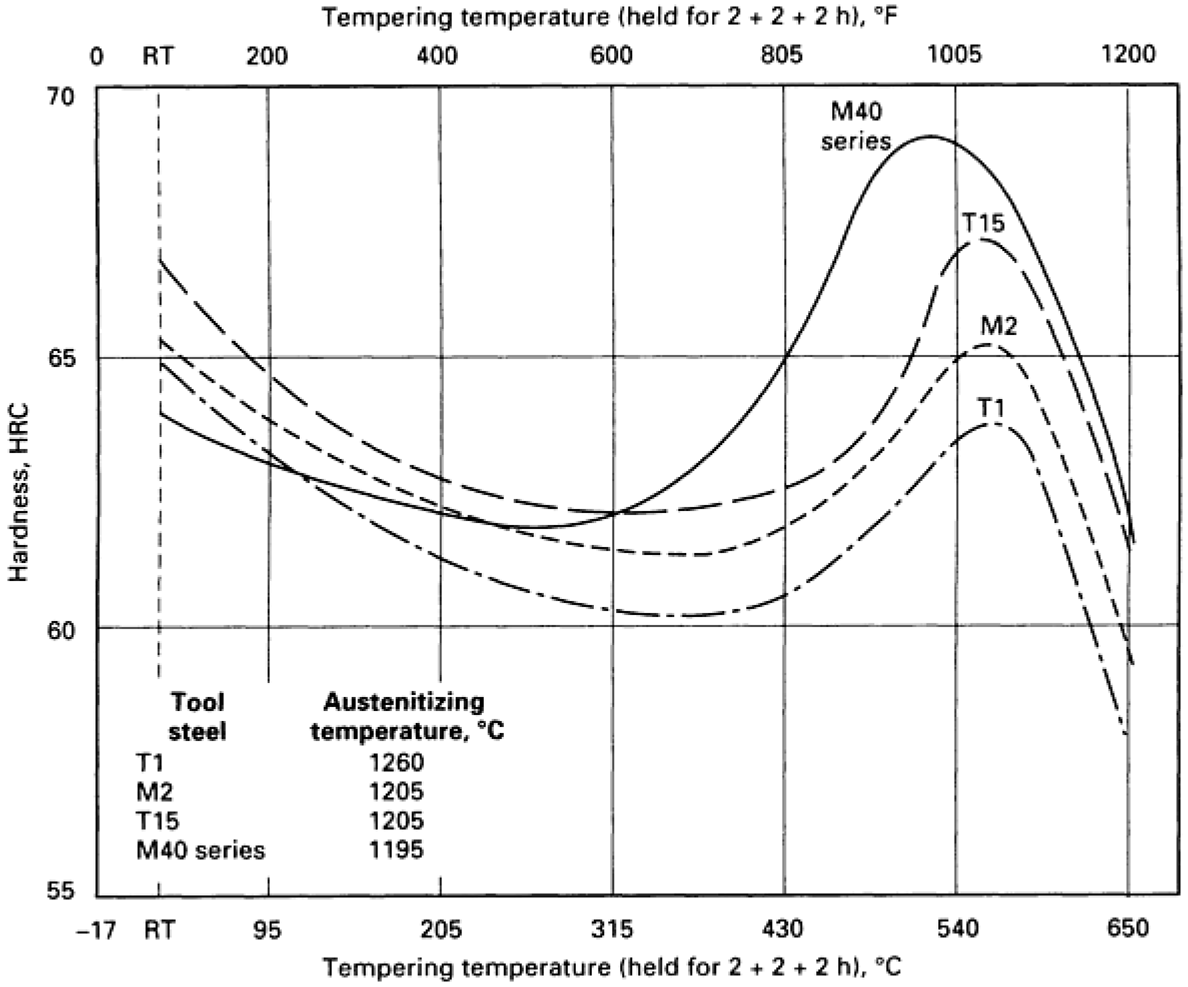

Fig. 4 Plot of hardness versus tempering temperature for selected high-speed tool steels. Source: Ref 4

Equipment for austenitizing tool steels is chosen on the basis of steel composition, size and shape of workpieces, amount of stock removal after hardening, and production requirements. Vacuum furnaces, atmosphere furnaces, and salt baths have proved satisfactory for service over the entire austenitizing temperature range of 760 to 1300 °C (1400 to 2375 °F). Lead pots are suitable for the temperature range of about 760 to 925 °C (1400 to 1700 °F).

Workpieces must be supported during austenitizing. Lead and salt provide some of the support, but in atmosphere furnaces, special attention must be given to prevent workpieces from sagging or making contact with the furnace brickwork.

During austenitizing, continuous control of the furnace internal environment must be maintained to prevent workpieces from becoming carburized or decarburized. Salt baths must be rectified; atmospheres must be controlled for proportion of gases and dew point; lead baths must be kept free of contamination. Vacuum furnaces must be maintained at low leak rates and partial pressure control at austenitizing temperatures, above 1095 °C (2000 °F).

Preheating for Austenitizing. Preheating tool steels before austenitizing is sound practice, but it is not always required. For small pieces of simple shape, preheating may be eliminated. Preheating normally is employed as a safeguard against the cracking and extreme distortion resulting from the thermal shock undergone by a cold workpiece when it is exposed to the high temperature of the austenitizing furnace.

Preheating is especially beneficial for the highly alloyed hot work and high-speed steels, because it gives them a greater length of time to reach thermal equilibrium and eliminates most of the risk of prolonged exposure to austenitizing temperatures such as decarburization and the tendency for surfaces of large sections to experience longer exposure times.

Tools that are to be austenitized in salt are usually preheated in salt, but they may be preheated in an atmosphere furnace if it is more convenient. Tools that are to be austenitized in an atmosphere furnace are preheated in a gaseous atmosphere.

Procedure. Preheating is usually done in a furnace adjacent to the austenitizing furnace, although it is possible to preheat and austenitize in the same furnace. In the latter procedure, once the workpiece is heated through to the preheat temperature, the furnace temperature is raised to the austenitizing temperature and the workpiece is thus brought to the austenitizing temperature without leaving the furnace. The practicality of this one-furnace procedure depends on the difference between preheating and austenitizing temperatures for the type of steel being treated and on production requirements. Some experts do not recommend this procedure for high-speed steels, especially where high-inertia furnaces are used, because the difference between preheating and austenitizing temperatures for these steels may be as much as 485 °C (875 °F). In high-volume operations, where preheating is frequently performed solely to shorten production time, separate furnaces can be used for preheating and austenitizing.

Quenching

Quenching from the austenitizing temperature may be done in water, brine, oil, salt, inert gas, or air, depending on composition and section thickness. The quenching medium must cool the workpiece rapidly enough to obtain full hardness; it is poor practice, however, to use a quenching medium with a cooling capacity that exceeds requirements, because of the possibility that cracking or excessive distortion may occur.

Tool steels that will harden during air cooling are frequently hot quenched to the range 540 to 650 °C (1000 to 1200 °F) after austenitizing. Quenching time is long enough for decomposition of austenite to begin. After hot quenching, the steels are air cooled or oil quenched to ambient temperature. Hot quenching minimizes distortion without adversely affecting hardness and spaIls away or prevents the hard scale from forming on most air-hardening steels during air cooling. Additional information is available in the article "Quenching of Steel" in this Volume.

Martempering is often utilized to minimize distortion without sacrifice of hardness in oil-hardening tool steels or in extremely thin sections of water-hardening tool steels (see the article "Martempering of Steel" in this Volume). Workpieces are quenched from the austenitizing temperature in an agitated bath of oil or salt. Bath temperature should be near the temperature at which martensite starts to form on cooling (M_s), usually about 31 °C (57 °F) above it. Time in the bath should be just sufficient for temperature to equalize throughout the workpieces, which are then air cooled to room temperature prior to tempering.

Tempering

Tempering modifies the properties of quench-hardened tool steels to produce a more desirable combination of strength, hardness, and toughness than obtained in the quenched steel (see the article "Tempering of Steel" in this Volume). The as-quenched structure of tool steel is a heterogeneous mixture of retained austenite, untempered martensite, and carbides. More than one tempering cycle may be necessary to produce an optimum structure. It is normally desirable to transform all retained austenite to ensure complete hardness, improve toughness, and minimize distortion during service. This can be more nearly accomplished by two or more shorter tempering cycles than by a single and longer cycle (see Fig. 4).

In the higher-alloy tool steels, a small amount of untempered martensite is formed from retained austenite during the cool-down from the first tempering cycle. It is good practice to double temper to ensure more nearly complete transformation of retained austenite and to temper freshly formed martensite. For some highly alloyed grades of tool steel, triple or quadruple tempering is recommended.

The changes that take place in the microstructure during tempering of hardened tool steels are time-temperature dependent. Time at tempering temperature should not be less than 1 h for any given cycle.

Most manufacturers of high-speed steels recommend multiple tempers of 2 h or more each to attain the desired microstructure and properties. Maintaining recommended tempering times, temperatures, and number of tempers (a

minimum of two) ensure attainment of consistent tempered martensitic structures and overcomes uncertainties caused by variations in the amount of retained austenite in the as-quenched condition. These variances are functions of differences in heat chemistry, prior thermal history, hardening temperatures, and quenching conditions. Other factors that influence the tempering requirements of high-speed steels are:

- Increasing the free (matrix) carbon content increases the amount of retained austenite in the as-quenched condition
- The amount of retained austenite significantly affects the rate of transformation, particularly for short tempering cycles. Multiple tempering is more important to attain an acceptable structure if short tempering times are used
- Cobalt in alloys such as M42 reduces the amount of retained austenite in the as-quenched condition and accelerates the transformation of the retained austenite during tempering

Enough time should be allowed during tempering for the temperature to be distributed uniformly throughout the tools before time at temperature is counted. This is especially true for low tempering temperatures and for tools that have large sections. Table 7 indicates the time needed for various section sizes to reach uniform temperature in different kinds of furnaces. If not enough time is allowed for the tool to reach the tempering temperature, the result will be nonuniform tempering and possible damage to the tool. Color of the oxide film should not be used as a guide in tempering, because these temper colors indicate only the surface temperature of the tool, not the internal temperature. Grinding cracks in hardened tools may be caused by inadequate tempering.

Table 7 Approximate heating time to attain tempering temperature

Tempering temperature		Time required to reach furnace temperature[a]:

(a) Data are given in minutes per millimeter, and in minutes per inch, of diameter or thickness, with furnace maintained at the temperature indicated in column 1. Data may be used as a guide for charges of irregular shapes and quantities by estimating total size of charge and applying the above allowance to the number of inches from outside to center of charge.

(b) Times indicated are for tools with dark or scaled surfaces. If surfaces are finish ground, or otherwise brightened, twice as much time should be allowed in a still hot air oven. No extra allowance need be made for bright surfaces in a circulating oven or in an oil bath.

(c) Oil baths are usually not used above 205 °C (400 °F).

Proper tempering depends on the accurate determination of the temperature of the load and on proper spacing of workpieces in the load to ensure that it is uniformly heated. The most common medium used for tempering tools is recirculating-atmosphere furnaces, where the atmosphere may be flue gas, nitrogen, argon, or even a partial vacuum. Regardless of the medium used for tempering, accurate means of temperature control are mandatory for reproducible results.

Procedure. Before a tool steel part is tempered, it should be cooled in the quenched medium or in air until it can be held in the hand without discomfort (near 50 °C, or 120 °F, for most steels). For particularly large or intricate parts, it is essential to temper as soon as possible after the quench, to prevent cracking.

Heating to the tempering temperature should be slow, to obtain uniform distribution of temperature within the tool and to prevent the nonuniform relief of hardening stress that could cause cracking or warping. Satisfactory results may be obtained by charging the tools into a freely circulating medium at the desired tempering temperature and then permitting them to reach this temperature. If tempered in a liquid medium, the tools should be placed in a basket and not permitted to come in contact with the hot walls or bottom of the pot or tank. Heat transfer is most rapid for molten lead baths, less rapid for salt and oil baths, and slowest in still air.

Cooling after tempering should be relatively slow in order to prevent development of residual stress in the steel. Still air cools at a satisfactory rate.

Equipment. Recirculating-air furnaces have several advantages over most other types of equipment used for tempering. For example, such a furnace can be cooled rapidly between batches of tempering temperatures so that successive work loads may enter the furnace safely at a low temperature. Another advantage of the recirculating-air furnace is its relatively low heat transfer rate, which permits the load to be brought to temperature more slowly. As-quenched tools heated too rapidly may develop cracks. Recirculating-air furnaces also usually afford a wider range of useful tempering temperatures than other tempering mediums, with no hazards of fire or burns from splashing of hot liquids.

Surface Treatments and Cold Treating

Carburizing of tool steels is usually restricted to special applications. Mold steels, however, are commonly carburizing and then case hardened. A marked increase in surface carbon renders most tools too brittle for their intended uses. However, tools made of shock-resisting steel, hot work steel, and especially the lower-carbon types of high-speed steel are sometimes carburized to advantage for use in certain die applications involving severe wear. Carburizing is also useful for applications such as cold work dies that require extreme wear resistance and that are not subjected to impact or highly concentrated loading. All the common methods of carburizing (gas, pack, and liquid) have been employed for these special applications (see the articles "Gas Carburizing," "Pack Carburizing," and "Liquid Carburizing and Cyaniding" in this Volume). Case depths are shallower, about 0.05 to 0.25 mm (0.002 to 0.010 in.), rather than the 0.75 to 1.5 mm (0.030 to 0.060 in.) that is common on conventional carburizing steels.

Carburizing temperatures, typically 1040 to 1065 °C (1900 to 1950 °F) are held for 10- to 60-min durations. The carburizing treatment also serves as an austenitizing treatment for the whole tool. A carburized case on high-speed steels has a hardness of 65 to 70 HRC but does not have the high resistance to softening at elevated temperatures exhibited by normally hardened high-speed steel.

Nitriding successfully increases the life of all types of high-speed steel cutting tools. For nitrided high-speed steel taps, drills, and reamers used in machining annealed steel, five-fold increases in life have been reported, with average increases of 100 to 200%. Obviously, if this nitrided case is removed when the tool is reground, the tool must then be retreated, which reduces the cost advantage of the process.

Gas nitriding, however, produces a case that is too brittle for most applications. Gas nitriding of tool steels is limited to applications such as hot work tool steels (H grades) and tooling for aluminum extrusion dies. Additional information is available in the article "Gas Nitriding" in this Volume.

Liquid nitriding of finished high-speed steel tools in cyanide-base salt baths at 510 to 565 °C (950 to 1050 °F) is a common method of increasing tool life because it provides a light case, increasing both surface hardness and resistance to adhesion. Nitriding time ranges from 15 min to 2 h, resulting in case depths up to about 0.05 mm (0.002 in.). Due to environmental considerations, sources for liquid nitriding are becoming rare. Additional information is available in the article "Liquid Nitriding" in this Volume.

Vacuum Nitriding. Vacuum furnaces, especially vacuum tempering furnaces, can be used for nitriding of tools. The tempering furnace is ideally suited for this purpose because it is designed to operate in the nitriding temperature range. For high-speed steels and other tools tempered at 455 to 595 °C (850 to 1100 °F), the nitriding cycle can be incorporated into the final tempering cycle, by introducing a partial pressure of ammonia during the final temper. In this way, the vacuum furnace operates similar to a normal nitriding furnace, except that nitrogen or the vacuum itself acts as the dilutant for nitriding, replacing dissociated ammonia. Cycle times would be the same as for gas nitriding.

Plasma Nitriding. Another process used for nitriding tool steels is plasma nitriding, also known as ion nitriding. It is used in the nitriding of high-speed (M and T series), cold work (A and D series), and hot work (H series) tool steels (Ref 5). This process is also a vacuum process, but employs the principle of glow discharge to provide energy for heating and nitriding (see Fig. 5). Because it relies on electrical energy to dissociate gases, activate surfaces, and to provide energy for reaction, ordinary nitrogen at pressures in the range 0.1 to 1 kPa (1 to 10 mm Hg) are all that is required for nitriding. In addition, by adjusting the amount of nitrogen, the surface white layer can be closely controlled or eliminated. As in the other methods, the cycles are very short. In addition, the temperature range is greatly expanded, to as low as 350 °C (660 °F), because the glow discharge reaction is not dependent on ammonia breakdown as in gas nitriding. This permits greater flexibility in choice of nitriding temperature so that surface hardness, case depth, and core hardness can be optimized for a given steel.

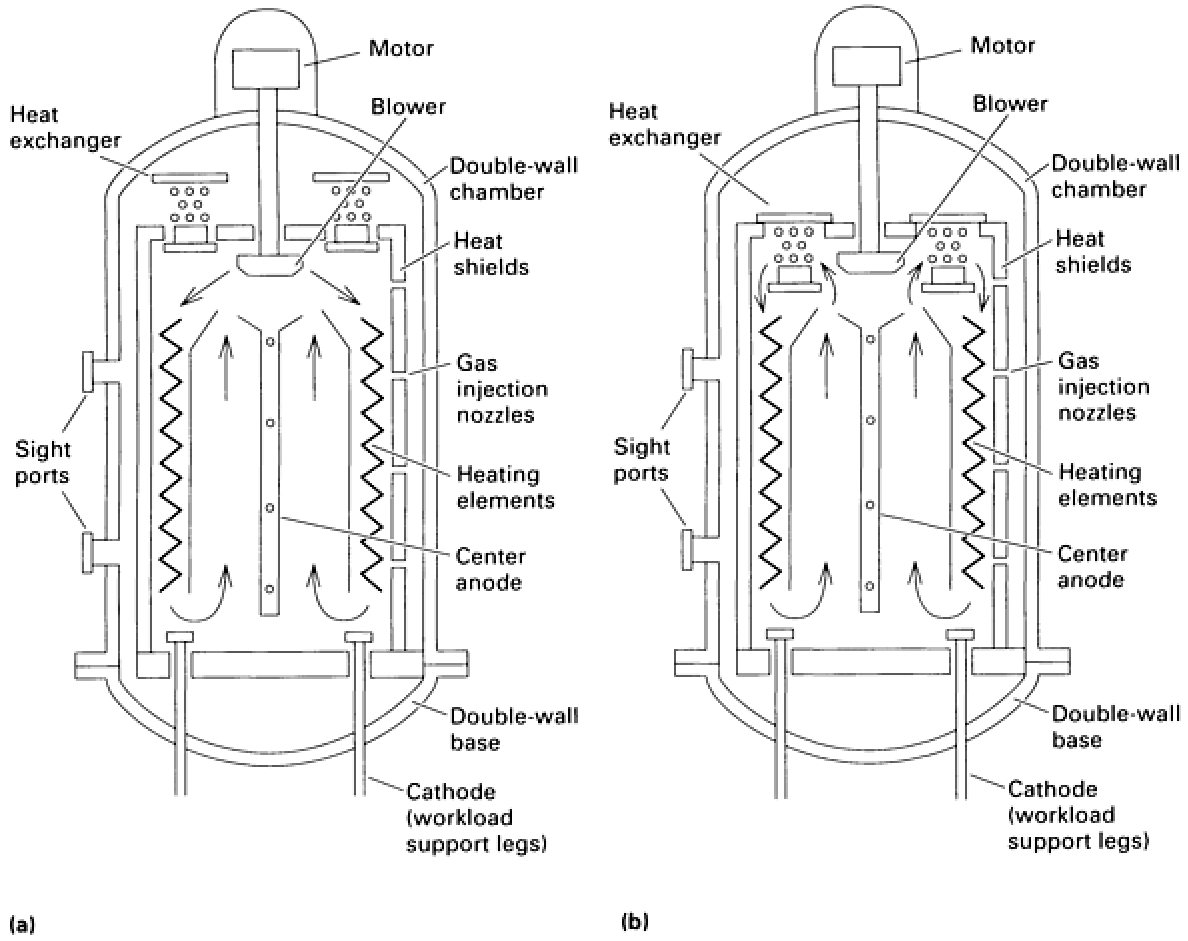

Fig. 5 Schematic of plasma-nitriding furnace showing gas circulation during (a) heating and (b) cooling. Source: Ref 5

Titanium Nitride Coatings. Several techniques are being used for the application of nitride coatings. Most processes are proprietary and carried out on a commercial basis. The most frequently applied material is titanium nitride. Very thin coatings in the 0.025 mm (0.001 in.) thickness range or less produce 69 HRC high hardness, cutting edges on drills, reamers, and other cutting tools. See the article "High-Speed Tool Steels" in Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Sulfide Treatment. A low-temperature (190 °C, or 375 °F) electrolytic process using sodium and potassium thiocyanate provides a seizing-resistant iron sulfide layer. This process can be used as a final treatment for all types of hardened tool steels without much danger of overtempering.

Oxide coatings, provided by treatment of the finish-ground tool in an alkali-nitrate bath or by steam oxidation, prevent or reduce adhesion of the tool to the workpiece. Oxide coatings have doubled tool life--particularly in machining of gummy materials such as soft copper and nonfree-cutting low-carbon steels.

Chromium plating of finished high-speed steel tools with 0.0025 to 0.0125 mm (0.1 to 0.5 mil) of chromium also prolongs tool life by reducing adhesion of the tool to the workpiece. Chromium plating is relatively expensive, and precautions must be taken to prevent tool failure in service due to hydrogen embrittlement.

Electroless nickel plating has been used successfully as a replacement for chromium plating, both in routine production and for salvage plating operations on tool steel parts. Because plating by this method is accomplished by means of chemical reduction, it does not depend on any galvanic coupling between dissimilar metals, and there is no electrolysis involved. Therefore, there is no danger of hydrogen embrittlement. Plated hardness is in the high Rockwell 50's range, with good, uniform plated thickness on all surfaces, and the plated surfaces have a low coefficient of friction.

Cold Treating. The main purpose of cold treating tool steels (to -75 °C, or -100 °F, or lower) is to transform retained austenite in the unfinished tool and thus to provide dimensional stability in subsequent finishing operations. The use of cold treatment on properly heat-treated cutting tools does not affect tool performance. When used, cold treatment should be performed between the first and second tempering operations. Although cold treating an as-quenched tool is more effective in transforming retained austenite than after the first temper, it does increase the chance of cracking.

Additional information is available in the article "Cold Treating and Cryogenic Treatment of Steel" in this Volume.

Processes and Furnace Equipment for Heat Treating of Tool Steels

Bruce A. Becherer, Teledyne Vasco

Introduction

THE HEAT TREATMENT of tool steels is as important to their success as the selection of the grade itself. Machine tools or production dies made from tool steels should never have their rigid metallurgical requirements compromised or out-weighed by cost considerations. Attempting to reduce production costs by bypassing steps in the heat treat processing of tool steels will yield an end product that fails to meet tool life expectations and does not justify its high initial expense. These metallurgical requirements involve the control of the surface condition and chemistry, accurate control of the temperatures often up to 1315 °C (2400 °F), the time at a given temperature, and the control of the heating and cooling rates. Special attention must be paid to these requirements in the design, construction, and operation of the furnaces used to heat treat tool steels, especially those used for hardening, where the metallurgical factors involved become all-important.

Tool steels are typically heat treated in ceramic-lined salt bath furnaces, in vacuum furnaces, in controlled atmosphere furnaces, and in fluidized-bed furnaces.

Salt Bath Furnaces

Molten salts of various compositions are well adapted to all operations in the heat treatment of tool steels. For tools that cannot be ground after hardening or for tools that require an excellent surface condition and the maintenance of sharp edges, salt bath heating provides excellent results. Table 1 lists various salt bath compositions and processing temperatures for the heat treating of tool steels. The salt bath method of hardening is predominant with high-speed steel

tools. With correct operating conditions, tools can be heat treated without carburization, decarburization, and scaling. The surface will be fully hard with a minimum of distortion. Three types of salt baths are generally used:

- Preheating baths
- High-temperature baths
- Quenching baths

Table 1 Typical compositions and recommended working temperature ranges of salt mixtures used in heat treating tool steels

Salt mixture No.	**Composition, %**						**Melting point**		Working range

Preheating serves to minimize thermal shock, equalize temperature, and minimize the amount of time required at the high-temperature stage. The high-temperature salt bath serves as the austenitizing step. The function of the quenching bath is to equalize the temperature as well as to ensure a clean surface after heat treatment.

Most tools heat treated in salt baths are fully hard from surface to core regardless of the section thickness. Because salt baths provide temperature uniformity in preheating, in high-temperature heating, and in quenching, distortion and residual stress are minimized.

Tools that are heat treated in molten salt baths are heated by conduction with the molten salt providing a ready source of heat as required. Although steels come in contact with heat through the tool surfaces, the core of a tool rises in temperature at approximately the same rate as its surface. Heat is quickly drawn to the core from the surface. Salt baths provide heat at a rate equal to the heat absorption rate of the total tool. Convection or radiation heating methods are unable to maintain the rate of heating necessary to reach equilibrium with the rate of heat absorption. The ability of a molten salt bath to supply heat at a rapid rate enhances the uniformity of properties and resultant high quality of tools heat treated in salt baths. Heat-treating times are also shortened; for example, a 25 mm (1 in.) diam bar can be heated to

temperature equilibrium in 4 min in a salt bath, while 20 to 30 min would be required to obtain the same properties in convection or radiation furnaces.

Salt baths are an efficient method of heat treating tool steels; about 93 to 97% of the electric power consumed in a salt bath operation goes directly into heating. Tool steels that are heat treated in molten salts typically are processed in ceramic-lined furnaces with submerged or immersed electrodes containing chloride-base salts.

Immersed-Electrode Salt Bath Furnaces

Ceramic-lined furnaces with immersed (over-the-side) electrodes have greatly extended the useful range and capacity of molten salt equipment when compared with externally heated pot furnaces (see Fig. 1). Detailed information is available in the article "Salt Bath Equipment" in this Volume.

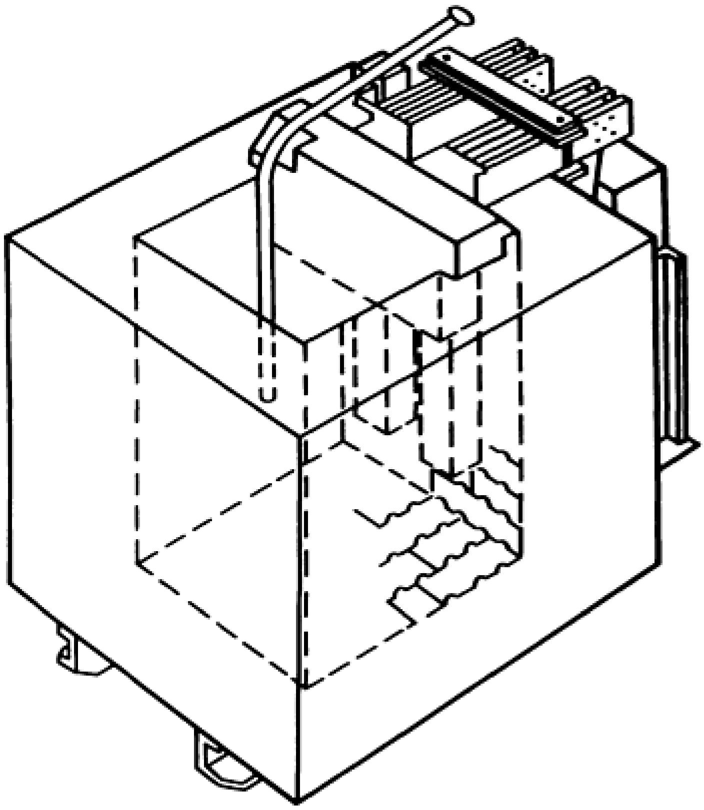

Fig. 1 Salt bath furnace used for neutral heating applications. Furnace features a ceramic pot and over-the-top (immersed) electrodes.

Submerged-Electrode Salt Bath Furnaces

Submerged-electrode furnaces have the electrodes placed beneath the working depth for bottom heating. Figure 2 is a cutaway showing typical construction of a submerged-electrode furnace. Detailed information is available in the article "Salt Bath Equipment" in this Volume.

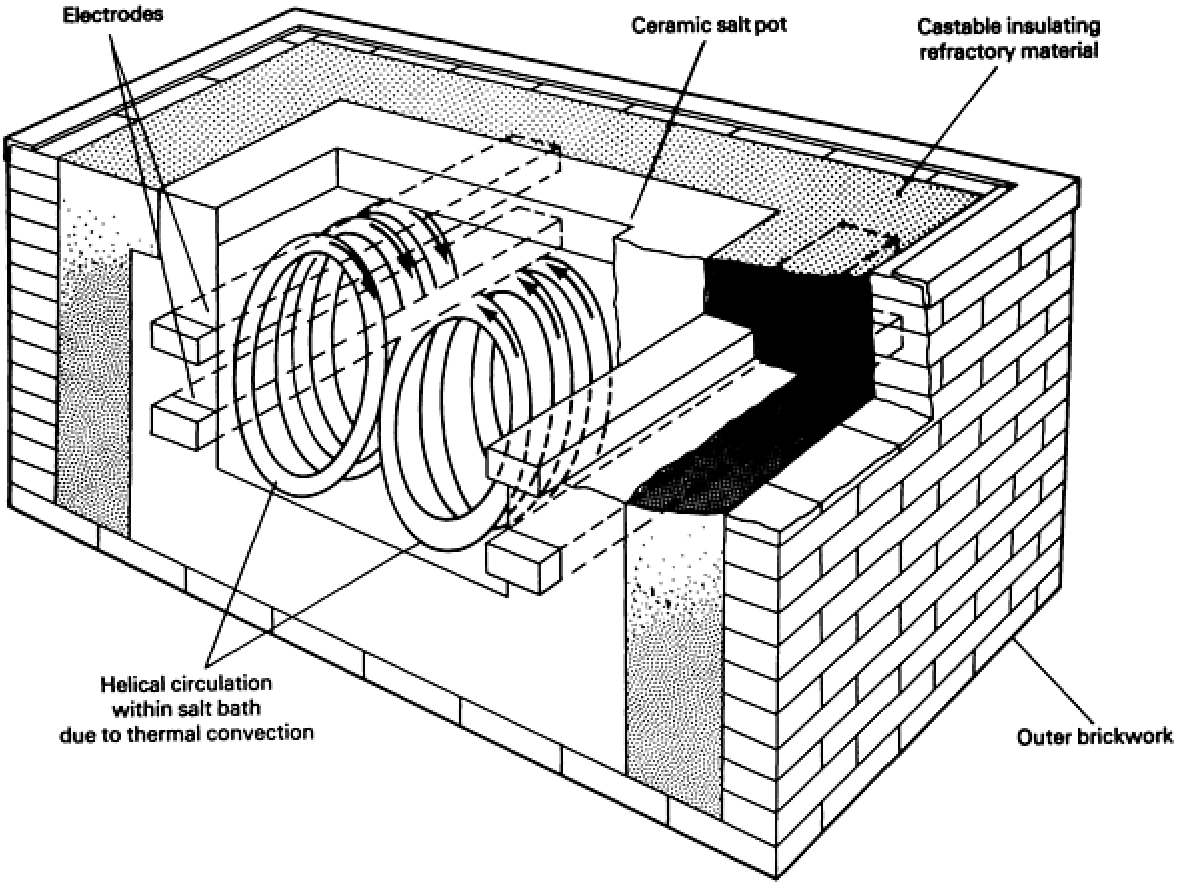

Fig. 2 Typical submerged-electrode salt bath furnace

Automatic Heat Treating of Tool Steels

Figure 3 illustrates three different heat treating arrangements for the production heat treatment of tool steels. Table 2 gives relative process times and temperatures for heat treating, and Table 3 gives process times for twist drills. The systems are equipped for cycles ranging from less than 1 min to 10 min. The parts are suspended on tong-type fixtures and are carried through the process by a chain conveyor on carrier bars. To facilitate rapid transfer of the tool steels, rotary transfer arms are placed between the preheat and the high heat units and between the high heat and the quench units. Transfer-arm placement is chiefly governed by the production rate; however, transfer arms are always required between the high heat and the quench units to satisfy metallurgical conditions. The lines also have areas above the furnaces to accommodate air cooling of the tools. In special cases, lines will be made with a station for an isothermal nitrate quench after the neutral salt quench. This additional stage allows rapid reduction of the temperature of the tools and reduces the air cooling time from 24 times to 6 times the time at the high-heat temperature. *Caution: If as little as 600 ppm of nitrate salts are allowed to enter the high heat furnace, extreme surface damage can be done to the tool being heat treated.*

Table 2 Relative process times and temperatures for automated heat treating of tool steels

Process stage	**Operating temperature**		Total time in furnace[(a)]
	°C	**°F**	
First preheat	650-870	1200-1600	**X**
Second preheat	760-1040	1400-1900	**X**

High heat	1010-1290	1850-2350	**X**
Isothermal quench	540-705	1000-1300	**X**
Air cool	Room temperature	Room temperature	**6X, 12X, 24X**
Wash, hot water	80-95	180-200	**6X**
Rinse, hot water	**80-95**	**180-200**	**X**

(a) See Table 3 for drill sizes and times in the high heat indicated by an "X" in this table.

Table 3 Time cycles for heat treating twist drills

Diameter		Time
mm	**in.**	
2.54-4.78	0.100-0.188	**1 min 30 s**
4.80-8.08	0.189-0.318	**1 min 40 s**

76 mm (3 in.) diam end mills		**10 min**
Pieces in high heat on smaller diameters		
2.54 mm (0.100 in.) = 160 pieces/tong = 480 pieces in bath = 1.2 kg (2.6 lb)		

4.78 mm (0.188 in.) = 85 pieces/tong = 255 pieces in bath = 3.5 kg (7.65 lb)
6.50 mm (0.256 in.) = 63 pieces/tong = 188 pieces in bath = 5.6 kg (12.3 lb)
8.08 mm (0.318 in.) = 25 pieces/tong = 75 pieces in bath = 3.9 kg (8.6 lb)
12.90 mm (0.508 in.) = 16 pieces/tong 48 pieces in bath = 8.3 kg (18.2 lb)

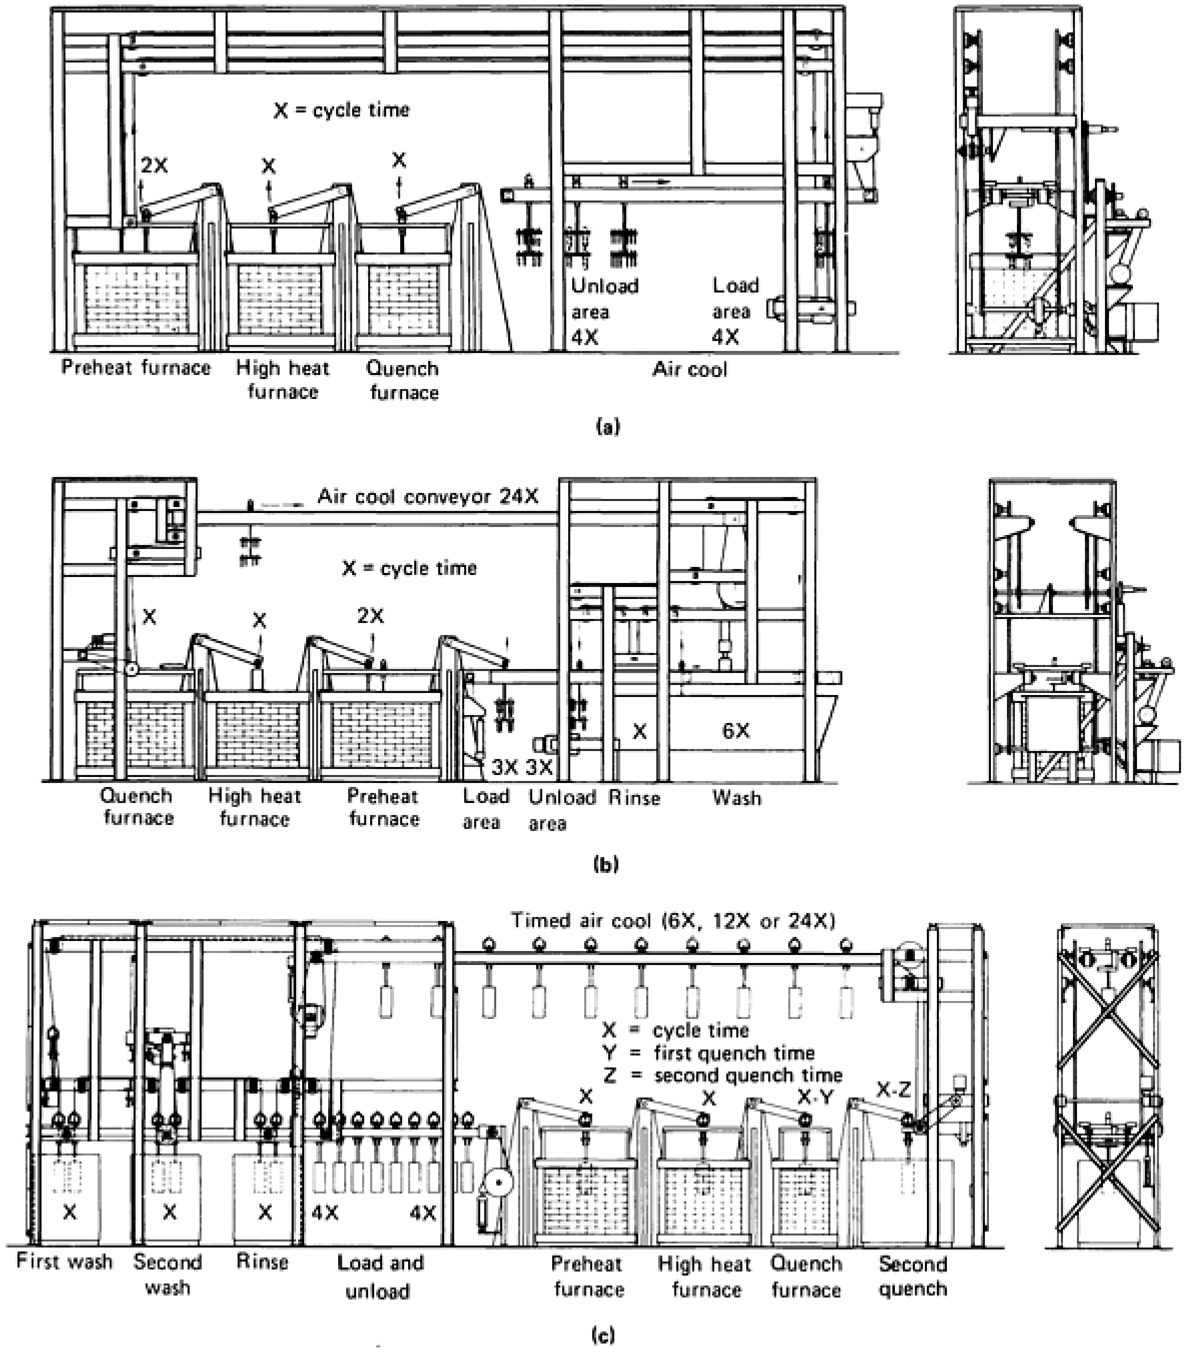

Fig. 3 Process designs for automated salt bath furnaces for heat treating high-speed tool steels. Installations can be custom designed to meet specific customer requests. (a) Does not include wash and rinse. (b) Similar to (a), but includes wash and rinse operation necessitating relocation of load and unload operations. (c) Similar to

(b), but includes second quench and a variation in wash cycles specified by customer

Rectification of Salt Baths

Neutral salts used for austenitizing steel become contaminated with soluble oxides and dissolved metals during use, resulting from a reaction between the oxide layers present on fixtures and workpieces and the chloride salts. Because the buildup of resulting oxides and dissolved metals renders the bath oxidizing and decarburizing toward steel, the bath must be rectified periodically.

Baths of salts such as salt mixtures No. 1 and 2 in Table 1 can be rectified with silica, methyl chloride, or ammonium chloride. The higher the temperature of operation, the more frequent the need for rectification. Baths in which the electrodes protrude above the surface require daily rectification with either ferrosilicon or silicon carbide. Baths operated above 1080 °C (1975 °F) require rectification a minimum of at least once a day, with more frequent rectification certainly recommended. During rectification of a bath, the silica combines with the dissolved metallic oxides to form silicates. Although these silicates settle out as a viscous sludge that can be removed, sufficient soluble silicates can remain to cause the bath to become decarburizing. If the bath is not rectified, it becomes more viscous than water. Any sludge or salts obtained as a by-product of the heat treatment must be disposed of in accordance with federal, state, and local regulations.

Methyl chloride bubbled through the bath or the submerging of ammonium chloride pellets in a perforated cage in the bath are more effective methods of rectifying salt baths. The ammonium chloride pellets react with the oxides to regenerate the original neutral salt without sludge formation or bath thickening. To remove dissolved metals from high-temperature baths, graphite rods are introduced at operating temperature. The graphite reduces any metallic oxides to metals that adhere to the rod. The metal can be scraped off and the rod reused.

To control the decarburizing tendency of high-temperature baths, test specimens frequently should be hardened by quenching in oil or brine. A file-soft surface indicates a need for more rectification. This test may be supplemented by analysis of the bath. High-heat baths containing in excess of 0.5% BaO are likely to be decarburizing to steel.

The following method can be used to rectify austenitizing baths such as salt mixtures No. 2 and 3 of Table 1:

- Add 57 g (2 oz) of boric acid for each 45 kg (100 lb) of salt, after every 4 h of operation
- Insert a 75 mm (3 in.) graphite rod into the bath for 1 h for every 4 h of operation

Controlled Atmosphere Furnaces

In selecting an atmosphere that will protect the surface of tool steel against the addition or the depletion of carbon during heat treatment, it is desirable to choose one that requires no adjustment of composition to suit various steels. An ammonia-based atmosphere (American Gas Association, or AGA, class 601) meets this requirement and has the advantage of being sufficiently reducing to prevent oxidation of high-chromium steels. In the range of dew points generally found in this gas, -40 to -50 °C (-40 to -60 °F), there is no serious depletion of carbon, because the decarburizing action is slow and any loss of carbon at the surface is partially replaced by diffusion from the interior. For applications in which high superficial hardness is important, a carburized surface can be obtained by the addition of about 1% methane (CH_4) to the atmosphere. Although ammonia-based atmosphere costs more than an endothermic gas atmosphere, this seldom becomes important because tool treating furnaces generally are comparatively small and therefore require a correspondingly small quantity of gas.

Endothermic-based atmospheres are often used for the protection of tool steel during heat treatment. Suggested ranges of dew point for an AGA class 302 endothermic atmosphere when used for hardening some common tool steels are listed in Table 4. Relatively short heating times for hardening small tools allow treatment to be carried out with the theoretical carbon balance of the atmosphere varying over a rather wide range. However, for the hardening of large die sections, the particular composition of the die steel being treated requires careful control of the atmosphere if carburization or decarburization is to be avoided during the relatively long heat-treating cycle.

Table 4 Ranges of endothermic-atmosphere dew point for hardening tool steels

Data compiled for short times at temperature; furnace dew point; AGA class 302 atmosphere

Steel	**Furnace temperature**[(a)]		Dew point range	
	°C	**°F**	**°C**	°F
W2, W3	800	1475	7 to 13	**45 to 55**
S1	925	1700	4 to 7	**40 to 45**
S2	870	1600	4 to 16	**40 to 60**
O1	800	1475	7 to 12	**45 to 55**
O2	775	1425	7 to 12	**45 to 55**
07	855	1575	-4 to 2	**25 to 36**
D2, D4	995	1825	-7 to -1	**20 to 30**
D3, D6	955	1750	-7 to -1	**20 to 30**
H11, H12, H13	1010	1850	2 to 7	**35 to 45**
T1	1290	2350	-18 to -12	**0 to 10**
M1	1205	2200	-15 to -12	**5 to 10**
F2, F3	**830**	**1525**	**5 to 1**	**23 to 34**

(a) Approximate midrange of austenitizing temperatures for the specific types of tool steels

Vacuum Furnaces

One of the most important considerations that must be met when heat treating tool steels is that the treatment must be accomplished with minimal change of the surface of the workpiece. Minimizing the exposure to air during heat treatment by minimizing or reducing the quantity of air in a vessel as with creating a partial vacuum is an excellent method for retaining workpiece surface integrity. Vacuum furnaces with pressures of 26 Pa to 1.3 mP (200 to 0.01 μm Hg) are possible with the sophisticated pumping equipment integral to vacuum furnaces.

Vacuum furnaces have historically been popular with heat-treating processes such as brazing, sintering, and outgassing. More recently, vacuum furnaces have become predominant for hardening of selected tool steels. One reason for the widespread use of vacuum furnaces is the freedom from environmental problems they afford the user. In contrast to salt bath heat treating, disposal problems are eliminated with the use of vacuum furnace heat treating. Another reason for the widespread use of vacuum furnaces is their flexibility. Vacuum furnaces can be designed for operating temperatures in excess of 2760 °C (5000 °F) and can be programmed to run an almost limitless variety of stress relieving, preheating, hardening, and quenching cycles. Design of computer hardware and software will allow these steps to be programmed individually or sequentially to enhance productivity.

Hot Wall Furnaces. Until recently, vacuum furnaces were inhibited by technical considerations in their use for hardening of tool steels. Two factors limited their use of vacuum furnaces in early hot wall designs. First, the retort in which the vacuum was developed lost considerable strength when it was heated and would tend to collapse. Secondly, a retort was limited in the type of cooling or quenching techniques which are required by tool steels.

Cold Wall Furnaces. Vacuum furnaces now incorporate a heating unit inside a vacuum chamber that is of double-wall construction. Between the two walls, water or coolant is circulated for effective cooling of the vacuum chamber, therefore enabling high-temperature operation. These cold wall vacuum furnaces have been designed by various manufacturers and offer countless variations in size, pumping capacity, heating capacities, quenching methods, speed, computerization, and so on.

In cold wall furnaces, the electric heating elements are located inside the retort. The heating elements can be made of a refractory metal (molybdenum) or from graphite rods or cloth. The heating elements are surrounded by refractory metal baffles to provide insulation and direct radiant reflection. Centered or positioned within the furnace is a refractory (metal) hearth on which a fixtured or basketed work load can be positioned.

Single-Chamber Vacuum Furnaces. A simple vacuum furnace (Fig. 4) consists of one chamber in which the workpiece is both heated and cooled. Cooling or quenching is accomplished by back filling or blowing inert gas across the workpieces. In order to quench rapidly enough to obtain the desired microstructure of tool steel, it is necessary to increase the pressure of the quench gas (usually nitrogen). This is accomplished by high-velocity, high-pressure blowers which have reported cooling gas pressures of up to 60 kPa (6 bar).

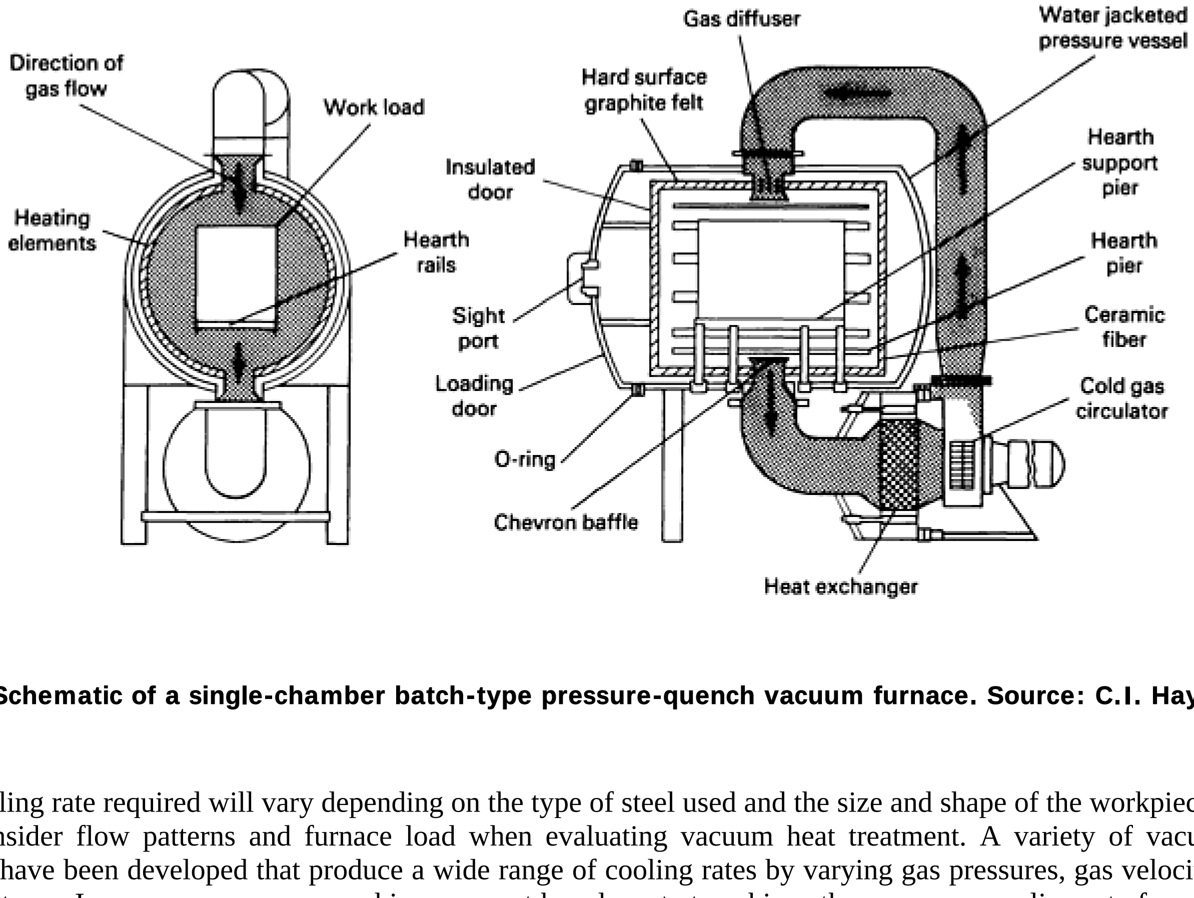

Fig. 4 Schematic of a single-chamber batch-type pressure-quench vacuum furnace. Source: C.I. Hayes, Inc.

The cooling rate required will vary depending on the type of steel used and the size and shape of the workpiece. One must also consider flow patterns and furnace load when evaluating vacuum heat treatment. A variety of vacuum furnace designs have been developed that produce a wide range of cooling rates by varying gas pressures, gas velocities, and gas flow patterns. In some cases, gas quenching may not be adequate to achieve the necessary cooling rate for a component, and other quenching methods may need to be considered (that is, salt bath, fluidized bed, or oil quenching) (see Table 1).

Multiple-chamber vacuum furnaces or integrated quench furnaces have been designed to improve throughput or enhance quench rate. Vacuum furnaces typically have thermocouples available at several locations in the furnace as well as on the surface of the load or within the confines of the load itself.

Multiple-chamber furnaces (see Fig. 5) allow nearly continuous hardening of components. In such systems three chambers of modules exist:

- A purge (loading chamber)
- A multiple-zone heating chamber
- A quench chamber

A loaded tray automatically moves into the purge chamber where decompression begins. Once the vacuum level is similar to the level in the heating chamber, the tray or basket is moved through an insulated door for heating. Heating is accomplished by transfer through multiple preheating zones and one final high-heat zone. Meanwhile, another tray has moved into the purge chamber. Once the preprogrammed time interval has elapsed in the high-heat zone, the basket is transferred to the final quench chamber for immersion. Ultimately, the basket is transported from the quench chamber through a door to an unloading tray.

Additional information is available in the article "Heat Treating in Vacuum Furnaces and Auxiliary Equipment" in this Volume.

Furnace Kinetics. The suitability of a vacuum furnace to harden a particular component is governed by many factors, not the least of which is the quenching capability. With gas quenching, the effects of gas variables such as pressure, velocity, and flow patterns are significant.

Fundamentally, in the cooling of any steel, the process is limited by:

- Gas parameters which control the rate of heat from the surface of the component (surface thermal resistance)
- Component parameters which control the rate of heat transfer within the component from the center to the surface (component thermal resistance effect) of the workpiece

In general, the gas parameters predominate in determining the cooling rate in large diameter components (greater than 250 mm, or 10 in., diameter). Both types of parameters must be taken into consideration.

Gas Parameters. The gas parameter constituent of heat removal is described by the following equation:

$$Q = h\,A \cdot \Delta T \qquad \textbf{(Eq 1)}$$

where Q is the heat removal rate, h is the heat transfer coefficient, A is the surface area of component, and ΔT is the temperature difference between the component and the gas.

During the initial cooling period, the gas temperature has only a minor effect on the workpiece. However, after this initial cooling period, the component cooling rate becomes increasingly sensitive to changes in gas temperature with the cooling rate decreasing as the gas temperature increases.

Two important features of furnace design that affect gas temperature are:

- Heat exchanger type, location, and size, because these factors control the bulk gas temperature into the furnace
- Flow distribution, which controls the local gas temperature around the workpiece

High gas temperatures usually occur only in the initial cooling period of a workpiece, when the effect of gas temperature, as discussed previously, is minimal.

The effect of heat transfer coefficient on the cooling rate of a 25 mm (1 in.) diameter slug is shown in Fig. 6.

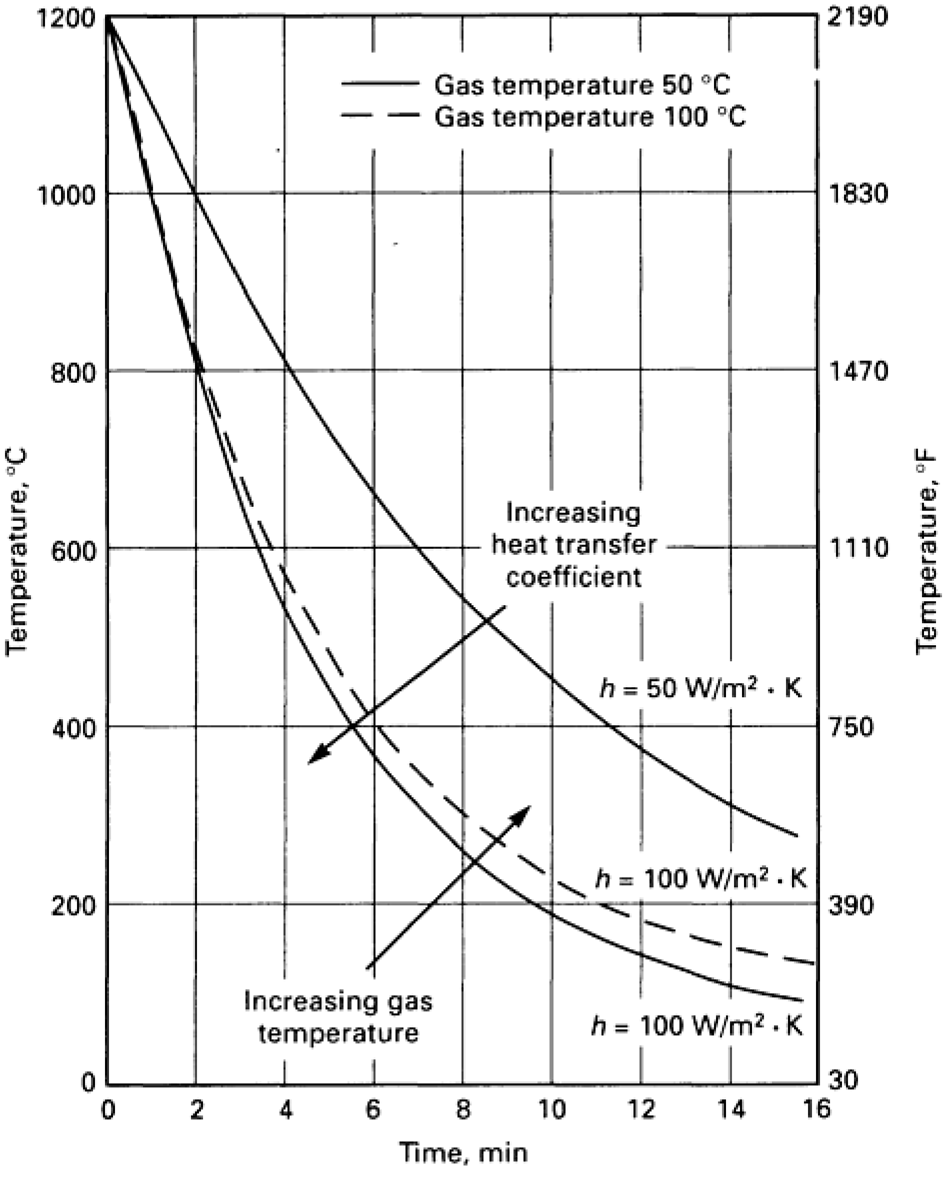

Fig. 6 Plot of temperature versus time showing the effect of gas temperature and heat transfer coefficient, *h*, on the cooling of 25 mm (1 in.) diam steel slugs. Source: Ref 1

The heat transfer coefficient, *h*, for a given gas is related to local gas velocity, *V*, and gas pressure, *P*, as follows:

$$h = C(VP)^m \qquad \textbf{(Eq 2)}$$

where m and C are constants which depend on the furnace type, component size, and workload configuration.

Equal increases in either the local gas velocity or the pressure have the same effect on the heat transfer coefficient and hence on the cooling rate of a component.

The effect of increased gas velocity on cooling is shown in Fig. 7. Local gas velocities were increased around the 25 mm (1 in.) diameter components by increasing the gas flow rate from 2.1 m^3/s (4400 ft^3/min) to 3.5 m^3/s (7500 ft^3/min). The effect of increased gas pressures on the cooling of similar components is shown in Fig. 8.

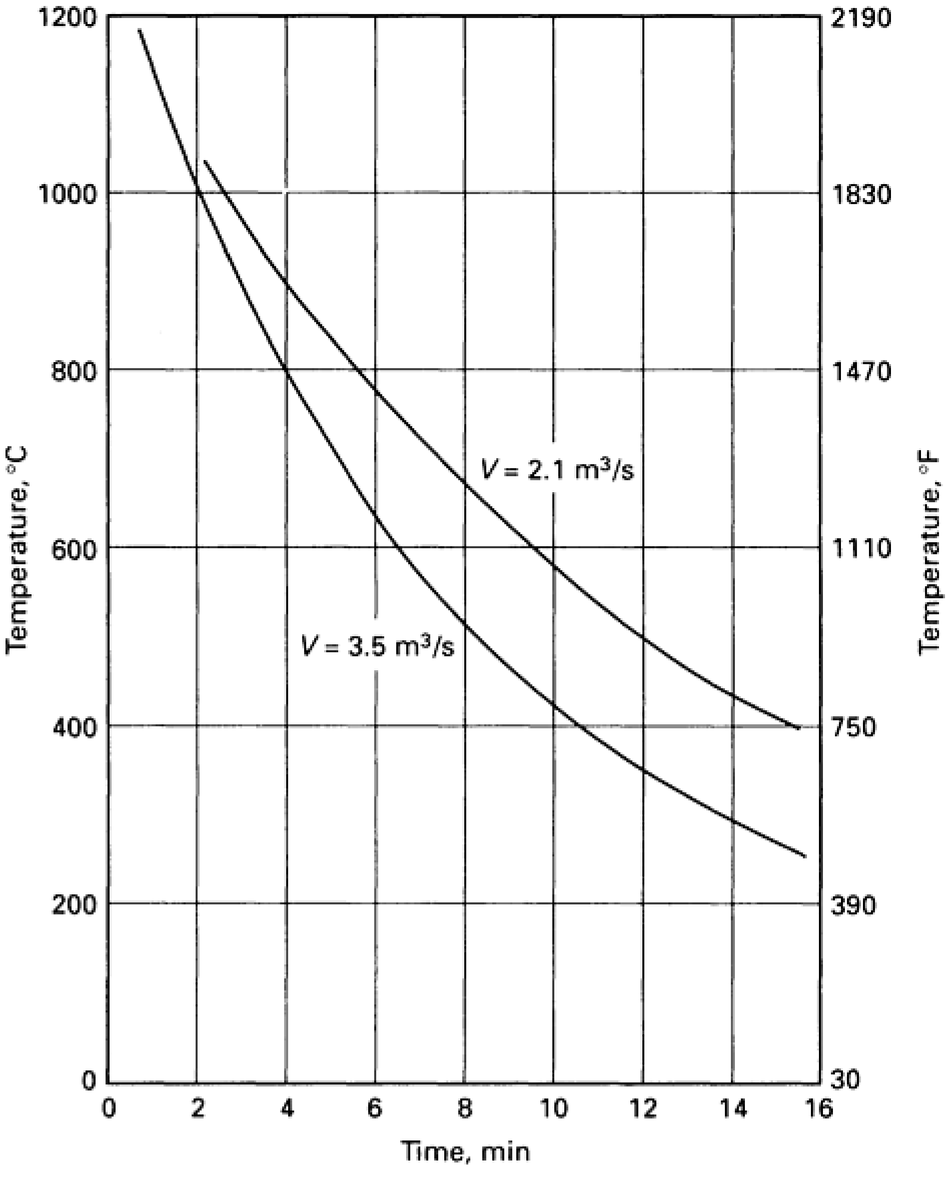

Fig. 7 Plot of temperature versus time showing the effect of local gas velocity, *V*, on the cooling of 25 mm (1 in.) diam steel slugs. Slugs are cooled with 105 kPa (15 psig) N_2 quench gas. Load size is 836.4 kg (1844 lb). Source: Ref 1

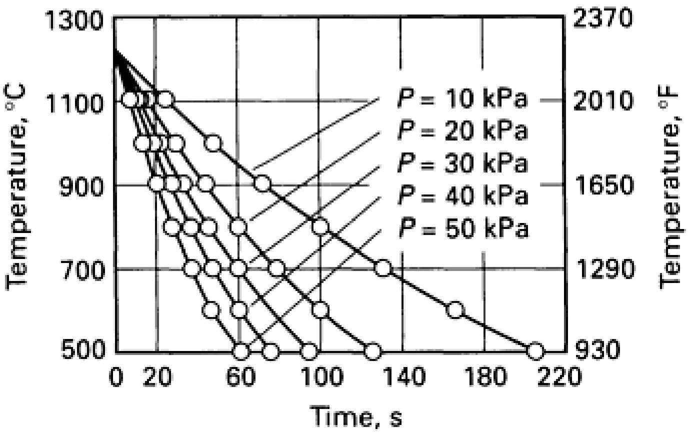

Fig. 8 Plot of temperature versus time showing the effect of nitrogen gas pressure, *P*, on the cooling of 25 mm (1 in.) diam by 48 mm ($1\frac{7}{8}$ in.) long M2 tool steel slugs. Source: Ref 1

Two practical considerations to be taken into account when increasing either gas velocity or pressure are:

- High-pressure vacuum furnaces are required to be designed and built to stringent safety regulations
- Increases in both gas velocity and pressure affect the design of the blower and the power required to recirculate the gases (doubling the gas velocity increases the blower power by a factor of eight, while doubling the gas pressure only increases the blower power by a factor of two)

The heat transfer coefficient, *h*, is also a function of the gas properties. The effect of four gases on the cooling of 25 mm (1 in.) diameter slugs is demonstrated in Fig. 9. Nitrogen is usually the gas of choice because:

- Hydrogen is explosive and must be used with extreme care
- Helium is expensive
- Argon gives poor cooling rates

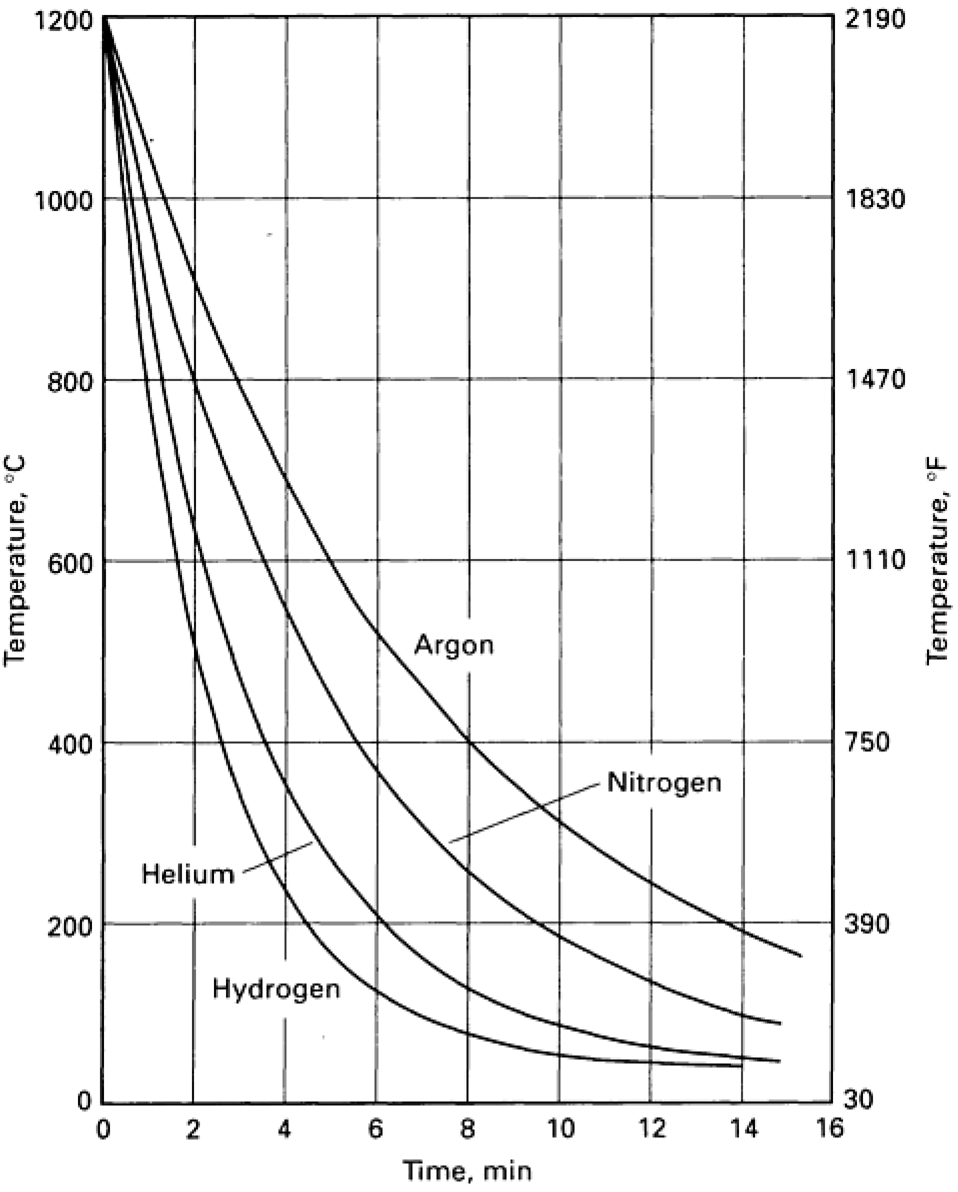

Fig. 9 Plot of temperature versus time showing the effect of selected gases on the cooling of 25 mm (1 in.) diam tool steel slugs. Source: Ref 1

Thus, it is evident that the cooling rates of steel components are not only determined by gas parameters such as gas temperature, gas velocity, and gas pressure but also depend on the physical properties (that is, conductivity, density, and viscosity) of the gas itself.

In practice, it is the gas velocity and the gas pressure that are the most significant factors in controlling component cooling rates.

Component Parameters. Component size, shape, and material properties control the rate of heat transfer within components from the center of the material core to the surface of the material. Material properties (that is, density, specific heat, and thermal conductivity) vary only marginally from one steel to another and hence have been considered constants for the purpose of this discussion. Component size and shape can vary greatly.

The effect of diameter on cooling is shown in Fig. 10. At the surface of the component, the cooling rate is inversely proportional to the component diameter; thus, increasing the diameter by a factor of two decreases the cooling rate by a factor of two. The temperature at the center of the component lags behind the temperature at the surface of the

component. This effect is more clearly shown in Fig. 11, where the ratio of surface temperature to center temperature of the component is plotted over a wide range of diameters and heat transfer coefficients.

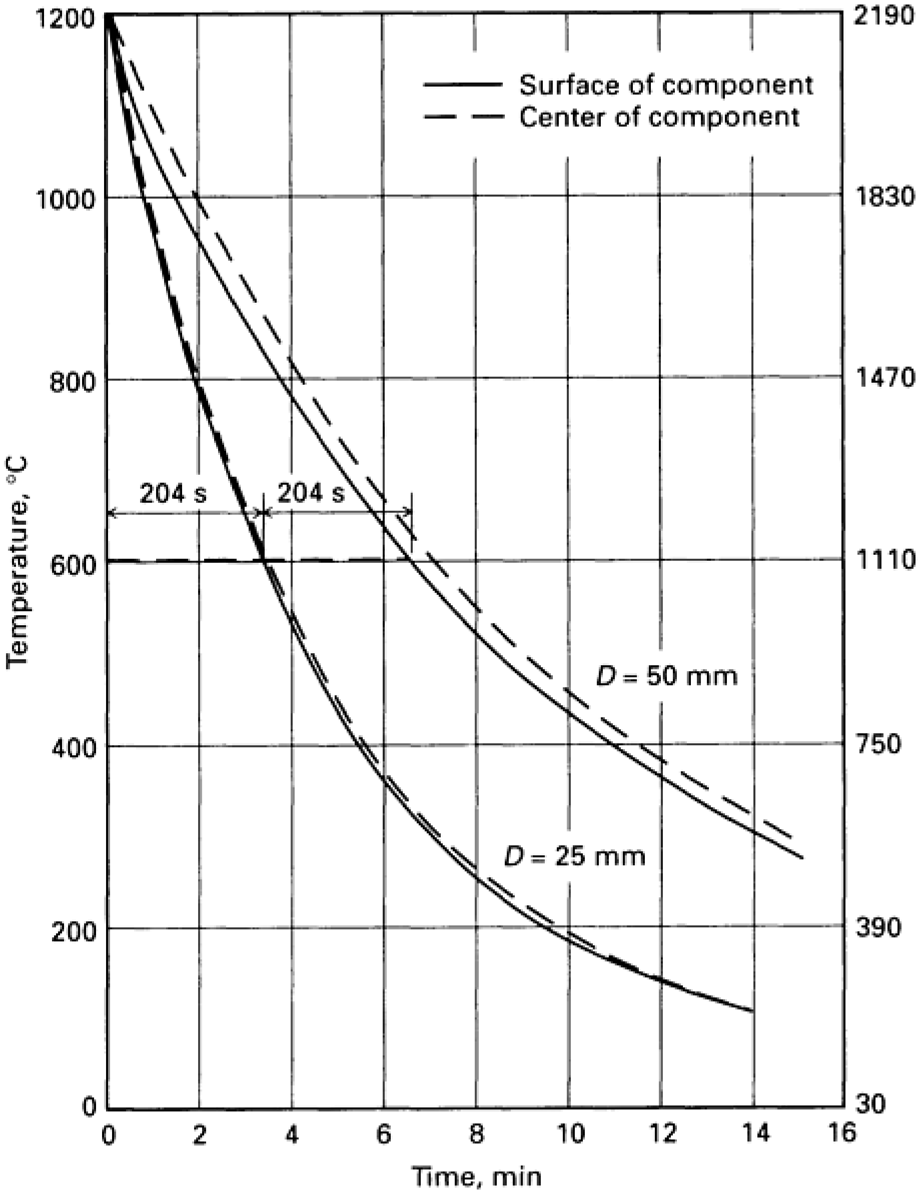

Fig. 10 Plot of temperature versus time showing the effect of varying diameter, *D*, on the cooling of tool steel slugs. Source: Ref 1

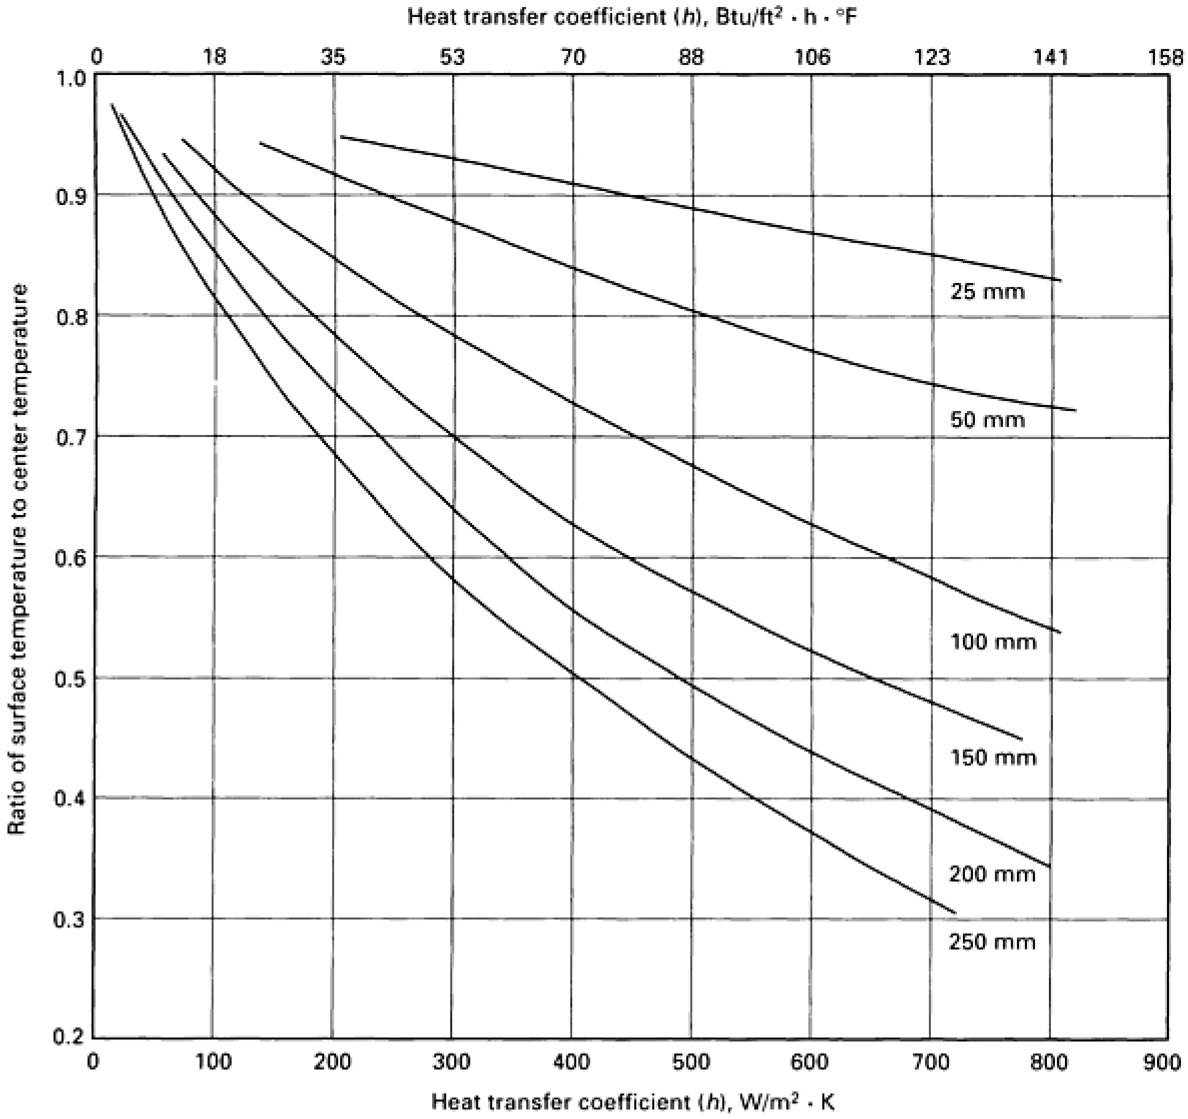

Fig. 11 Plot of surface-to-center temperature ratio versus the heat transfer coefficient to show the effect of varying tool steel slug diameters ranging from 25 to 250 mm (1 to 10 in.). Source: Ref 1

At low heat transfer coefficient values, gas parameters predominate over the cooling rate and negligible differences exist between the temperature at the surface and the temperature at the center of the component. As the heat transfer coefficient is increased, the component parameters begin to restrict the cooling rate of the component and large differences begin to develop between the temperature at the surface and the temperature at the center of the component. These temperature differences can cause distortion and cracking in large diameter components.

It is usually the cooling rate at the center of the component that is of most interest. The variation in center cooling rate in M2 tool steel over the temperature range 1200 to 600 °C (2190 to 1110 °F), is plotted for a range of heat transfer coefficients in Fig. 12.

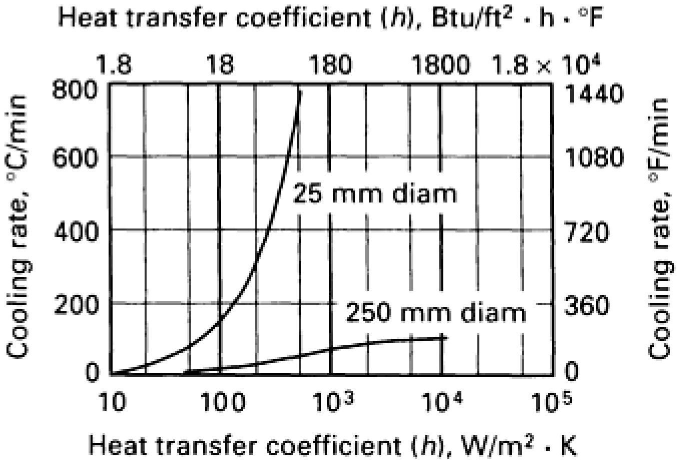

Fig. 12 Plot of cooling rate at the center of the slug versus the heat transfer coefficient of M2 tool steel to show effect of varying diameters over the temperature range of 1200 to 600 °C (2190 to 1110 °F). Source: Ref 1

For the large 250 mm (10 in.) diameter component, the center cooling rate increases only marginally with large increases in the heat transfer coefficient when compared to increases in the center cooling rate gained in a small component. For such large diameter components, even fast oil or salt quenching (*h* is approximately 1000 to 5000 $W/m^2 \cdot K$, or 200 to 900 $Btu/ft^2 \cdot h \cdot °F$) may not provide the center cooling rate required to develop the desired steel hardness properties.

Two important conclusions drawn from this discussion of how component parameters affect cooling rates are:

- High heat transfer coefficients can cause large variations in temperature between the center and surface of components (particularly as the diameter increases) that may result in cracking and/or distortion
- Even high heat transfer coefficients may not be able to cool the center of large diameter components fast enough to harden them adequately

Fluidized-Bed Furnaces

Fluidized-bed furnaces offer another method of heat treating tool steels (see also the article "Fluidized-Bed Equipment" in this Volume). This method uses a solid rather than a liquid or gas for the heat transfer medium. In general, the furnace is composed of a layer of small mobile particles of an inert refractory (for example, aluminum oxide or silica sand) in a container which is heated and fluidized by a flowing stream of gas. Objects to be heat treated are immersed directly into the bed of particles.

A fluid bed results when a gas is passed upward through a bed of small solid particles at a rate fast enough to lift these particles and to create turbulence. This motion of particles, similar to that of a fluid, is shown in Fig. 13. When gas is forced upward through small holes in a supporting plate, two forces meet to raise the particles: the buoyancy of the gas and the retarding force known as aerodynamic drag.

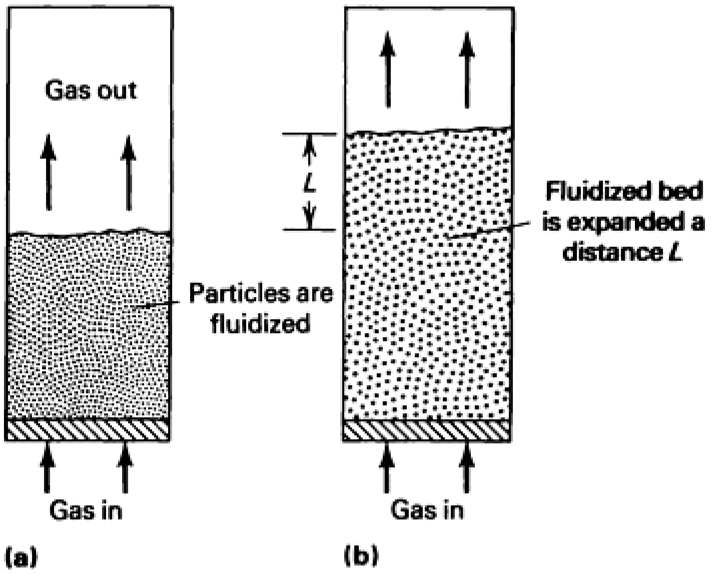

Fig. 13 Schematic showing principle of the fluidized-bed furnace. (a) Initially, the gas flows upward through the permeable base to agitate the particles as the pressure is gradually increased. (b) Eventually, the gas flow is sufficient to lift the small particles of refractory materials and to transform the particle movement into a violent turbulent motion. Although the particles are actually solid, the fluidized bed simulates the motion of a liquid. Source: Ref 2

Most fluidized-bed furnaces are used at temperatures below 1095 °C (2000 °F), although some manufacturers have furnaces capable of treating components to temperatures through 1205 °C (2200 °F). This temperature limitation is related to the exposure damage or wear and tear on the retort materials. Fluidized beds have been designed to perform a wide variety of heat-treating tasks including stress relieving, preheating, hardening, quenching, annealing, and tempering as well as a variety of surface treatments such as carburizing, nitriding, and steam tempering. This discussion will deal primarily with aspects of neutral hardening of tool steels.

Heat transfer with fluidized-bed furnaces is particularly good and offers characteristics approaching that of molten salt bath furnaces. Heating properties of the fluid bed can be adjusted through a wide range because there are many parameters that can be varied. Some of the major variable parameters are:

- Particle properties (size, shape, bulk density, and absolute density)
- Properties of the gas used to fluidize the bed (density, viscosity, heat capacity, and thermal conductivity)
- System properties (flow of gas through the bed, total weight of the particles in a given bed, cross section and shape of the retort or bed container, and type of permeable plate used to support the particles)

One of the major attributes of the fluidized bed is the high rate at which heat can be transferred from the bed of particles to an immersed object. Coefficients of heat transfer on the order of 400 to 740 $W/m^2 \cdot K$ (70 to 130 $Btu/ft^2 \cdot h \cdot °F$) are possible. This heat flow rate is two to ten times higher than that provided by normal convection or radiation. In addition, the rate of heat transfer in the full bed is relatively independent of the emissivity of the object which is immersed and the temperature level. The turbulence of the fluidized bed is important in mixing and can effectively minimize thermal gradients within the bed.

Figure 14 illustrates the nature of heat transfer in a fluidized bed. Under curve 1, the bed is nonfluidized in a static state with low heat transfer rates that increase only slightly with velocity. After the minimum fluidization velocity (V_{mf}) is reached, the heat transfer coefficient, h, increases rapidly over a comparatively narrow velocity range (curve 2). At a certain optimum velocity (V_{opt}), the heat transfer coefficient reaches a maximum (h_{max}) and then tends to diminish as the fluidized bed attains more gas-like properties (curve 3). The actual heat transfer rate experienced in the fluidized bed depends on the fluidizing gas velocity and its thermal conductivity, the size and density of the bed particles, their thermophysical properties, and on the geometry and structural design features of the furnace. Generally, the principal

parameter, other than velocity, that affects the heat transfer coefficient is the particle size with the coefficient rising as the particle diameter is decreased. These parameters result in heat transfer coefficients as high as 570 W/m^2 · K (100 Btu/ft^2 · h · °F), which is up to five times that which can be obtained in a conventional open-fired furnace and is similar to that obtained in liquid baths. The comparison of the heating rate in a fluidized-bed furnace with other typical modes of heating is shown in Fig. 15.

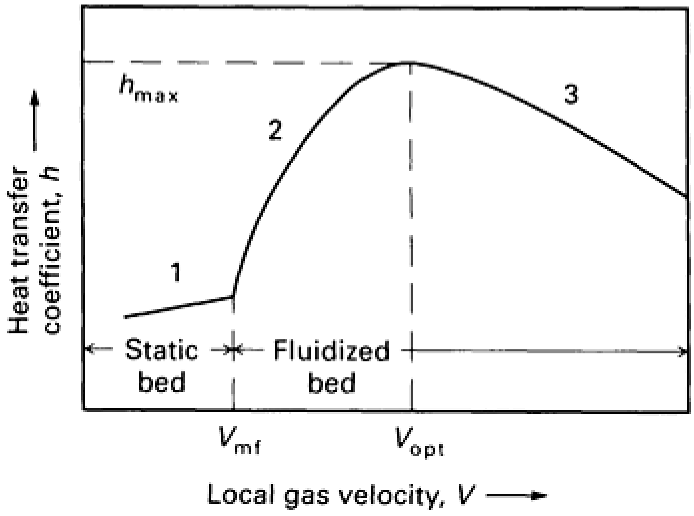

Fig. 14 Heat transfer coefficient rises with the increase in velocity of the fluidized bed until a peak value, h_{max}, is reached at the optimum velocity V_{opt}. Source: Ref 3

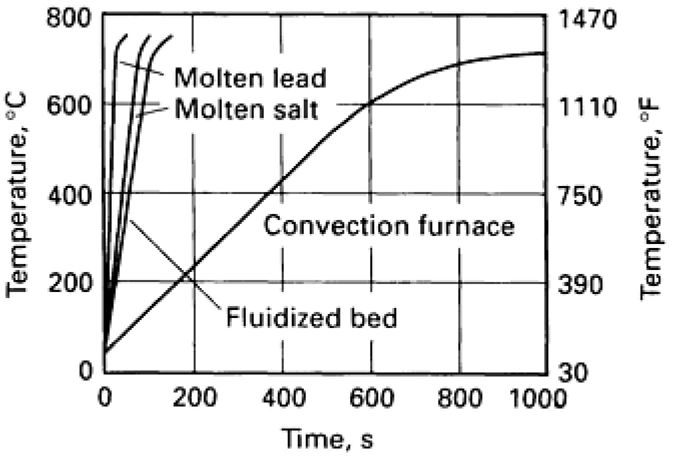

Fig. 15 Fluidized-bed heating compared with conventional immersion (molten salt and molten lead baths) and convection heating methods for 16 mm ($\frac{5}{8}$ in.) diam steel bars. Source: Ref 3

Fluidized-bed heat-treating furnaces are manufactured by several suppliers and are available in three fundamental configurations. Two of the configurations are fluidized by the products of combustion and are known as internally fired and externally fired types. For the third configuration, known as the indirectly heated type, the fluidization and the heating are accomplished independent of one another. The indirectly heated type is most often used for neutral hardening and therefore is more applicable to tool steel heat treating.

Because the heating and fluidization modes of an indirectly heated fluidized-bed furnace are independent of one another, this type of furnace is used where special atmospheres are required by the product. Literally, any gas may be used for fluidization and this type of furnace can accommodate a wide range of processes such as carburizing, carbonitriding,

steam treating, and bright annealing. An example of an indirectly heated fluidized-bed furnace is shown in Fig. 16. Although the furnace shown is heated electrically, it should be emphasized that a fluidized-bed furnace may also be fuel fired (simply by replacing the electric elements on the outside with a suitable burner system) or both fuel fired and electrically heated. In special configurations, furnaces may also be cooled to operate at subambient temperature conditions.

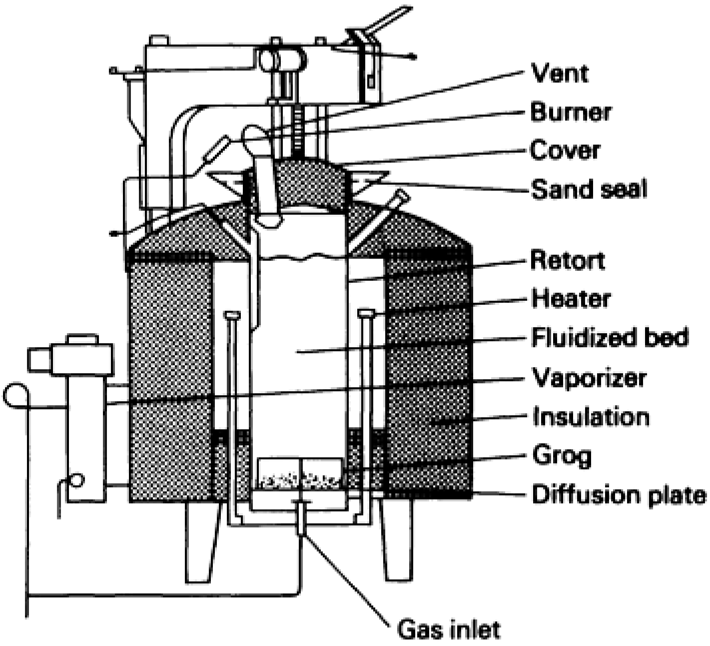

Fig. 16 Schematic of an indirectly heated fluidized-bed heat-treating furnace. The gas enters the furnace from the supply line on the bottom left. Source: Ref 4

The fluidized-bed particles offer some similarities to salt baths and can provide a supporting neutral environment. The fluidized particles do not collect on the work surface and therefore there is no dragout or subsequent cleaning required. The aluminum oxide or silica oxide particles can become contaminated but are typically not considered an environmental hazard as are lead and salt compounds used in the other heat treat methods. The workpiece, upon removal from the high-temperature bed, can, however, be exposed to surface contamination such as decarburization during transfer to a quenching media. Because multiple fluidized-bed furnaces or a combination of furnaces are typically used in conjunction with each other during tool steel heat treatment, such factors must be considered in the overall layout of a heat treat department.

Heat Treating of Specific Classes of Tool Steels

Introduction

HEAT-TREATING PROCEDURES vary significantly among classes of tool steels and with intended application. The preferred heat-treating and hardening procedures, as well as mechanical properties and applications are discussed in this

article with respect to: water- and air-hardening tool steels, oil-hardening and high-carbon, high-chromium cold-work steels, low-alloy and special-purpose high-speed tool steels, and shock-resisting tool steels. Specific examples of heat-treating procedures for specific applications for hot-work tools are given.

Water-Hardening Tool Steels

Water-hardening tool steels containing 0.90 to 1.00% C are the most widely used. Carbon content affects heat-treating temperatures as indicated in Table 1, which outlines recommended heat-treating practices for these steels.

Table 1 Recommended heat-treating practices for water-hardening tool steels

Temperature		**Carbon content**	**Hardness after treatment**	Procedure
°C	**°F**			
Normalizing				
815	1500	0.60-0.75	. . .	**Heat through uniformly; hold for 15 min (light sections) to 1 h (heavy sections), then air cool**
790	1450	0.75-0.90		
870	1600	0.90-1.10		
870-925	1600-1700	1.10-1.40		
Annealing				
740-760	1360-1400	0.60-0.90	156-201 HB	**Heat through uniformly; hold for 1-4 h[a]; furnace cool to 510 °C (950 °F) at 22 °C/h (40 °F/h), then air cool**
760-790	1400-1450	0.90-1.40		
Hardening[b]				
790-845	1450-1550	0.60-0.80	65-68 HRC	**Hold at austenitizing temperature for 10-30 rain; quench in water or brine (very small pieces may be oil quenched)**
775-845	1425-1550	0.85-1.05		
760-830	**1400-1525**	**1.10-1.40**		

(a) Holding times vary from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and large furnace charges.

(b) For large tools and tools with intricate sections, preheating at 565 to 650 °C (1050 to 1200 °F) is recommended.

As a class, water-hardening tool steels are relatively low in hardenability, although they are arbitrarily classified and available as shallow-hardening, medium-hardening, and deep-hardening types. Their low hardenability is frequently an advantage, because it allows tough core properties in combination with high surface hardness. Low cost and adaptability to simple heat treatment are additional advantages offered by these steels.

Water-hardening tool steels are so termed because they are most commonly quenched in an aqueous medium. There are exceptions, however; for example, thin sections may be satisfactorily quenched in oil with less distortion and danger of cracking than if quenched in water or brine.

Example 1: Analysis of Maximum Diameter in Oil-Quenched Water-Hardening Steel Punch Yielding Minimum 60 HRC Hardness at Selected Austenitizing Temperatures.

In one plant, it was desirable to harden small-diameter punches in oil to reduce breakage and consequent downtime of the presses. A study was made to determine the maximum diameters of water-hardening tool steels that could be fully hardened to a minimum of 60 HRC by oil quenching. Results of the study, indicating the relationship between austenitizing temperature, type of steel, and punch diameter, are shown in Fig. 1.

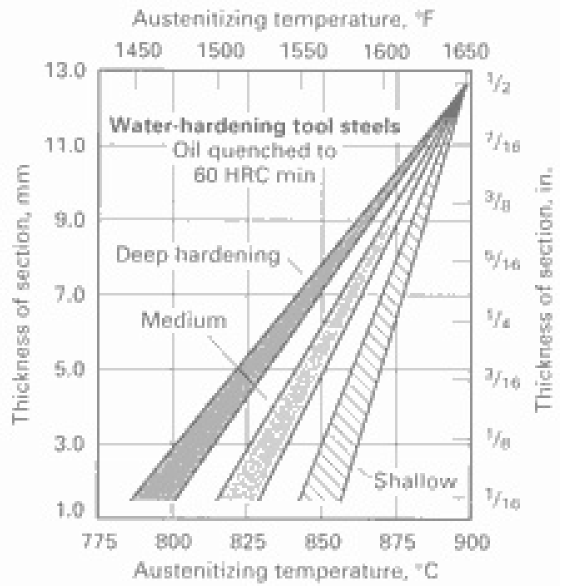

Fig. 1 Maximum section thicknesses of 3 classes of water-hardening tool steels that will develop minimum hardness of 60 HRC when oil quenched from various austenitizing temperatures

Experimentation proved that a greater degree of uniformity was obtained if the punches were normalized prior to hardening. Normalizing temperatures applied were: 870 °C (1600 °F) for punches up to 6.4 mm ($\frac{1}{4}$ in.) in diameter; 900 °C (1650 °F) for those over 6.4 mm ($\frac{1}{4}$ in.) in diameter. As indicated in Fig. 1, austenitizing temperature varied from 790 to 900 °C (1450 to 1650 °F), depending on punch diameter. The punches were austenitized by being heated vertically in a neutral salt bath. They were also quenched vertically, in a compounded oil containing additives. The quenching oil was maintained at 50 to 60 °C (120 to 140 °F) and circulated up and around workpieces at 190 L/main (50 gal/min).

Normalizing. Except in special instances where experience has proved it beneficial (as in the preceding example), normalizing is not recommended for water-hardening tool steels as received from the supplier. Normalizing is recommended for these steels after forging or before reheat treatment, for refining the grain and producing a more uniform structure. Recommended normalizing temperatures are given in Table 1; as indicated, optimum temperature varies with carbon content.

Decarburization during air cooling will be minimized if parts are heated in a protective atmosphere or a neutral salt bath. Parts heated in salt are additionally protected during the cooling period by the film of salt that adheres to their surfaces when they are removed from the salt bath. After parts have cooled, the film of salt can be easily removed (except from recesses such as tapped holes) by a water rinse. Additional information is available in the article "Normalizing of Steel" in this Volume.

Annealing. Tool steels of the W types are received from the supplier in the annealed condition. Thus, annealing by the user is usually unnecessary. Annealing is applied to forged or cold-worked carbon tool steel to soften it for easier machining, to relieve residual stress, and to produce a structure suitable for hardening. Annealing may be done in an atmosphere furnace (provided the furnace is of a type that can be cooled slowly to below 540 °C, or 1000 °F), in a vacuum, or in an ordinary air furnace after the piece has been protected against surface decarburization by being packed in a suitable container with an inert material. Protection against decarburization (but not against oxidation) may be obtained also by copper plating the surface or by applying a surface-protecting paint. (Not all of these paints are equally effective, and some are difficult to remove; the prospective user should investigate such a paint by trying it under his conditions of operation and then inspecting the treated part for decarburization.) The workpiece should be heated to the annealing temperature (Table 1) and held at temperature for from 1 h, for thin sections, to about 4 h, for heavy sections. When the steel has been placed in a pack to prevent surface reactions, a general rule of thumb is to allow the assembly to soak at temperature for 1 h per inch of pack cross section. Work should then be cooled in the furnace at a rate not exceeding 22 °C/h (40 °F/h), to 510 °C (950 °F). Below this temperature, cooling rate is not critical. Hardness after annealing should be in the range of 156 to 201 HB.

Stress relieving prior to hardening is sometimes employed to minimize distortion and cracking. The procedure consists of heating the work to 650 to 720 °C (1200 to 1325 °F) and cooling in air. Usually, stress relieving of water-hardening tool steel is limited to complex or severely cold-worked parts.

Example 2: Elimination of Cracking in a W2 Piston by Stress Relieving Prior to Hardening.

A piston of W2 steel for a pneumatic clay digger varied in section thickness by as much as 6 to 1. Cracking occurred in the cupped end section when the pistons were hardened by conventional practice. Stress relieving or preheating at 675 °C (1250 °F) prior to hardening eliminated this difficulty.

In most instances, stress relieving after hardening and grinding is not employed. Periodic stress relieving of tools that have been in service will reduce the stresses imposed by such service, and is believed to be beneficial in extending service life. Temperatures used for this purpose should never exceed those used for tempering the steel after hardening.

Austenitizing temperatures for water-hardening tool steels normally vary from 760 to 845 °C (1400 to 1550 °F), as indicated in Table 1. Higher temperatures are sometimes used for special purposes (Fig. 1). Hardenability increases as austenitizing temperature increases. The optimum time at austenitizing temperature is from 10 to 30 min. Preheating is unusual except for very large tools or those with intricate cross sections (such as the W2 piston cited in Example 2).

If surfaces are to be protected against scaling or decarburization, an atmosphere furnace, lead bath, or salt bath is required. It is particularly important to protect shallow-hardening steels against scaling and decarburization. Severe scaling can interfere with heat transfer during quenching and slow the required high rate of cooling. Decarburization will produce a soft surface on any tool steel, but in a deep-hardening steel it can be ground off until the underlying hard high-carbon area is reached. Grinding a shallow-hardening steel will frequently expose the soft core.

Atmospheres. Excellent results are obtained by austenitizing water-hardening tool steels in a slightly oxidizing atmosphere, as the data in Fig. 2, obtained in tests on type W2, indicate. Oxidizing atmospheres are inexpensive, and are usually produced by controlled direct-firing burners. The light scale that is produced is removed by the vigorous water or brine quench.

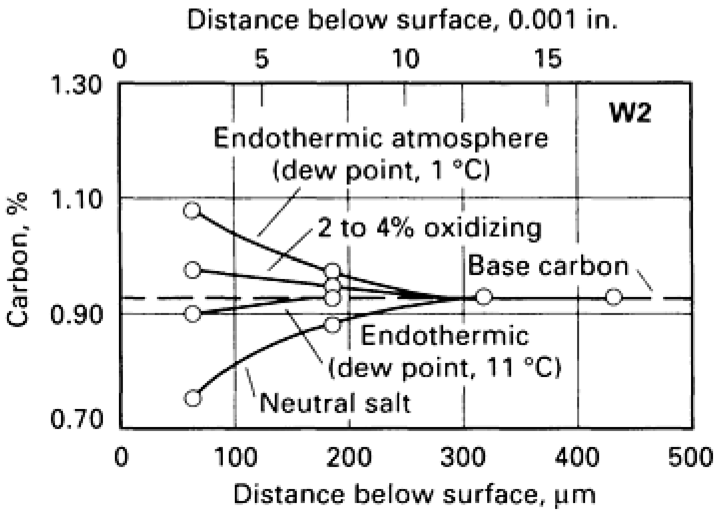

Fig. 2 Effect of furnace atmosphere on the surface carbon content of W2 tool steel. Specimens were heated at 790 °C (1450 °F) for 1 h, quenched in brine, annealed in lead at 705 °C (1300 °F), and machined in 0.13 mm (0.005 in.) cuts for analysis.

Endothermic atmospheres also are used, but close control is necessary to match the carbon potential of the atmosphere to the carbon content at the surface (Fig. 2). Also, endothermic installations are more expensive than the controlled-burner technique mentioned above.

Salt baths are widely used and frequently preferred over other heating mediums for hardening type W tool steels (see the article "Salt Bath Equipment" in this Volume).

Example 3: Advantages and Limitations of W1 and W2 Dies Heat Treated in Salt Baths.

In one plant, salt baths were found to be superior to atmosphere furnaces for heat treating die sections of W1 and W2 (0.90 to 1.05% C) because die sections could be hardened in limited areas by being suspended and only partly immersed in the salt bath, and because long sections, such as die wiper plates measuring 25 by 100 by 760 mm (1 by 4 by 30 in.), could be hardened in a salt bath with less distortion.

Salt baths are usually lower in initial cost than endothermic-atmosphere installations. Neutral salts such as No. 3 in Table 1 of the article entitled "Processes and Furnace Equipment for Heat Treating of Tool Steels" in this Volume, are commonly used. A salt of this type will operate satisfactorily in either steel-lined or ceramiclined pot furnaces, but maintenance cost will be less with ceramic linings. Immersed-electrode heating of these furnaces is recommended.

High-temperature salt baths will cause severe decarburization (see Fig. 2) if not closely controlled. A recommended method of rectification for control of these baths is indicated in the article, "Processes and Furnace Equipment for Heat Treating of Tool Steels" in this Volume.

Other disadvantages of salt baths are that salt dragout necessitates frequent replenishment of the bath, particularly when many small parts are being treated and that salt is sometimes difficult to remove from parts having complex shapes or tapped holes.

Lead baths also are used for austenitizing water-hardening steels and have advantages and limitations paralleling those of the salt bath, specifically with complex shapes and tapped holes, as described above. Both the Occupational Safety and Health Administration (OSHA) and the Environmental Protection Agency (EPA) have stringent regulations to avoid lead poisoning.

Fluidized-bed furnaces (see the article "Fluidized-Bed Equipment" in this Volume) represent a special class of atmosphere furnaces that exploit the excellent heat transfer properties of a ceramic medium that is liquefied via the

application of a gas flow. Fluidized-bed furnaces are extremely versatile furnaces because they have the capability to control blend gases that generate the desired carbon potential. In addition, fluidized-bed equipment can also be applied to processes such as ammonia gas nitriding and steam oxide surface coatings.

Quenching. To produce maximum depth of hardness in water-hardening tool steels, it is essential that they be quenched as rapidly as possible. In most instances, water or a brine solution consisting of 10% NaCl (by weight) in water is used. Occasionally, for an even faster quench, an iced brine solution is employed. Cooling rate is a function of size of workpiece as well as of quenching medium; for this reason, small pieces can be quenched in oil (Fig. 1). This is particularly useful when heat treating thin-section tools in an atmosphere furnace containing an integral oil quench.

Tempering. Water-hardening tool steels should be tempered immediately after hardening, preferably before they reach room temperature; about 50 °C (120 °F) is optimum. Salt baths, oil baths, and air furnaces are all satisfactory for tempering. However, working temperatures for both oil and salt are limited; the minimum for salt is about 165 °C (325 °F), and the maximum for oil is usually about 205 °C (400 °F).

All parts made of these steels should be tempered at temperatures not lower than 175 °C (350 °F). One hour at temperature is usually adequate; additional soaking time will further lower hardness. Figure 3 shows the effect of tempering temperature on hardness of water-hardening tool steels austenitized at 790, 815, and 845 °C (1450, 1500, and 1550 °F) and quenched in brine.

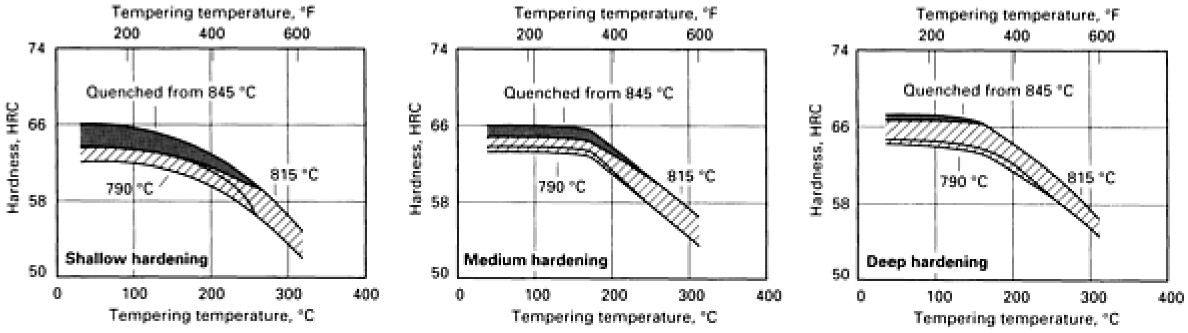

Fig. 3 Effect of tempering temperature on surface hardness of water-hardening tool steels austenitized at three different temperatures and quenched in brine. Specimens held for 1 h at the tempering temperature in a recirculating-air furnace. Cooled in air to room temperature. Data represent 20 25 mm (1 in.) diam specimens for each steel. Compositions of steels: shallow hardening, 0.90 to 1.00 C, 0.18 to 0.22 Mn, 0.20 to 0.22 Si, 0.18 to 0.22 V; medium hardening, 0.90 to 1.00 C, 0.25 Mn, 0.25 Si, no alloying elements; deep hardening, 0.90 to 1.00 C, 0.30 to 0.35 Mn, 0.20 to 0.25 Si, 0.23 to 0.27 Cr

Tools should be placed in a warm 95 to 120 °C (200 to 250 °F) furnace immediately after quenching and then brought to the tempering temperature with the furnace. This is particularly necessary when quenched tools are being accumulated for tempering in a single batch. Allowing quenched tools to stand at room temperature or placing them in a cold furnace will lead to cracking. Except for large pieces, the work will heat at about the same rate as the furnace. The low temperatures used in tempering eliminate the need for atmosphere control. A double temper is frequently used to temper any martensite that may have formed from retained austenite during quenching, and in the first tempering cycle.

The resistance to fracture by impact initially increases with tempering temperature to about 180 °C (360 °F) but falls off rapidly to a minimum at about 260 °C (500 °F). This is known as 500 °F embrittlement or tempered martensite embrittlement (see the article "Embrittlement of Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*). For tools subjected to impact loading, tempering temperature should be selected to give an optimum combination of hardness and impact resistance.

Shock-Resisting Tool Steels

Recommended heat-treating practices for shock-resisting tool steels are outlined in Table 2. These steels may be obtained with several variations in composition, for specific applications (for example, S1 steel is available with 0.30 or 0.50% Mo or with up to 0.90% Si). The user of these nonstandard compositions should: (a) obtain from the manufacturer

information as to the modifications required in heat treatment, or (b) select a heat treatment recommended for the shock-resisting tool steel of standard composition that most closely resembles the modified steel. The latter procedure should be followed only after the treatment has been tried on test samples.

Table 2 Recommended heat-treating practices for shock-resisting tool steels

Not rec, not recommended.

(a) Lower limit of range should be used for small sections, upper limit for large sections. Holding time varies from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(b) Maximum. Rate is not critical after work is cooled to about 510 °C (950 °F).

(c) Preferable for large tools to minimize decarburization.

(d) For open furnace heat treatment. For pack hardening, hold for $\frac{1}{2}$ h per inch of pack cross section.

Normalizing is not recommended for the shock-resisting tool steels.

Annealing. The high-silicon types (S2, S4, S5, and S6) are susceptible to graphitization and decarburization. Annealing these types at temperatures higher than those indicated in Table 2 may produce a softer structure, but it will also increase the danger of graphitization. The silicon types should not be soaked at temperature. Surfaces should be protected against decarburization by heating in a protective atmosphere or a vacuum furnace, by the use of pack annealing, or by the application of proprietary paints.

Pack annealing consists of surrounding parts with inert material inside a closed container, heating the container to the recommended temperature, and slow cooling. The selection of a packing medium for use with shock-resisting tool steels is difficult; the same general practice has produced different results in different plants. Dry silica sand is usually satisfactory for type S1, and a combination of new and used carburizing compound is usually satisfactory for S2, S4, and S5. Burned-off cast iron chips, spent pitch coke, lime, and mica are sometimes used, also. Cast iron chips decrease in carbon content and should not be used indefinitely; lime and mica should be used carefully, because they are insulators. Excessive thicknesses of inert material should not be packed around parts, because this complicates handling and lengthens heating time. Wrapping parts tightly in brown paper before surrounding them with packing material helps to keep the surfaces clean. Additional information is available in the article "Introduction to Heat Treating of Tool Steels" in this Volume.

Proprietary paints are available that are intended to protect steel surfaces from decarburization during annealing. The use of such paints is simpler than the use of a pack anneal, but not all of these paints are effective. Moreover, considerable difficulty may be experienced in removing such paints after heat treatment. The prospective user should test any such paint on a sample of steel prior to adopting it in practice.

Stress relieving before hardening is seldom required for shock-resisting tool steel, except for extremely intricate parts of widely varying section thickness (to minimize distortion and cracking) and parts subjected to excessive stock removal (to relieve stresses induced by machining). Treatment of such parts, which involves no microstructural transformation, consists of heating them to 650 °C (1200 °F), (soaking should be avoided), furnace cooling to about 510 °C (950 °F), and then removing them from the furnace to cool in air.

Stress relieving of tools after tempering is seldom done. In some instances, however, increased tool life has been obtained by removing tools from service and stress relieving them (at a temperature no higher than the original tempering temperature) before returning them to service.

Example 4: Doubling the Tool Life of Shock-Resistant Tool Steels Used in Swaging Stainless Steels with Stress Relief.

In one plant, shock-resisting steel tools used for swaging stainless steel would sink a definite amount after a time in service. If kept in service, these tools would crack after swaging about 40,000 parts. However, by withdrawing the tools after sinking had ceased and stress relieving them at 230 °C (450 °F) for 1 h per inch of cross section, tool life was more than doubled.

Austenitizing temperatures for shock-resisting tool steels vary from 815 to 955 °C (1500 to 1750 °F). Preheating is not mandatory, but it is sometimes desirable for large tools, to minimize distortion, shorten time at the austenitizing temperature, and speed up production.

These steels may be austenitized in electric or fuel-fired furnaces or in salt or lead baths. Generally, for austenitizing temperatures below 870 °C (1600 °F), a slightly oxidizing environment is best, whereas above 870 °C (1600 °F) a reducing atmosphere is required. If a semimuffle fuel-fired furnace is used, the desired atmosphere can be obtained at low cost by adjustment of burners. However, if electrically heated or full-muffle fuel-fired furnaces are used, a prepared atmosphere from an external source is required.

Neutral salt baths are a practical means of heating the type S steels. A salt mixture such as No. 3 in Table 1 of the article, "Processes and Furnace Equipment for Heat Treating of Tool Steels" in this Volume, is satisfactory for types S2, S4, and S5, whereas a mixture such as No. 2 in that table will be more suitable for heating S1. A recommended method of controlling these salts to prevent decarburization of the work is indicated in the discussion of rectification in the article, "Processes and Furnace Equipment for Heat Treating of Tool Steels."

If atmosphere furnaces or neutral salt baths are not available, the shock-resisting steels can be heated in a pack of neutral material such as burned pitch coke or cast iron chips. Packing mediums must be free of oil or other contaminants. Before being placed in the pack, tools should be wrapped with heavy brown paper, to prevent packing material from adhering to them as they are removed for quenching.

Types S2, S4, and S5 should be quenched soon after they reach the austenitizing temperature; types S1 and S7 are soaked at temperature for 15 to 45 min before being quenched (Table 2). Types S1 and S7 have the highest hardenability of these steels. The other types, although lower in hardenability than S1 and S7, are higher in hardenability than the W steels.

Tempering. Both the tungsten and the silicon types of shock-resisting tool steel resist softening from tempering to a greater degree than carbon tool steels. Secondary hardening does not occur in these steels, except to a minimal degree in some compositions of the tungsten type.

The effect of tempering temperature on the hardness of various types and compositions of the S steels is shown in Fig. 4.

Fig. 4 Effect of tempering temperature on surface hardness of shock-resisting tool steels

Tools made of shock-resisting steel should be tempered immediately after quenching, or cracking is likely to result, especially if they are quenched in water or brine.

Example 5: Study Conducted to Determine Maximum Elapsed Time Required Between Quenching and Tempering Treatments to Prevent Cracking.

One plant made an extensive study on how much time could be safely permitted between quenching and tempering of tools made of shock-resisting steels. Results of this study are given in Table 3.

Table 3 Allowable time between quenching and tempering of shock-resisting tool steels, for prevention of cracking

Values determined by an extensive study conducted in one plant. Allowable time may vary significantly with size and shape of part.

Steel	**Austenitizing temperature**	**Quenching medium**	Allowable time prior to tempering, min

	°C	°F		tempering, min
S1	900	1650	Oil	**30**
S1	980	1800	Oil	**15**
S2	845	1550	Brine	**10**
S2	900	1650	Brine	**5**
S3	815	1500	Brine	**10**
S3	870	1600	Brine	**5**
S4	870	1600	Brine	**10**
S4	925	1700	Brine	**5**
S4	900	1650	Oil	**30**
S4	955	1750	Oil	**15**
S5	870	1600	Oil	**30**
S5	**925**	**1700**	**Oil**	**15**

In this same plant, tool records indicate that double tempering is beneficial for tools made from the S steels. The first tempering operation is done at a temperature 30 to 55 °C (50 to 100 °F) lower than that of the second and final tempering operation.

Surface treatments such as carburizing and carbonitriding are often applied to S1 steel. Types S4 and S5 do not take an effective carburized case.

Oil-Hardening Cold-Work Tool Steels

Recommended heat-treating practices for oil-hardening cold-work tool steels is summarized in Table 4.

Table 4 Recommended heat-treating practices for oil-hardening cold-work tool steels

O7	900	1650	790-815	1450-1500	22	40	192-217	650	1200	790-830	1450-1525	10-30	Water	**64-66[d]**
										845-885	**1550-1625**	**10-30**	**Oil**	**64-66[d]**

(a) Holding time, after uniform through heating, varies from about 15 min, for small sections, to about 1 h, for large sections. Work is cooled from temperature in still air.

(b) Lower limit of range should be used for small sections, upper limit for large sections. Holding time varies from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(c) Maximum. Rate is not critical after cooling to below 540 °C (1000 °F).

(d) Sections larger than 38 mm ($1\frac{1}{2}$ in.) will be softer.

Normalizing is desirable and sometimes necessary for parts that have been forged or heated previously to temperatures much higher than the proper austenitizing temperature, because it produces a more uniformly refined grain structure. Recommended normalizing temperatures are given in Table 4. Work should be held at temperature for 15 min to 1 h, depending on section size; prolonged soaking is not desirable. When tools are to be hardened after normalizing, precautions must be taken in order to avoid decarburization during normalizing. If tools are to be subsequently machined, annealing is recommended in preference to normalizing.

Annealing. Finished or semifinished tools made from oil-hardening cold-work steels should be protected from decarburization or carburization during annealing. This can be accomplished by the use of dry exothermic furnace atmospheres. More often, however, it is accomplished by pack annealing, wherein work to be annealed is packed in a box and surrounded with inert protective material, such as clean cast iron chips or 6-to-8 mesh spent pitch coke. Pack annealing permits the use of an open furnace; also, slow heating and cooling occur naturally in the packed box. However, it is important that the work be soaked long enough to permit it to reach the annealing temperature. Recommended annealing temperatures, cooling rates, and expected hardness values are given in Table 4.

Type O1 steel may also be cycle annealed (Table 5). Cycle annealing offers little advantage for large loads, but with individual tools that can be conveniently handled in liquid baths or other conventional furnaces, it enables substantial savings in time.

Table 5 Cycle annealing treatments for four types of tool steel

Steel	Treatment
O1	**Heat to 730 °C (1350 °F), hold for 4 h; heat to 780 °C (1440 °F), hold for 2 h; cool to 690 °C (1275 °F), hold for 6 h; air cool**
A2	**Heat to 900 °C (1650 °F), hold for 2 h; cool to 760 °C (1400 °F), hold for 6 h; air cool**
A6	**Heat to 815 °C (1500 °F), hold for 2 h; cool to 650 °C (1200 °F), hold for 6 h; air cool**
D2	**Heat to 900 °C (1650 °F), hold for 2 h; cool to 775 °C (1425 °F), hold for 6 h; air cool**

Stress Relieving. In most instances, stress relieving of finished tools prior to final hardening does not noticeably lessen distortion during hardening. If extreme dimensional accuracy after hardening is required, tools should be stress relieved after rough machining but before final light machining. A recommended stress-relieving treatment consists of heating to 650 to 675 °C (1200 to 1250 °F), holding at temperature for 1 h per inch of thickness, and then air cooling.

Preheating of the O steels will minimize distortion during subsequent hardening. It is almost always required for tools that are to be austenitized in liquid baths. Recommended preheating temperatures are listed in Table 4. Open furnaces can be used for preheating, but if scale-free and oxide-free hardening is required, preheating must be done with atmosphere control.

Austenitizing. Recommended austenitizing temperatures for oil-hardening coldwork tool steels are given in Table 4. Work that has been preheated may either be transferred to an austenitizing furnace or be heated to the austenitizing temperature in the same furnace in which it was preheated.

Decarburization and scaling can be effectively minimized in liquid salt or lead baths, and in furnaces with controlled atmospheres (such as endothermic gas, dissociated ammonia, and argon or other inert gases). However, in all of these there is some danger of decarburization if conditions are not controlled. Oxides in the molten baths or excess water vapor in the various gases will cause decarburization. The atmospheres of gas-fired or oil-fired semimuffle furnaces can be adjusted to contain from 2 to 4% O_2, a condition that will eliminate decarburization but not oxidation. Types O1 and O2 can be satisfactorily austenitized in such an atmosphere, but it is not recommended for types O6 and O7. All type O steels may be austenitized in semimuffle furnaces if packed in inert materials such as spent pitch coke and clean cast iron chips. Adequate time must be allowed to ensure that packed work reaches prescribed temperature. If salt baths are used, a salt mixture such as No. 3 in Table 1 of the article, "Processes and Furnace Equipment for Heat Treating of Tool Steels" in this Volume, is recommended. For a suitable method of controlling this bath, see the discussion of rectification in that article.

Quenching. The optimum temperature range for quenching baths consisting of conventional oils is 40 to 60 °C (100 to 140 °F); agitation is recommended. Quenching oils that contain additives (fast oils) increase the cooling rate of the steel and permit more latitude in the operating temperature of the bath. Tools may be quenched in these oils at 80 °C (180 °F) without loss of hardness.

Martempering. If control of distortion is particularly important, martempering is sometimes advantageous. In martempering, the work is quenched in a bath of oil or molten salt that is usually held about 15 to 30 °C (25 to 50 °F) above the temperature (M_s) at which martensite starts to form from austenite on cooling, and is held in the bath long

enough to allow it to attain substantially equalized temperature throughout. The work is then removed from the bath and air cooled. The slow cooling through the martensitic transformation range permits the transformation of austenite to martensite to take place uniformly throughout the piece, thus minimizing distortion. Figure 5 presents a comparison of the dimensional changes in tools made of O1 steel that were oil quenched with those in tools of the same steel martempered at 230 °C (450 °F) for 10 min; the martempered tools exhibited markedly less distortion.

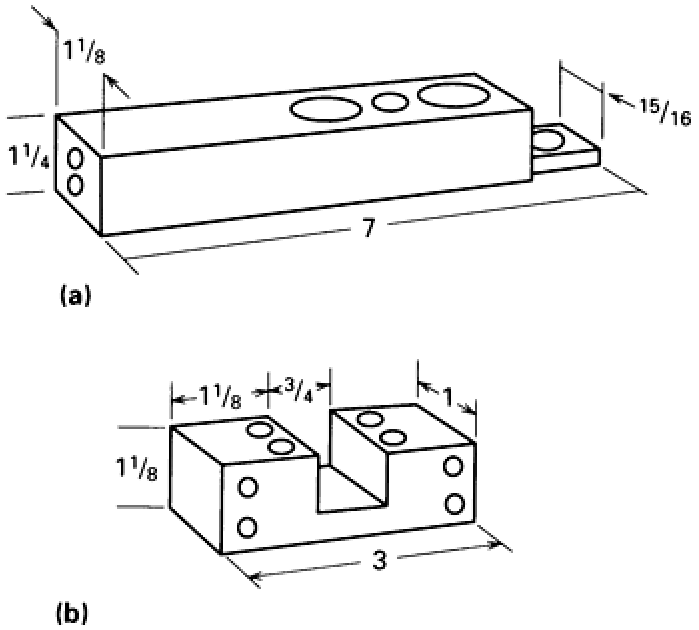

Fig. 5 Dimensional changes in O1 tools. Tools sketched, made of O1 steel, were used for comparison of dimensional changes resulting from martempering at 230 °C (450 °F) for 10 min, and from oil quenching. Five tools of each design, processed by each method, were measured on 5 different days. (a) Maximum change in flatness along the 180 mm (7 in.) dimension was 0.25 mm (0.020 in.) after oil quenching and 0.005 mm (0.0002 in.) after martempering. (b) Maximum change of the 19 mm ($\frac{3}{4}$ in.) slot width was 0.1 mm (0.0039 in.) after oil quenching and 0.33 mm (0.0012 in.) after martempering.

Tempering. The O steels should be tempered immediately after quenching (preferably before they reach room temperature). These steels usually are not tempered below 120 °C (250 °F) or above 540 °C (1000 °F); the most commonly used temperature range is from 175 to 205 °C (350 to 400 °F). Tempering times vary with section size. Often, a time at temperature of 1 h per inch of thickness (minimum dimension of heaviest section) or per inch of diameter, with a minimum of 1 h, is used.

Typical hardness values obtained with various tempering temperatures for oil-hardening tool steels are given in Fig. 6. The upper curve in each graph represents results from austenitizing at the higher side of the range of temperatures indicated, and the lower curve represents results from austenitizing at the lower side.

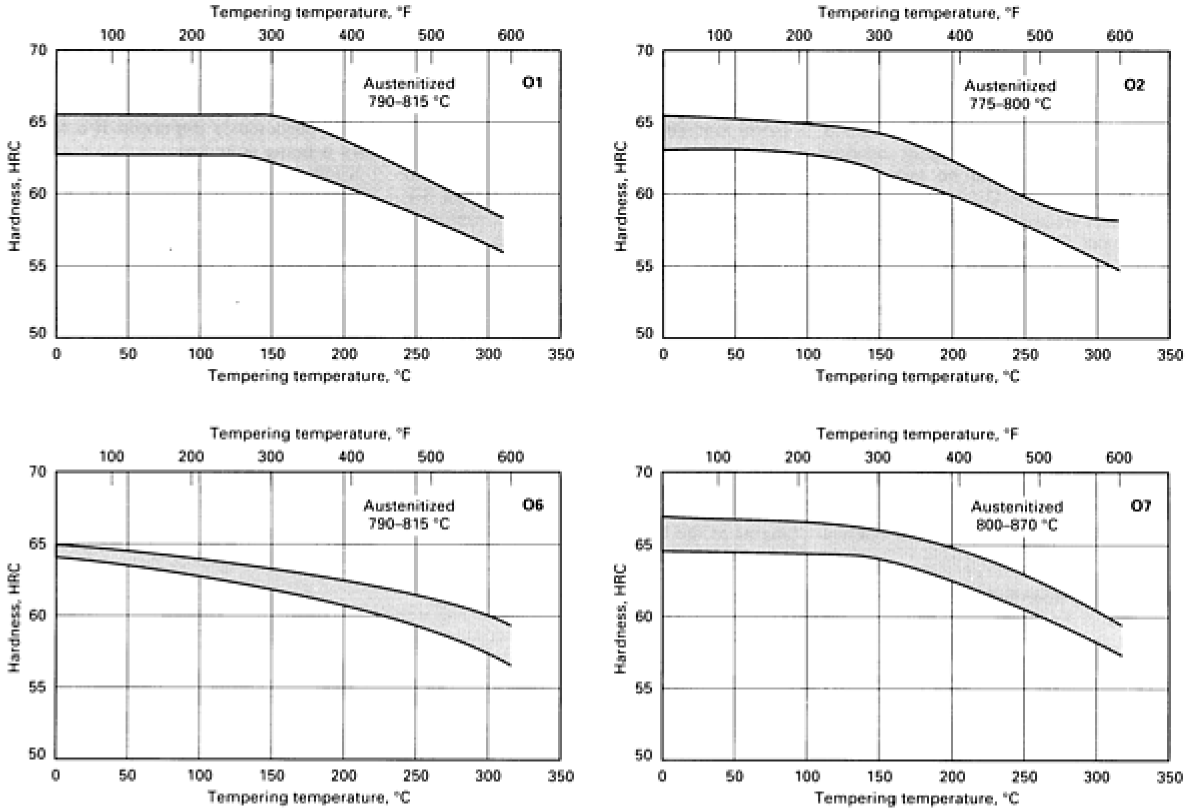

Fig. 6 Hardness as a function of tempering temperature, for oil-hardening cold-work tool steels. Steels O1, O2, and O6 were austenitized at the temperatures indicated, and then oil quenched. For O7 steel, large uniform sections were austenitized at 800 to 830 °C (1475 to 1525 °F) and water quenched, and other sections were austenitized at 830 to 870 °C (1525 to 1600 °F) and oil quenched. Duration of tempering was 1 h.

Conventional tools made from the O steels are seldom subjected to multiple tempering or subzero treatment. However, for some special tools, such as gages, where dimensional stability is critical, multiple tempering is desirable. In such instances the workpieces should be cooled to below 65 °C (150 °F) prior to each retempering. Subzero cooling to -75 °C (-100 °F) or lower is also helpful in achieving dimensional stability.

Medium-Alloy Air-Hardening, and High-Carbon High-Chromium, Cold-Work Tool Steels

Recommended heat-treating practices for medium-alloy air-hardening cold-work tool steels (group A) and high-carbon high-chromium cold-work tool steels (group D) are summarized in Table 6.

Table 6 Recommended heat-treating practices for medium-alloy air-hardening, and high-carbon high-chromium, cold-work tool steels

Not rec, not recommended.

(a) Holding time, after uniform through heating, varies from about 15 min, for small sections, to about 1 h, for large sections. Work is cooled from temperature in still air.

(b) Lower limit of range should be used for small sections, upper limit for large sections. Holding time varies from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(c) Maximum rate, to 540 °C (1000 °F) unless footnoted to indicate otherwise.

(d) To 705 °C (1300 °F).

(e) For open furnace heat treatment. For pack hardening, hold for $\frac{1}{2}$ h per inch of pack cross section.

(f) Hardness varies with austenitizing temperature.

(g) To 650 °C (1200 °F).

(h) One manufacturer recommends cooling from 760 to 540 °C (1400 to 1000 °F), then reheating to 730 °C (1350 °F) and cooling.

Normalizing. Except for type A10 (see Table 6), normalizing is not recommended for any of the steels in groups A and D.

Annealing. These steels are usually supplied in the annealed condition by the manufacturer. However, they should be annealed after forging and prior to rehardening. Annealing is required also for previously hardened or welded tools that are to be reworked.

Recommended annealing temperatures for the various types are given in Table 6. Tools should be heated slowly and uniformly to the annealing temperature. Slow heating is particularly important if a hardened tool is being annealed.

Cycle, or isothermal, treatments may be employed for annealing some A and D steels (Table 5).

Stress Relieving. Tools made of A and D steels that cannot be ground after hardening are sometimes stress relieved after rough machining. This is particularly advisable for delicate tools and tools that vary markedly in cross section. Stress relieving is used also on tools that are machined to final shape, if these tools can be straightened after stress relieving and before final heat treatment. There is little advantage in stress relieving completed tools if they cannot be straightened prior to hardening, because a good preheat will relieve stresses, and the distortion which occurs in either case will remain uncorrected. Recommended temperatures for stress relieving are:

A2, A7	650-675 °C	**(1200-1250 °F)**
A4, A5, A6	675-705 °C	**(1250-1300 °F)**
D1-D7	**675-705 °C**	**(1250-1300 °F)**

Usually, tools can be stress relieved at these temperatures without surface protection. Tools are commonly held at temperature for 1 h/in. of cross section (minimum of 1 h) and then air cooled.

Preheating. Steels of the A and D groups are usually preheated before being austenitized for hardening. Preheating reduces subsequent distortion in the hardened parts by minimizing nonuniform dimensional changes during austenitizing. Preheating simpler tools made of grades A4, A5, A6, and A10 can often be eliminated if they are austenitized in a furnace instead of a liquid bath, because these steels are austenitized at lower temperatures.

Recommended preheating temperatures are listed in Table 6. Holding time at temperature is usually 1 h per inch of maximum cross section. Preheating temperatures of 790 to 815 °C (1450 to 1500 °F) are used for tools made from A2, A3, A7, A8, or A9, or from any of the D steels. For these higher temperatures, a liquid bath or a protective furnace atmosphere is required in order to prevent scaling and decarburization.

Austenitizing. Steels of groups A and D can be austenitized in molten salt baths or in various types of furnaces using gaseous atmospheres. Because of their lower austenitizing temperatures, types A4, A5, A6, and A10 may also be austenitized in molten lead, or in open furnaces with oxidizing atmospheres. However, the latter methods are not satisfactory for the other A steels or for the D steels, because of their higher austenitizing temperatures.

If salt baths are used, salt mixtures such as No. 2 or No. 3 in Table 1 of the article, "Processes and Furnace Equipment for Heat Treating of Tool Steels," are recommended; the choice between the two depends on required working temperature range. These mixtures may be rectified (for the prevention of decarburization) by the method indicated in that article.

Procedures for austenitizing two different parts made of D2 steel by salt bath and by endothermic atmosphere furnace processes are shown in Table 7.

Table 7 Procedures for salt bath and endothermic atmosphere austenitizing of D2 inserts

Bending die inserts[a]	
Salt bath[b]	**Preheat in air furnace at 650 °C (1200 °F) for $1\frac{1}{2}$ h[c]; austenitize at 1010 °C (1850 °F) for 35 min[c]; air cool; remove salt**
Endothermic atmosphere[d]	**Charge directly into furnace at 705 °C (1300 °F) and preheat for $1\frac{1}{2}$ h[c]; austenitize at 1010 °C (1850 °F) for 2 h; air cool[c]**
Trim die inserts[e]	
Salt bath[b]	**Preheat in air furnace at 650 °C (1200 °F), 4 h[c], then in salt bath at 845 °C (1550 °F), 1 h[c][f]; austenitize at 1010 °C (1850 °F) for 1 h[c]; air cool[c]; remove salt**
Endothermic	**Charge directly into furnace at 705 °C (1300 °F), and preheat for 4 h[c]; raise furnace temperature, and**

atmosphere[d]	austenitize at 1010 °C (1850 °F) for 4 h; air cool[c]

(a) After austenitizing, inserts 200 by 305 by 38 mm (8 by 12 by $1\frac{1}{2}$ in.) were double tempered (2 h at 510 °C or 950 °F, air cool; 2 h at 510 °C or 950 °F, air cool) and then nitrided for 48 h at 510 °C (950 °F).

(b) Salt bath furnace was immersed-electrode type, 380 by 760 by 915 mm (15 by 30 by 36 in.) deep.

(c) Manual loading requires $1\frac{1}{2}$ min per piece.

(d) Furnace was radiant-tube type, 610 by 915 by 455 mm (24 by 36 by 18 in.) high.

(e) After austenitizing, die inserts were double tempered (4 h at 190 °C or 375 °F, air cool; 4 h at 190 °C or 375 °F, air cool).

(f) Second preheat was necessary because of faster heating rate of salt bath.

In some instances, austenitizing will cost more with atmosphere furnaces than with salt baths, and in other instances the reverse will be true. Atmospheres that have proved suitable for austenitizing the A and D steels are endothermic, dry dissociated ammonia, and dry hydrogen.

Endothermic gas produced by catalytic combination of air and fuel gas is the most widely used atmosphere. This relatively inexpensive gas can be adjusted for desired carbon potential and controlled by dew point.

Dry dissociated ammonia (dew point, -50 °C, or -60 °F) and dry hydrogen (dew point, -75 °C, or -100 °F) are used in applications in which complete freedom from discoloration is required. Vacuum, which excludes all atmosphere, can also be used to austenitize the A and D steels; it is particularly suitable for these steels because their air-hardening characteristics permit slow cooling rates.

Like the O steels, the A and D steels may be packed and then austenitized in semi-muffle furnaces. The packing materials and heat-treating procedures employed are similar to those described in the previous section on austenitizing of the O grades.

Steels of groups A and D must be held at their austenitizing temperatures long enough to obtain required carbide solution if they are to attain maximum hardness. However, hardening from excessively high austenitizing temperatures will increase the retained austenite. Although retained austenite can be decreased by repeated tempering or subzero cooling (or both), it should be avoided.

Quenching. Steels of groups A and D, except D3, will attain maximum hardness by cooling in still air, unless sections are extremely large. However, the hardenability of these steels varies with different types, as indicated in Table 8.

Table 8 Hardenability in still air of several A and D tool steels

Steel	Center hardening		Surface hardening	
	Size of section that fully hardens at center	Hardness, HRC	Size of section that fully hardens at surface	Hardness, HRC

A2, A4	75 mm (3 in.) diam	59-61	100 mm (4 in.) diam	**59-61**
A5	. . .	. . .	100 mm (4 in.) diam	**62-63**
A6	180 mm (7 in.) cube	59-60	180 mm (7 in.) cube	**60-61**
D1, D2, D5	**100 mm (4 in.) cube**	**60-61**	**125 × 125 × 255 mm (5 × 5 × 10 in.)**	**61-62**

Depending on section size, hardenability, and complexity of shape, the following methods are used to obtain increasingly accelerated cooling of nominally air-hardening steels:

- Cool in still air--that is, atmospheric air undisturbed by artificial circulation
- Cool in fan air--that is, the current of air discharged from a fan
- Cool in air blast--that is, the discharge from a high-pressure line
- Oil quench to black--that is, quench in oil until the steel is below the temperature at which it glows dull red, then cool to room temperature in air
- Oil quench by conventional practice

Tempering practices for A and D steels parallel those described for O steels in the preceding section. Tempering is usually begun when the work reaches a temperature of about 50 to 65 °C (120 to 150 °F). However, these steels retain some austenite at this temperature range. To maximize transformation of austenite to martensite, cooling to room temperature, or to subzero temperature (see the article "Cold Treating and Cryogenic Treatment of Steel" in this Volume), is sometimes applied.

Opinions vary greatly as to the merits of subzero cooling, because it increases the probability of cracking during the cooling cycle. The more usual practice is to begin tempering when parts reach about 50 to 65 °C (120 to 150 °F) and then double or triple temper. Multiple tempering is effective in decreasing the amount of austenite retained in A and D steels and is a common practice in heat treating them. The general precautions and tempering practices outlined for O steels in the preceding section are followed for the A and D steels. However, because most of the steels in groups A and D (except A4, A5, and A6) soften less rapidly than the group O steels with an increase in tempering temperature (Fig. 7 and 8), higher tempering temperatures can be used for the A and D steels. A minimum tempering temperature of 205 °C (400 °F) is a common requirement for A2, A7, and D steels. Tempering temperatures as high as 550 °C (1025 °F) are frequently used, and even higher temperatures are used for special requirements.

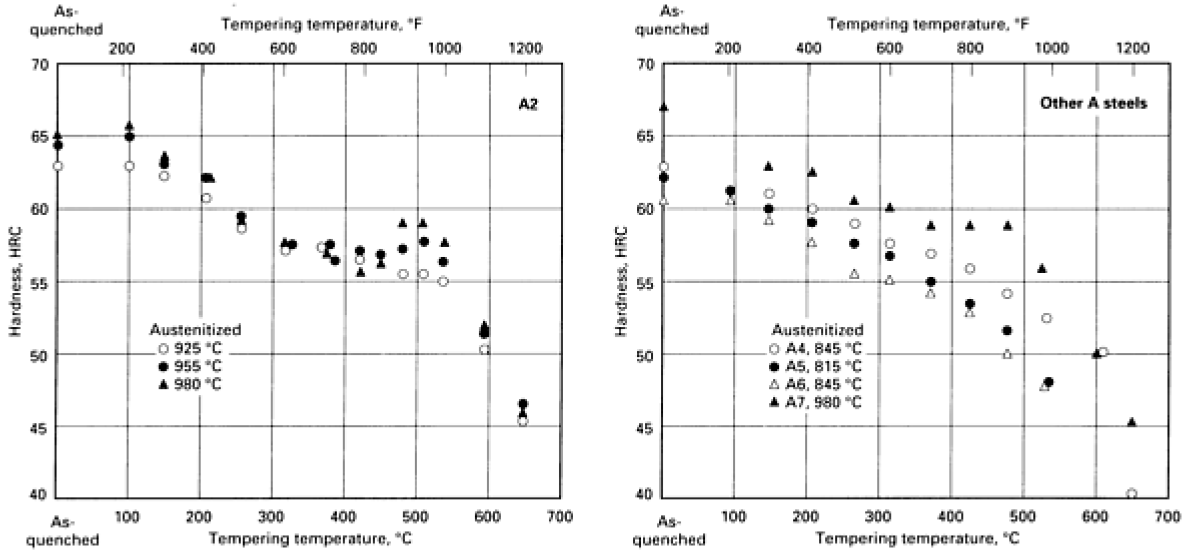

Fig. 7 Effect of tempering temperature on hardness of medium-alloy air-hardening steels

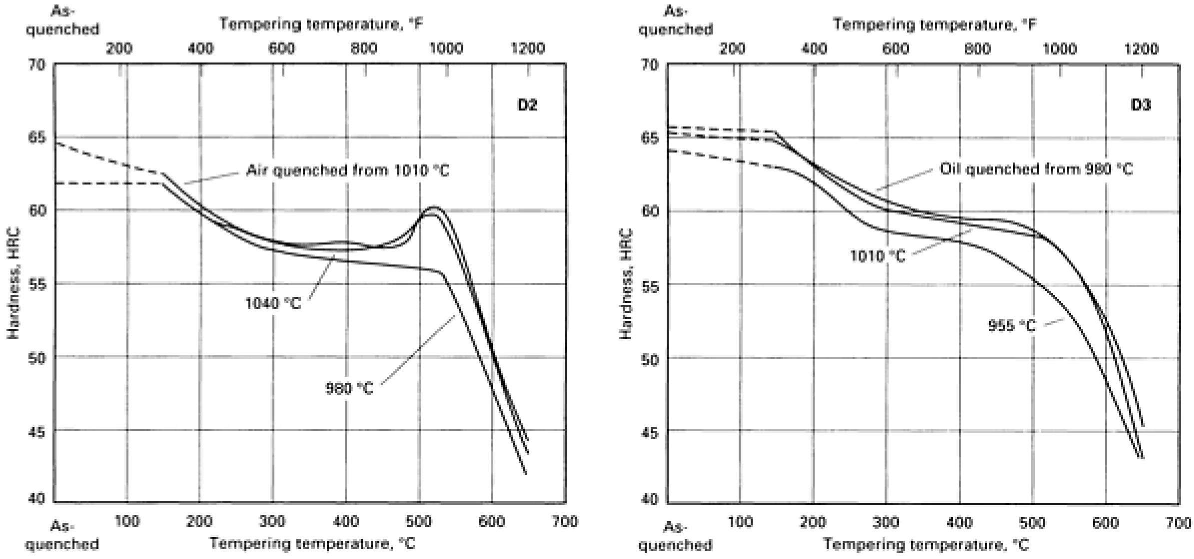

Fig. 8 Relation between tempering temperature and hardness for D2 and D3 tool steels. Steels were austenitized in an air furnace; a recirculating pit-type furnace was used for tempering. Curves representing steel from three suppliers; average of 5 hardness measurements made on each specimen from each supplier. Specimens were 25 mm (1 in.) in diam and 38 mm ($1\frac{1}{2}$ in.) long.

It will be noted in Fig. 7 and 8 that certain steels (notably A2 and D2) exhibit higher hardness after being tempered at about 540 °C (1000 °F) than after being tempered at temperatures 55 to 110 °C (100 to 200 °F) lower. This reversal in the usual relationship is known as secondary hardening, and is caused by transformation of retained austenite during tempering at the higher temperatures, near 540 °C (1000 °F). When a steel can be tempered to the same hardness at more than one temperature (for instance, D2 to 58 to 59 HRC), it is advisable to select the highest tempering temperature that will produce the desired hardness. This will yield added toughness and may prevent tool breakage in service.

Nitriding. The A steels (particularly A2 and A7) and the D steels are often nitrided after being hardened and tempered. Nitriding may be done either in a salt bath or in an atmosphere of dissociated ammonia. High tempering temperatures of 510 to 540 °C (950 to 1000 °F) are used on steels that are to be nitrided. Excessively high nitriding temperatures, with a

recommended range of 510 to 540 °C (950 to 1000 °F), will reduce hardness of the base metal and should not be used. Austenitizing at a higher temperature when hardening prior to nitriding will minimize loss of hardness during nitriding of some D steels (note graph for D2 in Fig. 8). For details, see the article "Gas Nitriding" in this Volume.

Hot-Work Tool Steels

Nominal compositions of chromium, tungsten, and molybdenum types of hotwork tool steels are given in Table 1 of the article entitled "Introduction to Heat Treating of Tool Steels " in this Volume. The steels in the group denoted in Table 1 as "Other Alloy Tool Steels" are included here in the discussion of hot-work tool steels, because they are also used extensively for hot-work applications. Table 9 summarizes the heat-treating practices commonly employed for this composite group of tools steels.

A, air; O, oil; S, salt; Not rec, not recommended; Not req, not required.

(a) Holding time, after uniform through heating, varies from about 15 min, for small sections, to about 1 h, for large sections. Work is cooled from temperature in still air.

(b) Lower limit of range should be used for small sections, upper limit for large sections. Holding time varies from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(c) Maximum rate, to 425 °C (800 °F) unless footnoted to indicate otherwise.

(d) For open furnace heat treatment. For pack hardening, hold for $\frac{1}{2}$ h per inch of pack cross section.

(e) Temper to precipitation harden.

(f) To 540 °C (1000 °F).

(g) To 480 °C (900 °F).

(h) To 370 °C (700 °F).

(i) To 205 to 175 °C (400 to 350 °F), then air cool.

(j) Temper immediately.

(k) For isothermal annealing, furnace cool to 650 °C (1200 °F), hold for 4 h, furnace cool to 425 °C (800 °F), then air cool.

(l) For isothermal annealing, furnace cool to 670 °C (1240 °F), hold for 4 h, furnace cool to 425 °C (800 °F), then air cool.

(m) (p) Cool with forced-air blast to 205 to 175 °C (400 to 350 °F), then cool in still air.

(n) Air cool from annealing temperature.

(o) Furnace cool, at 22 °C (40 °F), (max) per h, to 425 °C (800 °F), reheat to 595 ± 14 °C (1100 ± 25 °F), furnace cool to 425 °C (800 °F), then air cool.

(p) Furnace cool at 17 °C (30 °F) per h to 540 °C (1000 °F), reheat to 790 °C (1450 °F), furnace cool at 11 °C (20 °F) per h to 540 °C (1000 °F), then air cool.

(q) Heat in pack or in controlled atmosphere.

(r) To 50 °C (125 °F).

(s) Pack heating, 59 to 60 HRC; atmosphere heating, 54 to 55 HRC.

(t) For isothermal annealing. hold at 845 °C (1550 °F) for 2 h, furnace cool to 745 °C (1375 °F), hold for 4 to 6 h, then air cool.

Normalizing. Because these steels as a group are either partially or completely air-hardening, normalizing is not recommended except for the high-nickel steel 6F7. After forging or before reheat treating, 6F7 may be normalized by heating to 845 to 870 °C (1550 to 1600 °F), preferably in a controlled atmosphere, and cooling in still air.

Annealing. Recommended annealing temperatures, cooling practices, and expected hardness values are given in Table 9. Heating for annealing should be slow and uniform to prevent cracking, especially when annealing hardened tools. Heat losses from the furnace usually determine the rate of cooling; large furnace loads will cool at a slower rate than light loads. For most of these steels, furnace cooling to 425 °C (800 °F), at 22 °C max (40 °F max) per h, and then air cooling, will suffice.

For types 6F2, 6F3, and 6H1, an isothermal anneal (Table 9) may be employed to advantage for small tools that can be handled in salt or lead baths or for small loads in batch-type furnaces; however, isothermal annealing has no advantage over conventional annealing for large die blocks or large furnace loads of these steels.

To minimize scaling and decarburization, small parts are usually pack annealed, while large and heavy die blocks are more commonly annealed in controlled-atmosphere furnaces.

Packing material should preferably be spent cast iron chips or spent pitch coke-petroleum coke heated to 1205 °C (2200 °F) in a semiclosed container to drive off gas and moisture. Lime, sand, or mica is sometimes used, but under such material if mixed with a small amount of charcoal or other carburizing material, the steel may be decarburized. Packing material should be dry and free of all oxidizing materials, should separate all metal surfaces, and should fill the container. Containers should be sealed after packing. Holding time at the annealing temperature is 1 h per inch of container thickness. The H steels must have a neutral packing material, because they are extremely susceptible to both carburization and decarburization.

In controlled-atmosphere furnaces, the work should be supported so that it does not touch the bottom of the furnace. This will ensure uniform heating and permit free circulation of the atmosphere around the work. Workpieces should be supported so that they will not sag or distort under their own weight.

Grades 6F4 and 6F7 may be annealed without packing or controlled atmosphere if light scaling is not objectionable, because they are annealed at lower temperatures (Table 9).

Stress Relieving. It is sometimes advantageous to stress relieve tools made of hot-work steel after rough machining but prior to final machining, by heating them to 650 to 730 °C (1200 to 1350 °F). This treatment minimizes distortion during hardening, particularly for dies or tools that have major changes in configuration or deep cavities. However, closer dimensional control can be obtained by hardening and tempering after rough machining and prior to final machining, provided that the final hardness obtained by this method is within the machinable range.

Preheating prior to austenitizing is nearly always recommended for all hot-work steels except 6G, 6F2, 6F3, and 6F5. These four steels may or may not require preheating, depending on size and configuration of the workpieces. Recommended preheating temperatures for all the other types are given in Table 9.

Die blocks or other tools for open furnace treatment should be placed in a furnace that is not over 260 °C (500 °F). Work that is packed in containers may be safely placed in furnaces at 370 to 540 °C (700 to 1000 °F). Once the workpieces (or container) have attained furnace temperature, they are heated slowly and uniformly, at 65 to 110 °C (150 to 200 °F) per h, to the preheating temperature (Table 9) and held for 1 h per inch of thickness (or per inch of container thickness, if packed). Thermocouples should be placed adjacent to the pieces in containers. Controlled atmospheres or other protective means must be used above 650 °C (1200 °F) to minimize scaling and decarburization. A slightly reducing atmosphere is especially recommended for preheating of H41.

For certain parts--for example, intricate die-casting dies--preheating is omitted. Distortion of such parts is sometimes lessened by packing them and heating them slowly and uniformly throughout the entire range to the quenching temperature.

Austenitizing temperatures recommended for the hardening of hot-work tool steels are given in Table 9. Rapid heating from the preheating temperature to the austenitizing temperature is preferred for types H16 through H43 and for type 6F4.

Except for steels H10 through H14 (see Table 9), time at the austenitizing temperature should only be sufficient to heat the work completely through; prolonged soaking is not recommended. Time cycles for several specific conditions are indicated in the next section of this article entitled "Examples of Heat-Treating Procedure for Hot-Work Tools."

The equipment and method employed for austenitizing are frequently determined by the size of the workpiece. For tools weighing less than about 230 kg (500 lb), any of the methods would be suitable. However, larger tools or dies would be difficult to handle in either a salt bath or a pack.

Tools or dies made of hot-work steel must be protected against carburization and decarburization when being heated for austenitizing. Carburized surfaces are highly susceptible to heat checking. Decarburization causes decreased strength, which may result in fatigue failures; and on die-casting dies, the molten casting metal will weld on to decarburized surfaces and may cause washout because of poor wear resistance of the decarburized surface. However, the principal detrimental effect of decarburization is to mislead the heat treater as to the actual hardness of the die. To obtain specified hardness of the decarburized surface, the die is tempered at too low a temperature. The die then goes into operation at excessive internal hardness and breaks at the first application of load.

An endothermic atmosphere produced by a gas generator is probably the most widely used protective medium. The dew point is normally held from 2 to 7 °C (35 to 45 °F) in the furnace, depending on carbon content of the steel and operating temperature. A dew point of 3 to 4 °C (38 to 40 °F) is ideal for most steels of type H11 or H13 when austenitized at 1010 °C (1850 °F).

The packing of work in spent pitch coke before heating it for austenitizing has been used extensively in small shops where it has not been feasible to invest in special equipment. This procedure is generally used for small dies. New pitch coke is generally heated to 1040 to 1205 °C (1900 to 2200 °F) to burn off any combustibles that may be present as well as to remove any excessive moisture. The spent pitch coke is then sifted to remove the fines (the coke should also be sifted before re-use). Normal procedure for this method is to wrap the workpiece in plain brown wrapping paper and place it in

a heat-resistant metal box in the bottom of which is about 50 mm (2 in.) of spent pitch coke. The workpiece should be covered and surrounded with approximately 50 to 100 mm (2 to 4 in.) of spent pitch coke. The cover is then placed on the box and sealed with a refractory paste. The box is then ready to be placed in a furnace, which need not be provided with controlled atmosphere.

Quenching. Hot-work steels range from high to extremely high in hardenability. Most of them will achieve full hardness by cooling in still air; however, even with those types having the highest hardenability, sections of die blocks may be so large that insufficient hardening results. In such instances, an air blast or an oil quench is required to achieve full hardness. Hot-work steels are never water quenched. Recommended quenching media are listed in Table 9.

If blast cooling is used, air should be blasted uniformly on the surface to be hardened. All air must be dry. When being air quenched, dies or other tools should not be placed on concrete floors or in locations where water vapor may strike them.

Some of the hot-work steels (especially the tungsten and molybdenum types) will scale considerably during cooling to room temperature in air. An interrupted quench reduces this scaling by eliminating the long period of contact with air at elevated temperature, but it also increases distortion. The procedure is best carried out by quenching from the austenitizing temperature in a salt bath held at 595 to 650 °C (1100 to 1200 °F), holding in the quench until the workpiece reaches the temperature of the bath, and then withdrawing the piece and allowing it to cool in air. An alternative, but less precise, procedure is to quench in oil at room temperature or slightly above and judge by color (faint red) when the workpiece has reached 595 to 650 °C (1100 to 1200 °F); the piece is then quickly withdrawn and permitted to cool to room temperature in air. While cooling, the pieces should be placed in a suitable rack, or be supported by wires, in such a manner that air is permitted to come in contact with all surfaces.

Steel H23 requires a different type of interrupted quench, because ferrite precipitates rapidly in this steel at 595 °C (1100 °F) and M_s is below room temperature. Type H23 should be quenched in molten salt at 165 to 190 °C (325 to 375 °F) and then air cooled to room temperature. This steel will not harden in quenching but will do so by secondary hardening during the tempering cycle.

Parts quenched in oil should be completely immersed in the oil bath, held until they have reached bath temperature, and then transferred immediately to the tempering furnace. Oil bath temperatures may range from 55 to 150 °C (130 to 300 °F), but should always be below the flash point of the oil. Oil baths should be circulated and kept free of water.

Tempering. Hot-work tool steels should be tempered immediately after quenching, even though sensitivity to cracking in this stage varies considerably among the various types (for example, air-quenched 6F4 may be safely kept at room temperature for several hours before tempering, whereas 6G, 6F2, and 6F3 are susceptible to cracking if they are cooled substantially below 175 °C, or 350 °F, before tempering).

Hot-work steels are usually tempered in air furnaces of the forced-convection type. Salt baths are used successfully for smaller parts, but for large complex parts salt bath tempering may induce too severe a thermal shock and cause cracking. The effect of tempering temperature on hardness of hot-work tool steels is shown in Fig. 9(a), 9(b), and 9(c).

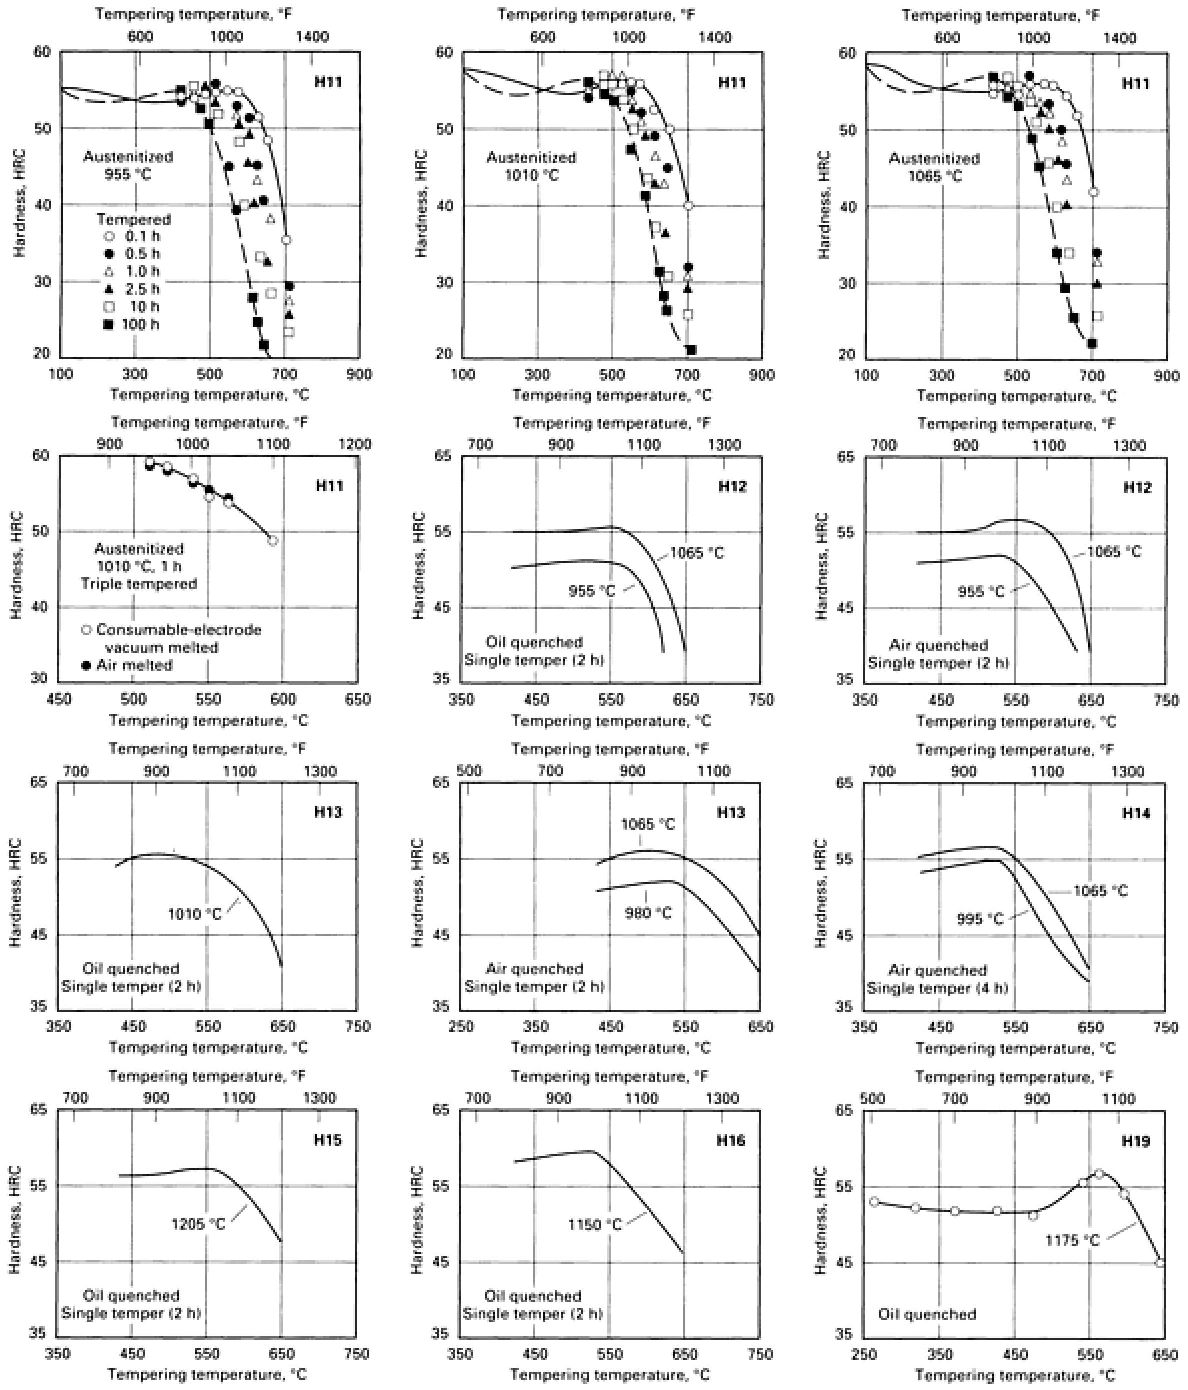

Fig. 9(a) Effect of temperature on hardness of chromium hot-work tool steels

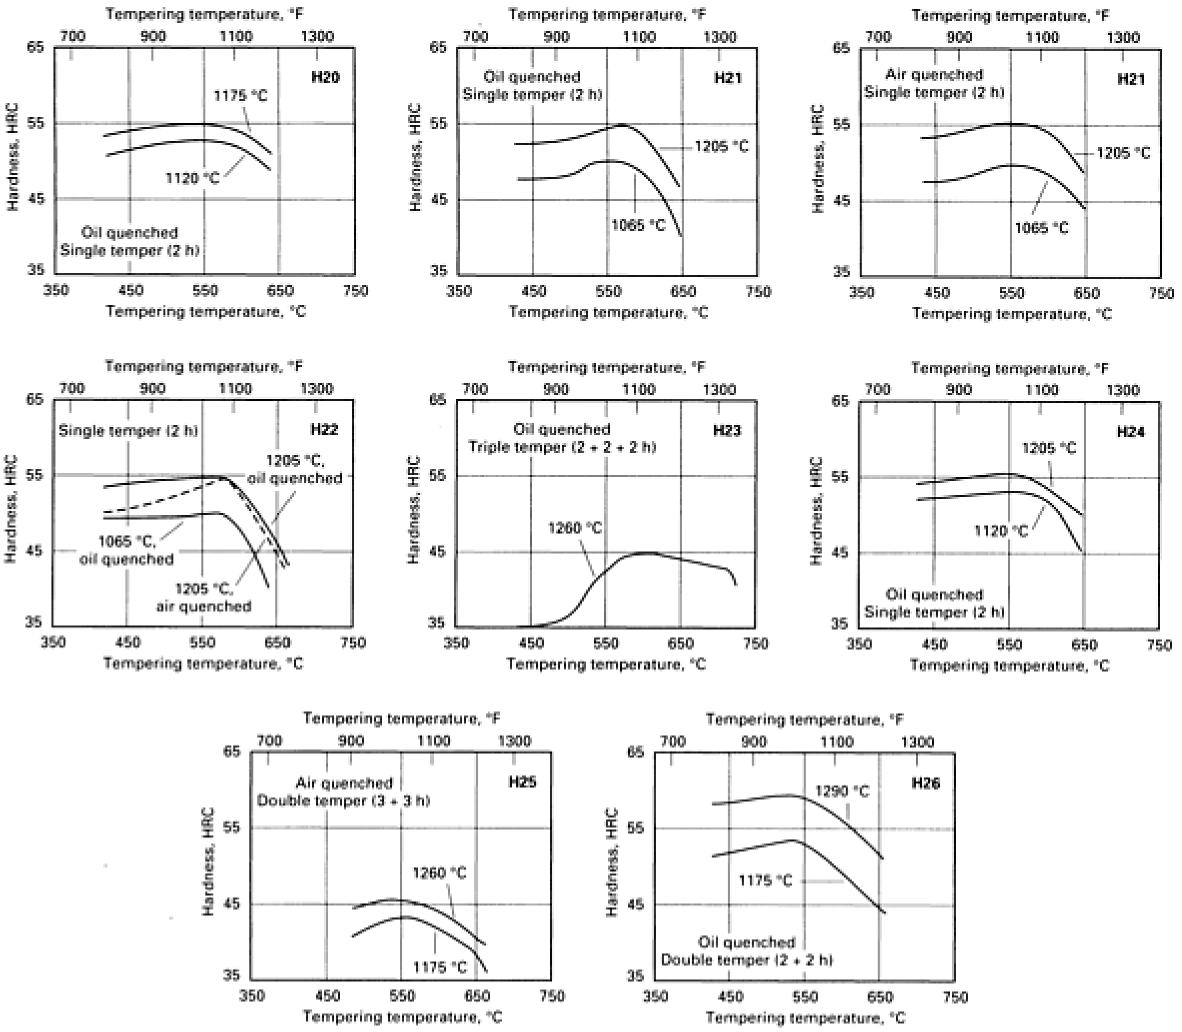

Fig. 9(b) Effect of temperature on hardness of tungsten hot-work tool steels

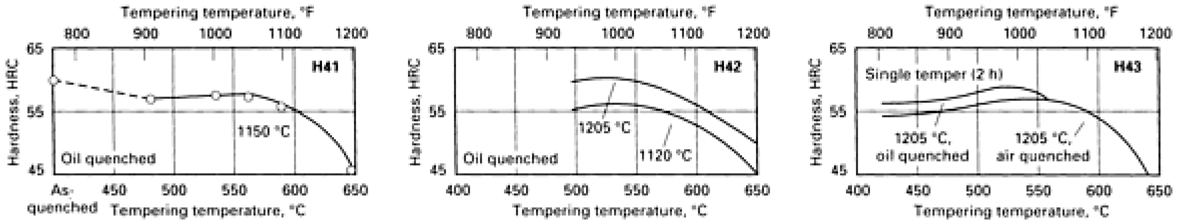

Fig. 9(c) Effect of temperature on hardness of molybdenum hot-work tool steels

Multiple tempering ensures that any retained austenite that transforms to martensite during the first tempering cycle is tempered before a tool is placed in service. Multiple tempering also minimizes cracks due to stress originating from the hardening operation.

Multiple tempering has proved particularly advantageous for large or sharp-cornered die blocks that are not permitted to reach room temperature before the first tempering operation.

Example 6: Heat Treatment of Selected Hot-Work Steels.

In one plant where many die blocks are heat treated, standard practice is as follows. When the dies have air cooled to 52 °C (125 °F), they are placed in a tempering furnace maintained at 565 °C (1050 °F). After the dies have reached furnace temperature, they are soaked for 1 h per inch of thickness. The dies are then air cooled to room temperature. Second and third tempering operations are carried out in the same manner, except that temperature may be increased as required in order to obtain desired hardness.

Most of the hot-work steels have secondary hardening characteristics; H23 is the most pronounced in this respect (Fig. 9(a), 9(b), and 9(c)). As with A2 and D2 (discussed previously), these secondary-hardening hot-work steels should be tempered at the highest temperature at which the desired hardness can be produced.

Surface Hardening. Although tools and dies made of the hot-work steels usually have sufficient hardness to perform the tasks for which they were designed, they are occasionally surface hardened to acquire improved resistance to wear or heat for special applications. The two principal processes that have been used for this purpose are carburizing and nitriding.

Carburizing is usually limited to hot-work steels having a carbon content of 0.35% or lower. Type H12 has been reported to achieve a carburized surface hardness of 60 to 62 HRC. The carburized case should be shallow--for example, 0.4 mm (0.015 in.) maximum--or severe embrittlement will occur. The greater the thermal shock (or gradient) present in service--as in die casting--the shallower the case must be.

Nitriding. Gas or liquid nitriding is sometimes applied to the hot-work steels to increase resistance to heat or wear, or both. For instance, dies for hot extrusion are sometimes nitrided to increase service life. One disadvantage of nitriding, however, is the difficulty it imposes on the reworking of tools or dies. Another disadvantage is that it may accentuate heat checking. Hot-work steels should be hardened and tempered before being nitrided, but should be neither decarburized nor carburized.

The quality and depth of the nitrided case are influenced by the chemical composition of the steel and by the time and temperature of nitriding. The presence of nitride-forming elements such as chromium and vanadium is helpful to the attainment of a satisfactory case. The fact that most of the hot-work steels reach a secondary hardening peak when tempered in the vicinity of 540 °C (1000 °F) is beneficial, because nitriding is usually accomplished in a range of 510 to 540 °C (950 to 1000 °F) over a period of 15 to 24 h. The nitrided case, in addition to being very hard, may be brittle. Brittleness increases with depth of case; hence, shallow, 0.08 to 0.2 mm (0.003 to 0.008 in.), nitrided cases are usually applied.

Examples of Heat-Treating Procedure for Hot-Work Tools

Tools and dies made of hot-work steel extend over an extremely wide range of sizes and weights (sometimes up to several tons, as in the largest die blocks). Therefore, details of heat-treating techniques may vary considerably. The following examples give details of procedures that have proved successful in practice:

Example 7: Heat Treating of an H21 Hot Extrusion Die.

A typical method for heat treating a 75 mm (3 in.) thick, 200 mm (8 in.) OD, 75 mm (3 in.) hole, hot extrusion die made of H21 steel comprises the following:

- Preheat at 815 to 845 °C (1500 to 1550 °F), either in a slightly oxidizing atmosphere or in neutral salt
- Transfer to furnace (6 to 12% reducing atmosphere or neutral salt bath) operating at 1175 °C (2150 °F). Hold in furnace for approximately 20 min after the die has reached 1175 °C (2150 °F)
- Cool in still air to about 65 °C (150 °F)
- Temper at 565 °C (1050 °F) for 4 h
- Cool to near room temperature
- Retemper at 650 °C (1200 °F) for 4 h
- Air cool

Example 8: Heat Treating of an H11 Mandrel.

Mandrels made of H11, used in conjunction with the H21 die in Example 7, above, are heat treated as follows:

- Preheat at 760 °C (1400 °F) in a slightly oxidizing atmosphere
- Transfer to atmosphere furnace (1 to 3% excess O_2) operating at 1010 °C (1850 °F) and hold for 20 min plus 5 min for each inch of thickness
- Air cool to near room temperature (oil quenching can also be used)
- Temper (or, preferably, double temper) for desired hardness

Example 9: Heat Treating of an H13 Die Block.

One plant employs the following procedure for heat treating die blocks made of H13 that weigh less than 23 kg (50 lb):

1. Insert eyebolt to facilitate handling
2. Wrap die block in waxed paper and place in a heat-resistant container on a bed of spent pitch coke 75 to 100 mm (3 to 4 in.) deep
3. Seal cover on container with asbestos paste
4. Place container in furnace (not atmosphere-controlled) operating at 760 °C (1400 °F); bring to furnace temperature and hold for 4 h
5. Raise furnace temperature at 30 °C (50 °F) per h to 1010 °C (1850 °F) and hold charge at this temperature for 6 h
6. Remove die block from container by use of eyebolt
7. Cool in still air to 345 °C (650 °F) (temperature-indicating crayons may be used), then place in furnace operating at 345 °C (650 °F) and cool in furnace at 30 °C (50 °F) per h to 95 °C (200 °F). (If the die block has no sharp corners or major changes in configuration, the interrupted cooling may be omitted)
8. Remove from furnace and cool in air to 40 °C (100 °F)
9. Place in tempering furnace operating at 565 °C (1050 °F), bring to furnace temperature and hold for 8 h, air cool to room temperature and check hardness
10. Repeat step 9, except that it may be necessary to increase tempering temperature so that final hardness will be 46 to 49 HRC

Example 10: Heat Treating of an H13 Die Block.

The following procedure has proved successful for heat treating large die blocks, 1590 kg (3500 lb), made of H13 steel:

1. Load die block into electrically heated bell-type furnace. The sequence of operations begins when furnace temperature reaches 95 °C (200 °F)
2. Raise furnace temperature at 30 °C (50 °F) per h to 370 °C (700 °F)
3. Introduce nitrogen atmosphere to furnace and increase furnace temperature at 55 °C (100 °F) per h to 790 °C (1450 °F); hold for 1 h, then shut off nitrogen, introduce endothermic atmosphere--dew point, 3 to 4 °C (38 to 40 °F)--and hold for an additional 5 h
4. Increase furnace temperature at 55 °C (100 °F) per h to 1040 °C (1900 °F) and hold for 6 h
5. Remove die block and air cool to 65 °C (150 °F)
6. Place die block in tempering furnace operating at 205 °C (400 °F); bring to furnace temperature and hold for 7 h
7. Increase furnace temperature at 40 °C (100 °F) per h to 565 °C (1050 °F) and hold for 16 h
8. Air cool to room temperature. Hardness is about 46 to 48 HRC
9. Temper die block a second time, repeating steps 6, 7, and 8 but increasing final temperature to 580 °C (1075 °F) because a finished hardness of 42 to 43 HRC is desired
10. Temper a third time, repeating steps 6, 7, and 8 without modification

Example 11: Heat Treatment of a Premium Grade H13 Die

(Ref 1). Most aluminum die casting dies fail by thermal fatigue of the die surface. Repeated cyclic stressing caused by alternate heating and cooling of the die surface leads to formation of a pattern of check-like cracks that are indicated as protrusions of the die casting surface and eventually expand and merge to cause further failure of the die.

Die life varies widely (20,000 to 2,000,000 shots are typical) depending on the aggressiveness of the process conditions, whether the die is preheated prior to being put into service, the metallurgy of the steel used, and the heat treat microstructure.

Hot-work die steels containing 5% Cr are normally used (H13 is the most common in the United States) because they have:

- A good combination of toughness and strength for safety and service
- Good hardenability in thick sections
- Good hot hardness and strength to resist cyclic stressing at operating temperatures up to 400 °C (750 °F)
- Good resistance to tempering during service which gradually lowers the surface hardness and the fatigue strength

Carbide precipitation, other than that produced during tempering, is known to be deleterious to the fatigue life of H13 tool steel. Fast quenching rates required to suppress intermediate precipitation of carbides (such as proeutectoid grain-boundary carbide, pearlite, or bainite) also produce large thermal gradients within the tool which can cause distortion or even cracking. The larger the tool, the greater the risk of cracking.

Austenitizing temperature was approximately 1040 °C (1900 °F) for the continuous cooling test. Test results are shown in Fig. 10.

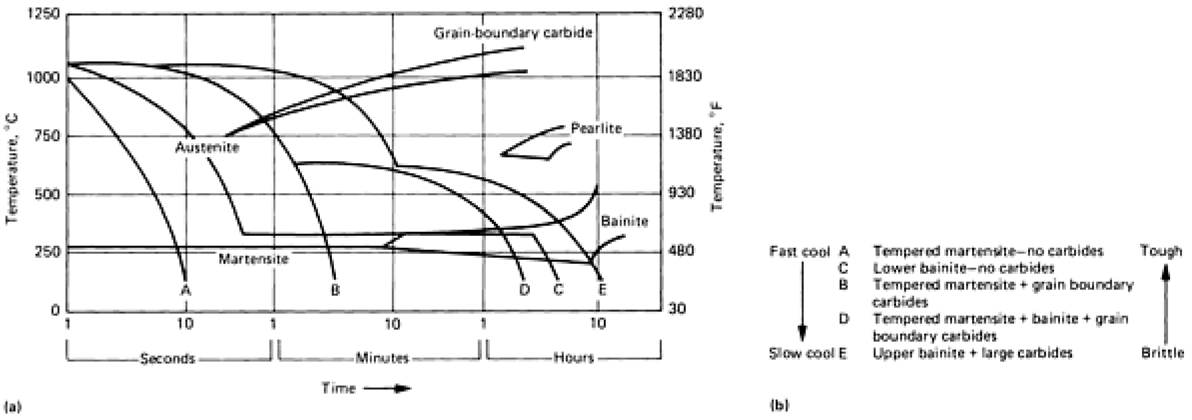

Fig. 10 Effect of intermediate cooling rates on the microstructure and toughness of H13 tool steel austenitized at 1075 °C (1970 °F). (a) Continuous cooling transformation (CCT diagram) showing variation in microstructure with varying cooling rates. (b) Variation in toughness as a function of carbides ejected from austenite. Hardness maintained at constant value. Source: Ref 1

After tempering to 46 HRC, the H13 bars were finish machined to produce specimens for impact energy testing.

As shown in Fig. 11, the results of the 12 treatments processed by continuous cooling indicate that three regimes of toughness occur. The slowest cooling rates of 2 to 4 °C/min (4 to 7 °F/min) produce structures with some pearlite and heavy grain-boundary carbides. These structures result in low toughness values of 3 to 8 J (2 to 6 ft · lbf) at room temperature for the Charpy V-notch test. Increasing the cooling rate to 10 to 31 °C/min (17 to 56 °F/min) eliminates the pearlite and provides martensitic/bainitic matrices but considerable quantities of grain-boundary carbide remain. These faster cooling rates produce room-temperature Charpy V-notch toughness values of 16 to 20 J (12 to 15 ft · lbf). The fastest cooling rates result in greatly reduced grain-boundary carbide precipitation and virtually 100% martensitic matrices. These structures have room-temperature Charpy V-notch toughness values of 24 to 26 J (18 to 19 ft · lbf).

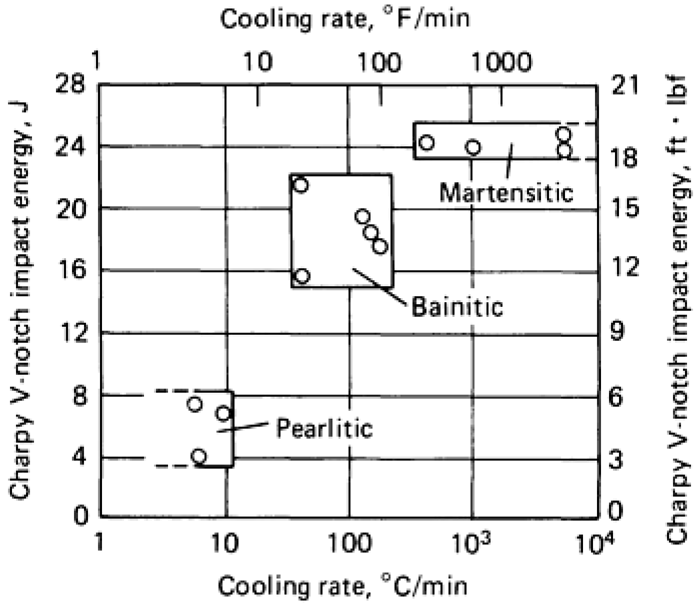

Fig. 11 Plot of impact energy versus cooling rate showing three distinct regions of toughness obtained for 12 treatments of premium H13 tool steel. Note that all test values lie inside these three regions.

This study clearly shows that increasing the quenching rate increased the impact strength but the effect is nonlinear.

Structures containing pearlite rates should be avoided by quenching at rates faster than 9.5 °C/min (17 °F/min) until below the nose of the pearlite curve. This results in bainite/martensite structures with some grain-boundary carbides and an anticipated notch impact strength of 15 to 22 J (11 to 16 ft · lbf).

Faster quenching at rates of over 58 °C/ min (105 °F/min) will give a martensite structure with less grain-boundary carbide. The small increase in impact strength to 23 to 26 J (17 to 19 ft · lbf) may not be considered worth the increased risk of cracking and distortion.

Example 12: Heat Treating of a 6F3 Forging Die.

In one plant, dies, 495 by 215 by 150 mm ($19\frac{1}{2}$ by $8\frac{1}{2}$ by 6 in.), used for forging pitman arms are heat treated to a final hardness of 40 to 42 HRC by the following procedure:

1. Preheat at 260 °C (500 °F)
2. When dies have attained furnace temperature, raise temperature at 55 to 85 °C (100 to 150 °F) per h to 915 °C (1675 °F); use controlled atmosphere above 760 °C (1400 °F)
3. Hold at 915 °C (1675 °F) for 6 h
4. Air-blast cool to 175 °C (350 °F) (temperature-indicating crayons used)
5. Place in tempering furnace operating at 175 to 205 °C (350 to 400 °F). When dies have attained furnace temperature, raise temperature at 85 °C (150 °F) per h to 595 °C (1100 °F) and hold for 9 h
6. Air cool to room temperature; check hardness
7. Retemper, repeating steps 5 and 6 except for final temperature, which will depend on hardness obtained from first tempering

6F2, 6F4, and H12 Components Used in Forging of Pinions. The following three examples indicate the procedures employed in one plant for heat treating 6F2, 6F4, and H12 components used for hot upset forging of pinions.

Example 13: Heat Treating of a 6F2 Heading Tool and Gripper Die.

Final hardness of 40 to 42 HRC is obtained on this tool by preheating, austenitizing, quenching, tempering, and retempering as follows:

1. Preheat at 260 °C (500 °F)
2. When dies have attained furnace temperature, raise temperature at 55 to 85 °C (100 to 150 °F) per h to 855 °C (1575 °F)
3. Hold at 855 °C (1575 °F) for 1 h per inch of thickness
4. Quench in oil at 55 °C (130 °F), to 175 °C (350 °F) (temperature-indicating crayons used); transfer as quickly as possible to tempering furnace
5. Place in tempering furnace operating at 175 to 205 °C (350 to 400 °F). When dies have attained furnace temperature, raise temperature at 55 to 85 °C (100 to 150 °F) per h to 595 °C (1100 °F) and hold for 1 h per inch of thickness
6. Cool in still air to room temperature; check hardness
7. Retemper, repeating steps 5 and 6 except for final temperature, which depends on hardness obtained from first tempering

Example 14: Heat Treating of a 6F4 Slab Insert.

These inserts, requiring final hardness of 39 to 41 HRC, are heat treated as follows:

1. Preheat at 260 °C (500 °F)
2. When inserts have attained furnace temperature, raise temperature at 55 to 85 °C (100 to 150 °F) per h to 815 °C (1500 °F) (use controlled atmosphere above 760 °C, or 1400 °F)
3. Solution treat at 1020 °C (1870 °F) for 1 h per inch of thickness
4. Cool in still air to room temperature. Note: When these inserts were quenched to only 95 °C (200 °F), threads broke out of the die during tapping
5. Precipitation harden by heating at 260 °C (500 °F) until temperature of insert equals furnace temperature, raising furnace temperature at 55 to 85 °C (100 to 150 °F) per h to 450 °C (840 °F), holding at 450 °C (840 °F) for 3 h plus 1 h per inch of thickness (minimum time, 4 h), and air cooling to room temperature

Example 15: Heat Treating of an H12 Punch Insert.

Heat treating to a desired final hardness of 40 to 42 HRC comprises the following procedure:

1. Preheat at 260 °C (500 °F)
2. When inserts have attained furnace temperature, raise temperature at 55 to 85 °C (100 to 150 °F) per h to 870 °C (1600 °F) (use controlled atmosphere above 760 °C, or 1400 °F)
3. Raise furnace temperature to 1010 °C (1850 °F); hold inserts at 1010 °C (1850 °F) for 1 h per inch of thickness
4. Quench inserts in still air until they are cool enough to be hand-held. Transfer immediately to the tempering furnace
5. Place in tempering furnace operating at 260 °C (500 °F). When inserts have attained furnace temperature, raise temperature at 55 to 85 °C (100 to 150 °F) per h to 595 °C (1100 °F). Hold at 595 °C (1100 °F) for 1 h per inch of thickness
6. Cool in still air and check hardness
7. Retemper, repeating steps 5 and 6 except for final temperature, which will depend on the hardness that was obtained from the first tempering cycle
8. Temper for a third time, if time permits

High-Speed Tool Steels

High-speed tool steels are used primarily for cutting tools, such as broaches, chasers, cutters, drills, hobs, reamers, and taps. Nominal compositions of these steels are given in Table 1 of the article, "Introduction to Heat Treating of Tool Steels," in this Volume. Recommended heat-treating practices are summarized for two standard groups of high-speed steels and one intermediate group in Table 10 of this article; note that normalizing of high-speed tool steels is not recommended.

O, oil; A, air; S, salt; Not rec, not recommended.

(a) Pack annealing is recommended, for minimum decarburization. Steels should be held at temperature for 1 h per inch of thickness of the container.

(b) Maximum. Rate is not critical after work (in pack, if employed) has been furnace cooled to 650 °C (1200 °F).

(c) If steels are austenitized in a salt bath, austenitizing temperatures should be 14 °C (25 °F) lower than those in the ranges given.

The market for tungsten high-speed steels is basically limited to Europe. Molybdenum high-speed steels are the materials of choice in the United States for machine tool applications.

Recommended Heat-Treating Procedures Based on Steel Group and Type

Steels in the intermediate group, M50 and M52, are less expensive than standard high-speed steels and may occasionally be used in place of standard high-speed steels.

The intermediate high-speed steels do not resist tempering to the same extent as M2, and therefore, they cannot be expected to perform as well as high-speed steels in applications where red hardness is important. For example, in such applications as lathe tools and drills, where the tool is in continuous contact with the workpiece and high surface temperatures are the rule, M50 and M52 steels would not be expected to perform as well as standard high-speed steels. When contact with the workpiece is intermittent or surface temperatures are low, in such applications as hack and band saw blades, blanking dies, and some special woodworking tools, M50 and M52 steels may perform adequately. M50 steel is also used in ball and roller bearing races used at elevated temperatures. Other applications include woodworking tools, hydraulic pump assemblies, pump pistons, and pump vanes. If greater abrasion resistance is required, but not as much as afforded by standard high-speed steels, then M52 may be a logical choice.

Annealing. High-speed steel must be fully annealed after forging or when rehardening is required. To minimize decarburization, pack annealing in tightly closed containers is recommended. The packing material can be dry sand or lime to which a small amount of charcoal has been added; burned cast iron chips also are satisfactory. Because the packing material acts to insulate the container and thereby slow down heating, the container should be filled in such a way with the steel to be annealed that a minimum amount of packing material is required.

After the steel has reached the annealing temperature range (Table 10), it should be held at temperature for 1 h per inch of thickness of the container and should then be slowly cooled in the furnace (at a rate not exceeding 22 °C, or 40 °F per h) until it reaches a temperature of 650 °C (1200 °F), when a faster rate of cooling is permissible.

Preheating. Austenite begins to form at about 760 °C (1400 °F), and preheating for hardening to slightly above this temperature will minimize stresses that might be set up because of the transformation. If the prevention of partial decarburization is important, a preheating temperature of 705 to 790 °C (1300 to 1450 °F) generally will be used. When this is not a problem, preheating at 815 to 900 °C (1500 to 1650 °F) is satisfactory.

Double preheating--in one furnace at 540 to 650 °C (1000 to 1200 °F) and in another at 845 to 870 °C (1550 to 1600 °F)--is often recommended to minimize thermal shock and to increase the productivity of the equipment.

If a single preheat is used, the T types of high-speed steels are preferably preheated at 815 to 870 °C (1500 to 1600 °F), and the remaining M types at 730 to 845 °C (1350 to 1550 °F). It is common practice to preheat for twice the length of time required at the austenitizing temperature. Accordingly, to ensure a uniform flow of work, the capacity of the preheating installation is generally twice that of the austenitizing installation.

Although preheating is recommended for all high-speed steels, small tools and those that do not incorporate sharp notches or abrupt changes in section, such as small tool bits and solid drill rod blanks, may be placed directly into the austenitizing furnace with reasonable safety. If consumable carbonaceous muffles are used, the preheating temperature must not exceed about 650 °C (1200 °F), because the type of atmosphere they provide is ineffective in preventing decarburization at higher temperatures. Decarburization is detrimental to a heat-treated tool requiring finished edges and surfaces.

Austenitizing. High-speed steels depend on the solution of various complex alloy carbides during austenitizing to develop their heat-resisting qualities and cutting ability. These carbides do not dissolve to an appreciable extent unless the steel is heated to temperatures near the melting point. Therefore, exceedingly accurate temperature control is required in austenitizing high-speed steel. Steels containing about 3% or more vanadium may be held at the austenitizing temperature approximately 50% longer than the lower-vanadium types. The relatively pure vanadium carbide phase inherent in the microstructure of the high-vanadium steels is virtually insoluble at temperatures below the melting point and acts to restrict grain growth, thus permitting longer soaking times without detriment. It should be noted that the tungsten, molybdenum chromium, and cobalt contents rather than the vanadium content are the key factors in determining the soaking time required in austenitizing. However, the recommended austenitizing temperatures for these steels should not be exceeded.

Single-point tools intended for heavy-duty cutting often can be effectively austenitized at 8 to 17 °C (15 to 30 °F) above the nominal austenitizing temperature. The higher temperature increases alloy solution, temper resistance, and hot hardness, but it also results in some sacrifice in toughness. To prevent rapid wear-out of fine-edged tools such as taps and chasers, austenitizing temperatures of 1040 to 1080 °C (1905 to 1975 °F) are recommended. Punches and dies that do not require maximum hardness may be austenitized for maximum toughness at temperatures 55 to 110 °C (100 to 200 °F) below the nominal temperature.

Other adjustments in austenitizing temperature depend on the type of heating equipment employed. Full-muffle furnaces employing a controlled atmosphere rich in carbon monoxide are usually operated at the higher temperature of the recommended range. Salt baths usually are operated 15 to 30 °C (30 to 50 °F) below the top of the range.

The effect of austenitizing temperature on the as-quenched hardness of M2 steel is shown in Fig. 12. Below 1175 °C (2150 °F), M2 cannot develop full hardness on quenching, because of insufficient carbide solution. At temperatures above approximately 1230 °C (2250 °F), the as-quenched hardness of M2 decreases because of too much carbon and alloy solution and an excess of retained austenite in the as-quenched steel.

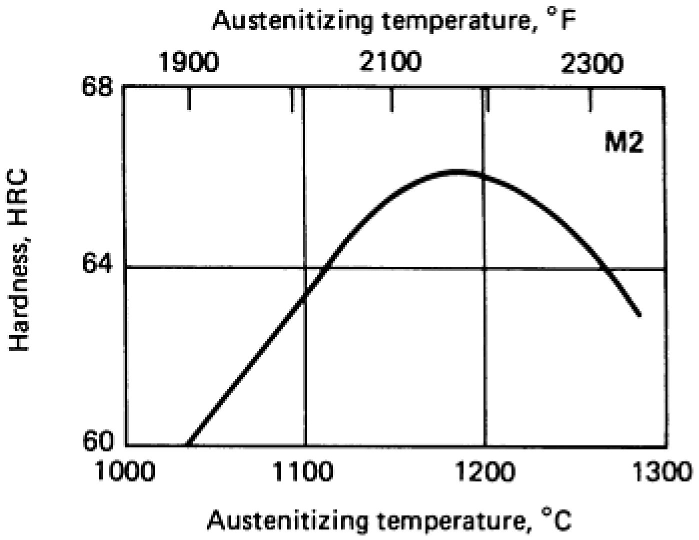

Fig. 12 Effect of austenitizing temperatures on the as-quenched hardness of M2 steel

Figure 13 illustrates the improved toughness of M2, as measured by the Izod unnotched impact test, that results from the use of lower-than-normal austenitizing temperatures. Numerous investigators have shown that the optimum means for attaining maximum toughness in high-speed steel is through reduced austenitizing temperatures rather than by full austenitizing and over-tempering to an equivalent hardness level.

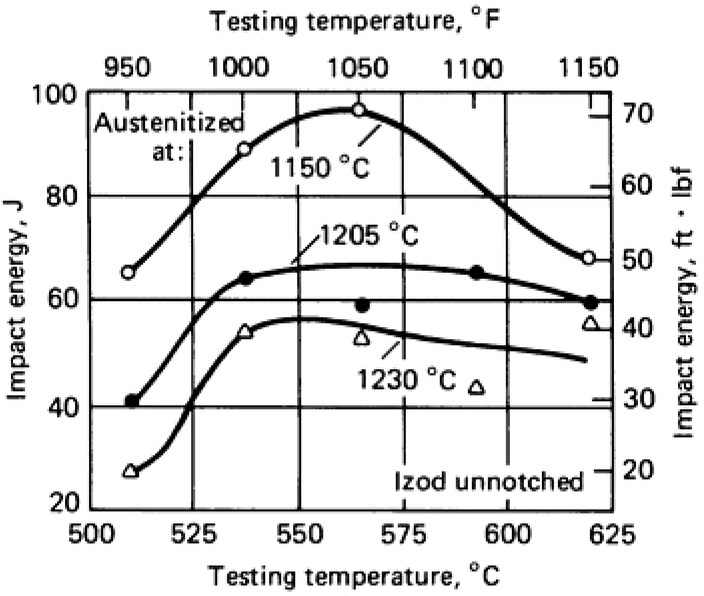

Fig. 13 Effect of austenitizing and tempering temperatures on impact strength of M2 steel

Figure 14 illustrates the sacrifice in high-temperature hardness of M2 that results from the use of reduced austenitizing temperatures.

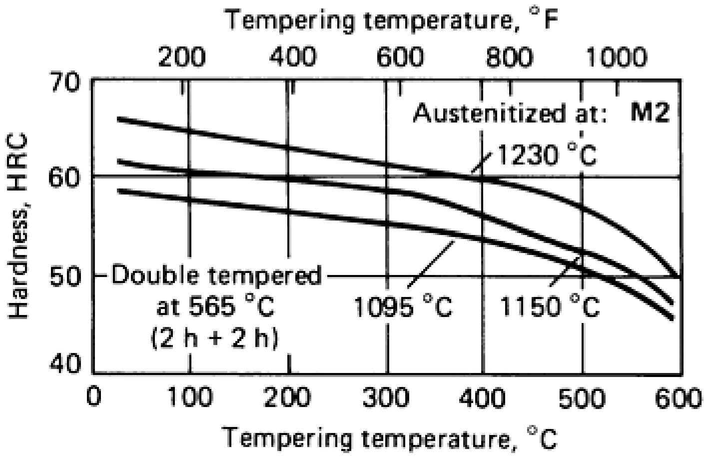

Fig. 14 Effect of austenitizing temperature on high-temperature hardness of M2 steel

Quenching. High-speed steels can be quenched in air, oil, or molten salt. However, except for thin tools, which are air quenched between plates to keep them straight, it is customary to quench in oil from muffle or semimuffle furnaces and in molten salt from a high-temperature salt bath. After its temperature has been equalized in the salt quench, the tool is air cooled. For large cutters heated in a furnace, an interrupted oil quench is often used to minimize quenching strains and prevent cracking. This consists of cooling the cutters in the oil only until they lose color (about 540 °C, or 1000 °F) and then cooling in air. Cooling rates ranging from 335 to 555 °C/min (600 to 1000 °F/min) are required to develop desirable microstructures (no carbide precipitation on grain boundaries) when cooling from austenitizing temperatures down to 760 °C (1400 °F).

After quenching, high-speed steel tools usually possess high residual stress, and to prevent cracking, it is good practice to transfer them from the quenchant to a tempering furnace before they have cooled to below 65 °C (150 °F). This is particularly important for large or intricate tools, for which a delay between quenching and tempering or permitting the work to cool to too low a temperature will usually induce cracking. If the work cannot be transferred to a tempering furnace at once, it should be put in a holding furnace maintained at 120 to 205 °C (250 to 400 °F) until a tempering furnace is available.

Vacuum furnaces equipped or modified to enhance quenching capabilities have found increasing use in high-speed steel hardening applications. Ongoing vacuum furnace technology developed since 1985 has been incorporated into the production of section sizes up to 75 mm (3 in.) with increases in the mechanical properties of high-speed steels over conventional vacuum furnace equipment produced components. Vacuum hardening has advantages over salt hardening in terms of environmental safety, and energy costs. With proper fixturing (see the article "Heat-Resistant Materials for Furnace Parts, Trays, and Fixtures" in this Volume), vacuum hardening can also minimize distortion.

Bainitic hardening has been used in a few applications. To produce a primary bainitic structure, this treatment is performed by arresting the quench from the austenitizing temperature at approximately 260 °C (500 °F), holding for 4 h, then cooling to room temperature. This produces a structure with about 55% bainite and the remainder retained austenite. Subsequent tempering at normal tempering temperature transforms the retained austenite and tempers the bainite to a Rockwell C hardness 1 to 3 points lower than normal for the selected tempering temperature.

Partial Hardening to Improve Machinability. Annealed high-speed steel may be partially hardened to approximately 270 to 300 HB to improve machinability. At these hardnesses, high-speed steels, including the sulfurized types, are less likely to tear in shaving or back-off operations. Typical heat treating to achieve this result consists of heating to 855 to 870 °C (1575 to 1600 °F), holding for at least 1 h, quenching in oil, and tempering at 635 to 665 °C (1175 to 1225 °F) to obtain the desired hardness. If the austenitizing temperature does not exceed 870 °C (1600 °F), this treatment will not cause grain coarsening in the final hardening operation.

Certain machining operations, such as drilling and rough milling, should be performed in the annealed condition to obtain maximum tool life.

Tempering. As shown in Fig. 15 for an M2 steel austenitized at 1220 °C (2225 °F), the hardness of high-speed steel is directly affected by tempering temperature and time. From the slope of the curves in Fig. 15, it can be seen that M2 undergoes secondary hardening at temperatures above approximately 370 °C (700 °F) and that secondary hardening proceeds at higher temperatures up to about 595 °C (1100 °F), depending on time at temperature. These temperatures approximate the practical limits for most tempering operations; lower temperatures do not evoke the secondary hardening response, and higher temperatures produce hardnesses considerably lower than are usually desired.

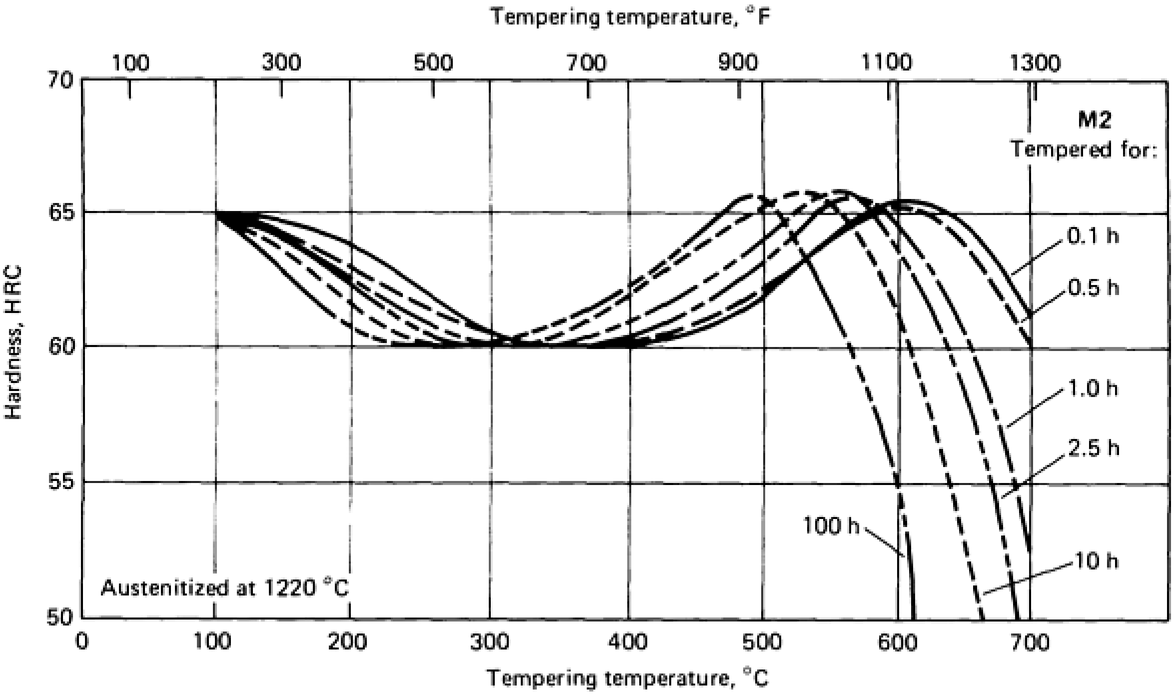

Fig. 15 Effect of tempering temperature and time on hardness of M2 high-speed steel

Emphasizing the practical time-temperature range, the response of several M and T types of high-speed steel to tempering at 425 to 705 °C (800 to 1300 °F) for periods ranging from $\frac{1}{2}$ to 10 h is indicated in Fig. 16.

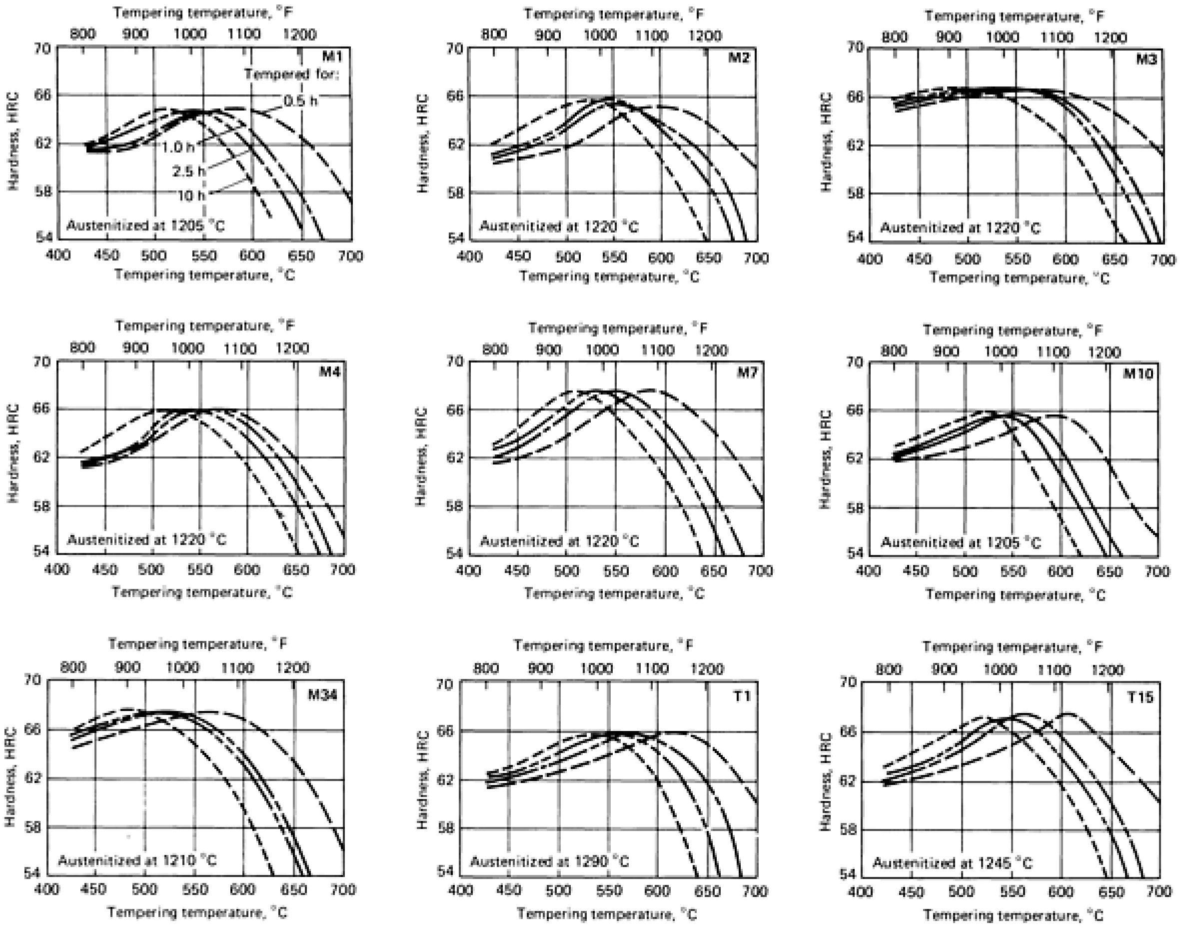

Fig. 16 Effect of tempering at temperatures from 425 to 705 °C (800 to 1300 °F) for periods of $\frac{1}{2}$ to 10 h on hardness of high-speed steels

The effect of austenitizing temperature on the tempering characteristics of several high-speed steels tempered from 480 to 675 °C (900 to 1250 °F) is shown graphically in Fig. 17. For all of the steels for which data are plotted, the highest austenitizing temperature results in maximum solution of alloy carbides--which, during subsequent tempering, produces the maximum response to secondary hardening.

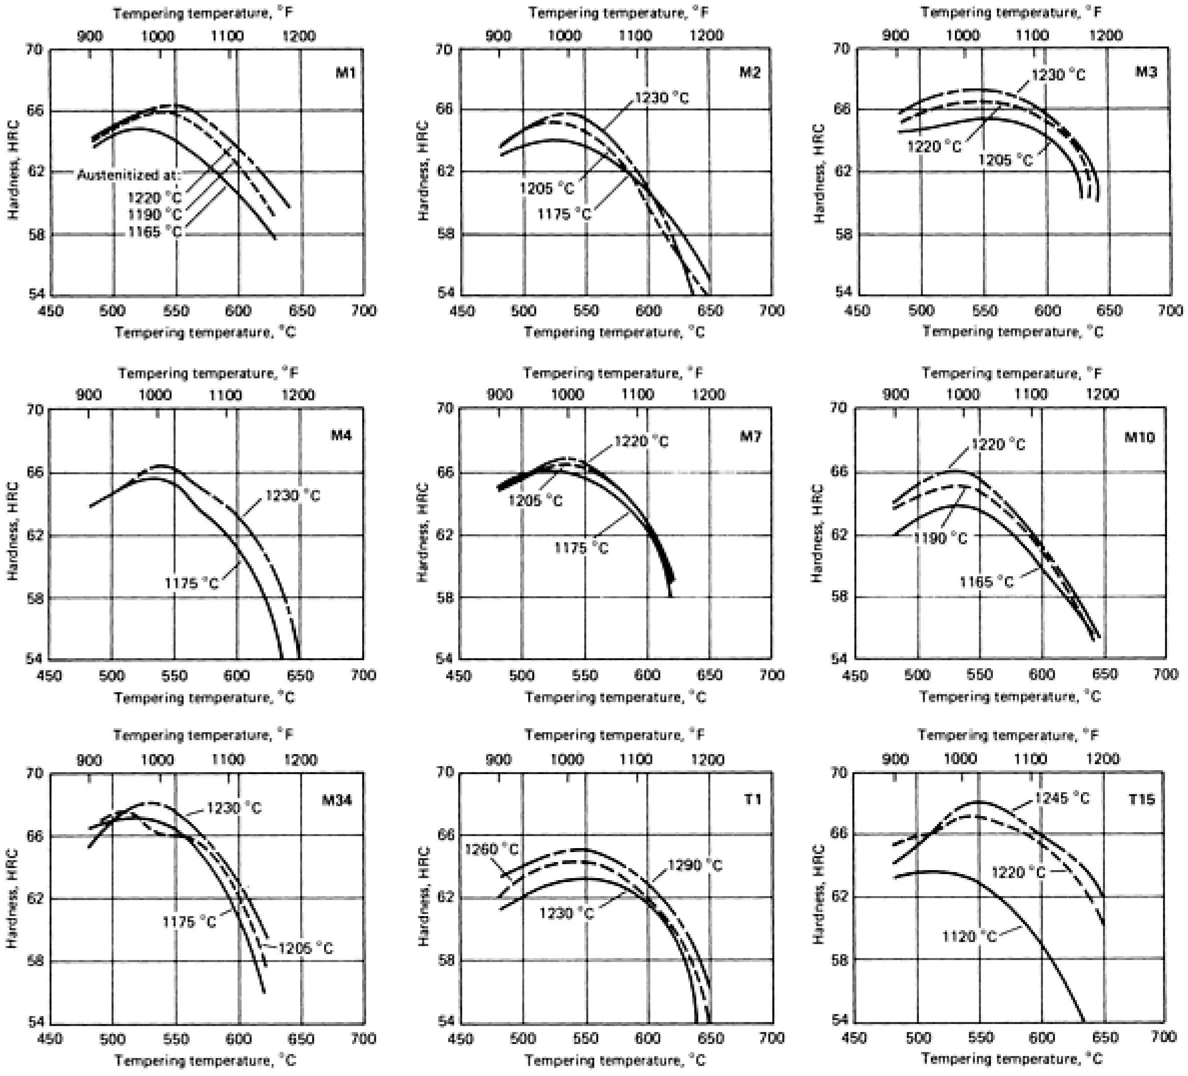

Fig. 17 Effect of austenitizing and tempering temperatures on hardness of high-speed steels. Steels were double tempered (2 h + 2 h).

High-speed steels normally are subjected to a minimum of two separate tempering treatments within the range of 540 to 595 °C (1000 to 1100 °F). The actual tempering temperature depends on tool type (for example, drills typically require temperatures of 540 to 555 °C, or 1000 to 1030 °F, and taps typically require temperatures of 560 to 580 °C, or 1040 to 1080 °F). The duration of each treatment is usually 2 h or more at temperature. This process ensures attaining consistent martensitic structures, because the amount of retained austenite in the as-quenched condition will vary significantly because of variations in heat chemistry, prior thermal history, hardening temperature, and quenching conditions.

It is essential that the time-temperature combination of the first tempering operation be adequate to condition the retained austenite. Consequently, the first tempering treatment is sometimes longer and at a slightly higher temperature than the second, because the latter is used to temper the freshly formed martensite that develops on cooling from the first temper. Moreover, multiple tempering gains in importance in attaining an acceptable structure if short tempering times are used. The hardness of single and double tempered M2 steel austenitized at various temperatures, as affected by tempering temperature, is shown in Fig. 18.

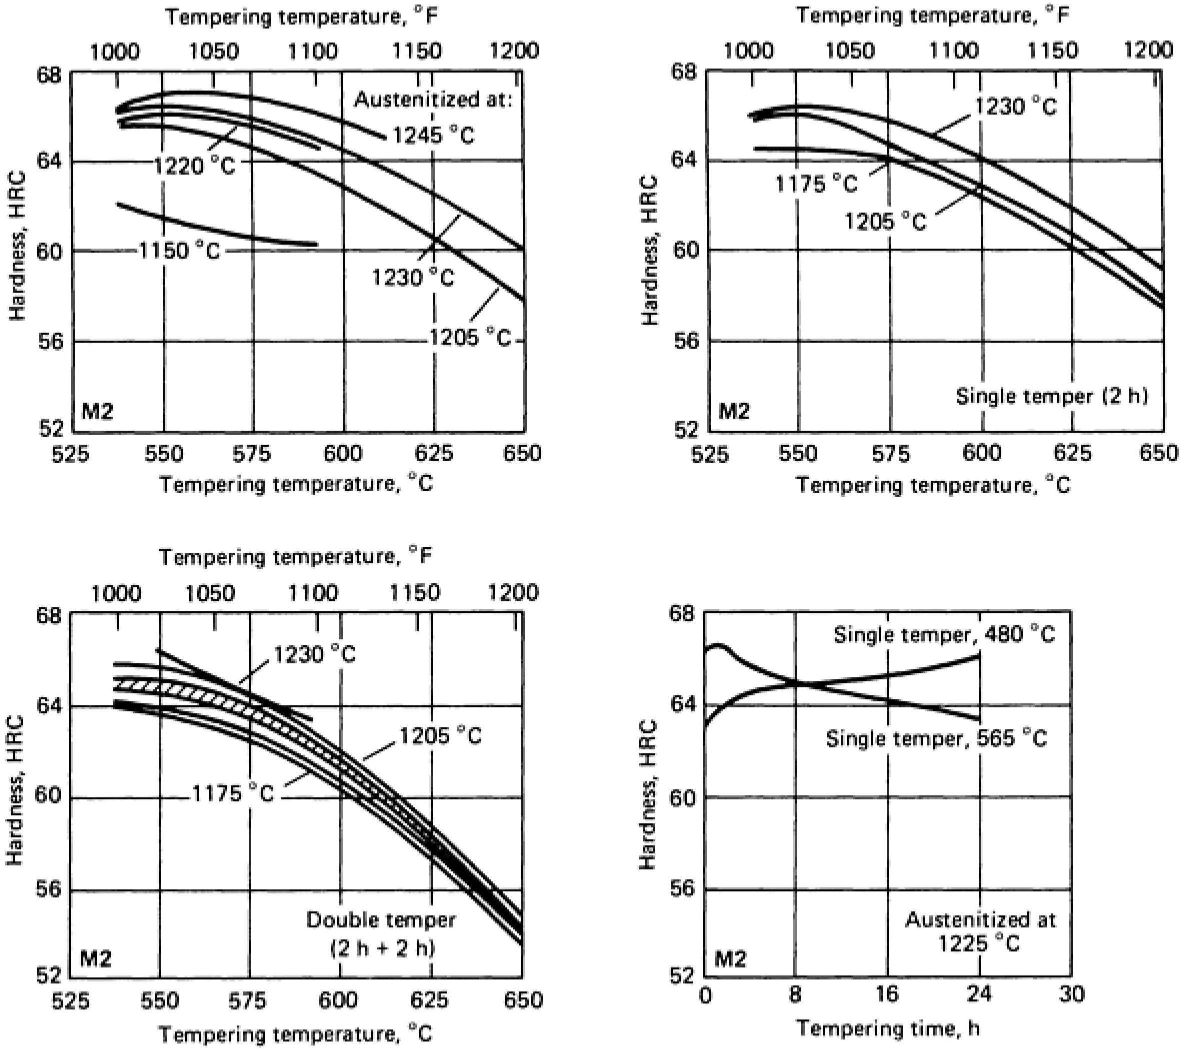

Fig. 18 Effect of austenitizing temperature and tempering conditions on hardness of M2 high-speed tool steel

Tempering at too low a temperature or for too short a time, or both, may not adequately condition the 20 to 30% retained austenite present after initial quenching, and the steel will still retain abnormally large quantities of austenite after cooling from the initial temper. This austenite will not transform until the steel is cooled from the second temper, and a third temper is then required to temper the martensite so formed. It should be noted that the second temper provides a negligible increase in hardness. In order to carry these reactions as near to completion as possible, high-speed steel should always be cooled to room temperature between tempers. The beneficial effect of multiple tempering on mechanical properties of T1 high-speed steel is shown in Table 11.

Table 11 Effects of single and double tempering on mechanical properties of T1

Time at tempering temperature	**Hardness, HRC**	**Bend strength, MPa (ksi)**	Torsion-impact strength, J (ft · lbf)
Single tempering at 565 °C (1050 °F)			
6 min	65.1	2150 (312)	**22 (16)**

1 h	65.7	1860 (270)	**41 (30)**
$2\frac{1}{2}$ h	65.0	2810 (408)	**65 (48)**
5 h	64.5	2590 (376)	**65 (48)**
Double tempering at 565 °C (1050 °F)			
$2\frac{1}{2}$ h + $2\frac{1}{2}$ h	**64.5**	**3130 (454)**	**85 (63)**

Forced-air furnaces are generally conceded to be the most desirable for tempering high-speed steel, because the heat is transmitted from the heating elements to the work by convection; consequently, the transfer of heat is gradual, and there is little danger of the work cracking as the result of thermal shock. It is advisable to place the work in a tempering chamber maintained in the temperature range of 205 to 260 °C (400 to 500 °F) and to bring the work up to the tempering temperature slowly with the furnace. This is particularly important for large or intricate tools, because too rapid a heating rate may lead to cracking.

The very rapid heating rates of molten lead or salt baths, and the attendant thermal shock, usually militate against their successful use for tempering high-speed steel tools of other than simple shape and design, unless they are preheated to about 315 °C (600 °F) before being introduced into the bath.

Refrigeration treatment may be employed to transform retained austenite. The application of a refrigeration treatment is recommended for high-alloy high-speed steels such as M42, M3 (class 2), and CPM Rex 60. Best results are obtained when the refrigeration treatment is performed after the quenching operation. The hardened or hardened and tempered tool is cooled to at least -85 °C (-120 °F) and then tempered or retempered at normal tempering temperatures. Carburized surfaces will respond satisfactorily to the -85 °C (-120 °F) treatment, even when they have been tempered prior to refrigeration.

Nitriding. Liquid nitriding is preferred to gas nitriding for high-speed steel cutting tools because it is capable of producing a more ductile case with a lower nitrogen content.

Although any of the liquid nitriding baths or processes may be used to nitride high-speed steel, the commercial bath consisting of 60 to 70% sodium salts and 30 to 40% potassium salts is most commonly employed. The nitriding cycle for high-speed steel is of relatively short duration, seldom exceeding 1h; in all other respects, however, the procedures and equipment are similar to those used for low-alloy steels.

The cyanide baths employed in liquid nitriding introduce both carbon and nitrogen into the surface layers of the nitrided case. Normally, the highest percentages of both elements are found in the first 0.025 mm (0.001 in.) surface layer. For carbon and nitrogen gradients, see the section on liquid nitriding.

The effect of time in a liquid nitriding bath at 565 °C (1050 °F) on the nitrogen content of the first 0.025 mm (0.001 in.) surface layer of a T1 high-speed steel is shown in Table 12. A nitrogen content of 0.06% was obtained in the first 3 min at temperature, and it gradually increased to 1.09% at the end of a 6-h cycle at this temperature.

Table 12 Effect of nitriding time on surface nitrogen content of T1 high-speed tool steel

Nitrogen content of first 0.025 mm (0.001 in.) layer

Time at 565 °C (1050 °F)	Nitrogen, %

3 min	**0.06**
10 min	**0.093**
30 min	**0.15**
90 min	**0.26**
3 h	**0.58**
6 h	**1.09**

As shown in Table 13, carbon also was absorbed by the steel, at nitriding temperatures as low as 455 °C (850 °F). In a 30-min nitriding cycle, the carbon content of the first 0.025 mm (0.001 in.) surface layer increased with an increase in the nitriding temperature. However, it was reported that only a portion of the carbon was absorbed by the steel, most of the carbon being mechanically attached to the surface, filling microscopic pits. (This pitting is not dangerous under normal conditions, because the pits are shallower than ordinary grinding or machining marks.)

Table 13 Carbon content of nitrided T1 high-speed tool steel

Carbon content of the first 0.025 mm (0.001 in.) surface layer of steel originally containing 0.705% C. Some of the carbon was in pits on the surface, rather than diffused into the steel.

Nitriding			Surface carbon, %
Temperature		**Time, min**	
°C	**°F**		
455	850	30	**0.85**
510	950	30	**0.99**
565	1050	30	**1.18**

High-speed steel tools that are nitrided in fresh baths or for short times show steep nitrogen and hardness gradients. To avoid these steep gradients, which are believed responsible for the brittleness of the case after such treatments, the use of longer immersion time, higher temperature, or a thoroughly aged bath is recommended. To avoid brittleness of case when relatively short immersion times are used, the cyanate content of the bath should exceed 6%. These conditions often will lower the surface hardness as well as the hardness gradient.

Figure 19 compares the hardness gradients obtained on specimens of T1 high-speed steel nitrided at 565 °C (1050 °F) for 90 min in a new bath and for various lengths of time in an aged bath.

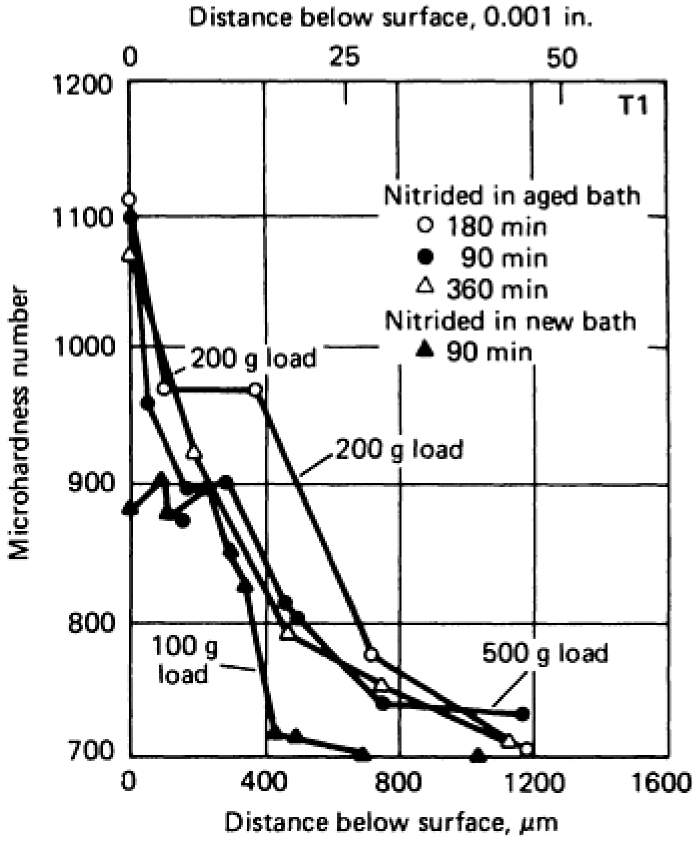

Fig. 19 Effect of bath condition and immersion time on hardness gradients in type T1 high-speed steel specimens nitrided at 565 °C (1050 °F)

Nitriding of decarburized high-speed steel tools should be avoided, because it results in a brittle surface condition. For those surfaces that have been softened from grinding, nitriding is frequently employed as an offsetting corrective measure.

Liquid nitriding provides high-speed steel tools with high hardness and wear resistance and a low coefficient of friction. These properties enhance tool life in two somewhat related ways. The high hardness and wear resistance lower the abrading action of chips and work on the tool, and the low frictional characteristics serve to create less heat at and behind the tool point, in addition to assisting in the prevention of chip pickup (see the article "Wrought Tool Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*).

Plasma nitriding (also known as ion nitriding, glow-discharge nitriding, and the glow-discharge deposition process) is a heat treatment that uses a large electrical potential to ionize (break down) a treatment gas into ions which are attracted to the surface of the workpiece. When the reaction is properly controlled, the hardened case obtained is similar to a liquid nitride case.

Detailed information is available in the article "Plasma (Ion) Nitriding" in this Volume.

Steam treating produces a nonuniform, soft layer of iron oxide on the surface of finished high-speed steel tools. This layer, approximately 0.005 mm (0.0002 in.) thick, has lubricant-retaining and antigalling properties, and in some applications will improve tool life by reducing tool-edge buildup. The oxide layer is removed from the tool after a short interval of operation; during this interval, the cutting surfaces of the tool develop a burnished surface that adds further to antigalling characteristics.

Steam treatment requires a special furnace with a sealed retort from which all air can be displaced by steam, which is admitted at controlled rates. The presence of excessive levels of moisture in the furnace prior to the admission of the steam will cause rusting and an unsatisfactory surface finish.

A typical processing cycle involves placing the work in the special furnace, heating to approximately 370 °C (700 °F), and equalizing. After a suitable equalizing time, which depends on the load, the steam is admitted at controlled rates for approximately $\frac{1}{2}$ h. The furnace is then partly sealed to develop positive steam pressure, and the temperature is raised to 525 °C (975 °F). The steam can then be shut off and the work removed from the furnace and cooled normally.

The treatment produces a blue-black film whose appearance is improved by subsequent dipping in oil. This treatment may sometimes be combined with normal tempering treatments, because the type of film produced is relatively insensitive to temperature up to approximately 580 °C (1075 °F). Steam treating offers an additional advantage for tools hardened in salt baths, because it effectively reduces the pitting that can result from adhering salt.

Carburizing is not recommended for high-speed steel cutting tools because of the extreme brittleness of the case so produced. However, it is suitable for applications requiring extreme wear resistance in the absence of impact or highly concentrated loading, such as are encountered with certain types of cold-work dies made from high-speed steel. At the same level of hardness, the carburized layer does not have the heat resistance of normal high-speed steel because carbides in the microstructure are predominantly Fe_3C, rather than the complex alloy carbides characteristic of high-speed steel.

Carburizing cycles for high-speed steel consist of packing in a carburizing medium, heating to approximately 1040 to 1065 °C (1900 to 1950 °F) long enough to develop the depth of case desired, and air cooling. The usual holding time at carburizing temperature is from 10 to 60 min, to produce a case 0.05 to 0.25 mm (0.002 to 0.010 in.) deep. Deeper cases should be avoided because of the extreme brittleness which develops. This treatment carburizes the surface and serves as the austenitizing treatment for hardening the entire piece. The carburized layer will harden to 65 to 70 HRC at the surface.

Hardening of Specific Machine Tools

High-speed tool steels are used extensively as materials for broaches, chasers, milling cutters, drills, taps, reamers, form tools, hobs, thread rolling dies, threading dies, tool bits, and bearing components.

Broaches require maximum edge hardness because of the continuous cutting action and light chip load to which they are subjected. This indicates a minimum hardness of 65 HRC for the standard grades and 66 HRC for the premium grades of high-speed steel.

Broaches should be suspended vertically in the hardening furnace to avoid undue distortion, and should be quenched under controlled and uniform cooling conditions. Broaches should be straightened while still warm from the hardening operation, and should be cooled to at least 65 °C (150 °F) before tempering. These precautions are particularly important for large diameters.

Chasers, because they usually are quite small, present no particular problem in hardening with regard to straightness or residual stress. Hardness recommendations for chasers depend largely on the type of application and the pitch of the thread. Recommended hardnesses for chasers used to cut threads in steel are listed in Table 14.

Table 14 Recommended hardness values for chasers and taps used to cut threads in steel

Threading tool	Hardness, HRC			
	Fine-pitch threads	**Coarse-pitch threads**	**Acme threads**	Pipe threads
Chasers	61-63	64-65	60-62	...
Taps	**63-65**	**63-65**	**62-64**	**62-64**

For cutting cast iron or plastics, chasers should be heat treated to the maximum attainable hardness, because these materials are cut without any significant cutting force but require maximum abrasion resistance. For Acme threads, however, it is sometimes advisable to underharden.

Milling Cutters. Fine-tooth cutters and those with fragile forms should be hardened to 63 to 64 HRC. Heavy-duty milling cutters and cutters for use on soft, abrasive materials should be hardened to the maximum hardness obtainable for the particular type of steel.

Drills. Hardening techniques for drills vary, depending on the diameter of the drill. Straightness of these tools is extremely important. Various jigging methods are employed, but it is usually advisable to heat treat drills vertically suspended by their shanks in order to reduce distortion in the hardening operation. Straightening is best accomplished in the as-hardened condition before tempering. In tempering, the tempering furnace must not be overloaded, and all drills must receive the correct tempering temperature and time at temperature.

Specific recommendations for the hardness of drills for cutting steel are as follows:

- Most drills 5 mm ($\frac{3}{16}$ in.) in diameter and smaller are usually hardened to 63 to 65 HRC. (Drills of this size used for plastics, aluminum, or magnesium may have hardness as high as 65 HRC)
- Drills over 5 mm ($\frac{3}{16}$ in.) in diameter, to 63 to 65 HRC
- Heavy-duty drills normally use grades of high-speed steel providing hardnesses equal to or higher than those noted above. (These drills generally are designed for maximum rigidity and require maximum abrasion resistance)

Taps, like drills, are slender in section and require hardening techniques that minimize distortion; this generally means hardening in the vertical position suspended in suitable jigs. Taps should be straightened in the as-hardened condition before tempering. Tempering of these tools must be carefully controlled to allow adequate heating time. Specific hardness recommendations for taps that are to be used to cut steel are listed in Table 14.

Reamers encounter a minimum chip load but require maximum wear resistance. For this reason, they are always hardened to the maximum hardness attainable for each grade of steel.

Form tools of all types also should have maximum hardness. In general, a minimum of 65 HRC is necessary, and for the premium grades hardnesses ranging from 68 to 70 HRC are frequently desirable.

Hobs. Because of their shaving action, hobs require maximum edge hardness. They may become oval in shape if they are not placed in the hardening furnace in the vertical position. Such placement may require special fixtures. Techniques and temperatures in both hardening and tempering must be accurately controlled if tools of this type are to be produced successfully and economically.

The hardness of fragile tooth forms may have to be reduced to 62 to 64 HRC to avoid breakage, although the lower hardness results in a shorter production life.

Thread rolling dies are usually made of A2 or D2 steel, although dies made of high-speed steel frequently afford superior results, particularly in rolling the harder materials. For fragile thread forms, thread rolls should be hardened to 60 to 62 HRC. For heavier thread forms and those used to roll high-strength materials, hardnesses of 63 to 65 HRC are recommended; however, at these higher hardnesses, dies are more susceptible to breakage.

Threading Dies. Most threading dies are made of carbon steel; however, button and acorn dies justify the use of high-speed steel. The relation between hardness and thread form for threading dies is the same as that recommended for taps and chasers.

Tool Bits. Standard tool bits, as well as cheeking tools, offset-head bits, and other special types, all require maximum hardness. Standard-duty tool bits should be hardened to 65 to 66 HRC, whereas tool bits made from the higher-alloy high-speed steels should be hardened to 67 to 69 HRC when possible.

Bearing Components. The heat treatment of M50 high-speed steel bearing components for aerospace applications must be capable of producing a part with high hardness, uniformly fine grain size, and dimensional stability over a wide temperature range.

M50 steel has a nominal composition of 0.83C-4.0Cr-4.0Mo-1.0V with a M_s temperature of approximately 163 to 166 °C (325 to 330 °F). The time-temperature transformation (TTT) diagram for M50 is illustrated in Fig. 20.

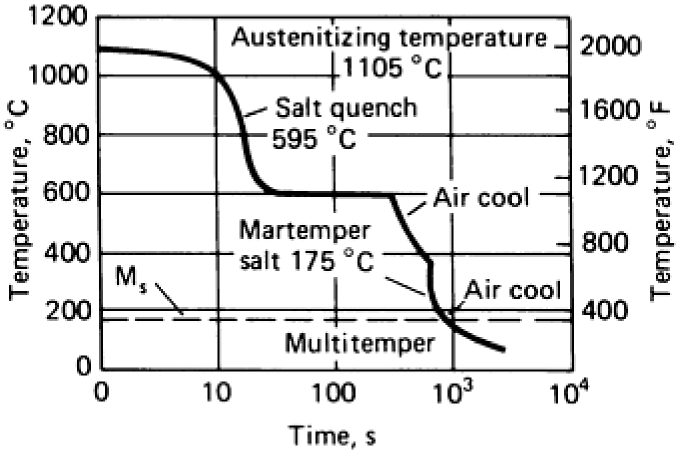

Fig. 20 TTT diagram for M50 steel

Virtually any cooling rate capable of cooling the austenitized part to 205 °C (400 °F) or below in 15 min will produce high hardness. To minimize distortion, residual stress and crack susceptibility, a cooling similar to the idealized rate shown in Fig. 20 is desirable.

The following practices and procedures are recommended for heat treating M50 bearing components to provide optimum bearing properties:

- M50 can be satisfactorily heat treated in vacuum or protective atmosphere furnace. However, most bearing manufacturers prefer to heat treat these bearing components in a neutral molten salt bath or baths
- Parts should be preheated prior to the austenitizing cycle to minimize the required soak time at the high austenitizing temperature. If a single preheat is employed, a bath temperature of 815 to 870 °C (1500 to 1600 °F) with a cycle of 5 to 15 min is recommended. If multiple preheat baths are available, recommended bath temperatures and cycles are listed in Table 15.
- The high-temperature bath cycle is the most critical operation in heat treating M50 steel. Following preheating, parts should be austenitized at 1105 to 1120 °C (2025 to 2050 °F) for 3 to 10 min, depending on cross section and gross load weight. Optimum cycles in the austenitizing bath may be established empirically by varying the soak cycle in the high-temperature bath in $\frac{1}{2}$-min increments and evaluating resultant grain size and hardness. Grain size is more easily measured on as-quenched samples; however, hardness should be checked on parts subsequent to final tempering operations. Ideally, the cycle will be as short as possible to minimize grain growth while producing desired hardness
- Following austenitizing, parts should be quenched in 540 to 595 °C (1000 to 1100 °F) molten salt for 5 to 10 min. The quench minimizes internal stresses and the core-to-surface thermal differential prior to subsequent air cooling and martempering operations
- Parts should be subjected to a 175 to 190 °C (350 to 375 °F) martemper bath for 5 to 15 min following quench or quench/air cool operations. The martemper bath, which operates between 15 and 30 °C (25 and 50 °F) above the M_s temperature for M50, equalizes core-to-surface thermal differentials and facilitates subsequent transformation of austenite into martensite with minimal residual stress, distortion, or cracking potential. To avoid undesirable intermediate transformation products, the interval between austenitizing and martempering should not exceed 15 min
- Following martempering, parts should be air cooled to room temperature prior to washing, tempering, or

subzero treatment. The air-cooling equipment and conditions should provide uniform cooling of parts from the 175 to 190 °C (350 to 375 °F) martempering bath to room temperature within 30 to 60 min. Shorter cooling rates may result in increased residual stress, distortion, or susceptibility to stress cracking

- M50 steel requires multiple tempers to provide maximum toughness and dimensional stability. Parts should be subjected to a minimum of three tempers of 540 to 550 °C (1000 to 1025 °F) for 2 to 4 h, with cooling to room temperature between each temper. Failure to cool to below 40 °C (100 °F) between tempers may result in retained austenite. Tempering may be performed either in neutral molten salts or in atmosphere or air furnaces
- Subjection to subzero temperatures prior to and/or after initial tempering enhances transformation of retained austenite to martensite. Common deep-freeze cycles for M50 are -70 to -85 °C (-90 to -120 °F) for 2 to 4 h. Use of lower temperatures provides little if any added benefit. The deep-freeze cycle provides maximum benefit when employed before tempering; however, it is not recommended for parts not subjected to martempering or parts susceptible to cracking. When parts are subzero treated before tempering, caution should be exercised to ensure that the total elapsed time between martempering and tempering does not exceed 5 h. Use of prior stress-relief cycles reduces effectiveness of deep-freeze operation. When equipment, time constraints, or part design are unfavorable for performing deep freezing prior to tempering, the parts should be subjected to deep freeze between the first and second tempering operations
- Parts requiring re-treating should be annealed prior to rehardening to minimize susceptibility to developing duplex/nonuniform grain

Table 15 Recommended bath temperatures and cycle times for preheated M50 bearing steel

Cycles	**Temperature**		Time[(a)], min
	°C	**°F**	
Two preheat baths			
1	675-730	1250-1350	**10-15**
2	815-870	1500-1600	**5-15**
Three preheat baths			
1	675-730	1250-1350	**10-15**
2	815-870	1500-1600	**5-15**
3	**955-1010**	**1750-1850**	**5-10**

Low-Alloy Special-Purpose Tool Steels

Nominal compositions of the low-alloy special-purpose tool steels are given in Table 1 of the article entitled "Introduction to Heat Treating of Tool Steels" in this Volume. These steels are similar in composition to the water-hardening tool steels,

except that the addition of chromium and other elements provides the L steels with greater wear resistance and hardenability. Types L1, L3, L4, and L7 are similar to the production steel 52100 and are used for similar applications.

Because of their relatively low austenitizing temperatures, the L steels are easily heat treated. Recommended heat-treating practices are summarized in Table 16.

Table 16 Recommended heat-treating practices for low-alloy special-purpose tool steels

Steel	**Normalizing temperature**[a]		**Annealing**					Hardening				
			Temperature[b]		**Cooling rate**[c]		**Annealed hardness, HB**	**Austenitizing temperature**[d]		**Holding time, min**	**Quenching medium**	Quenched hardness, HRC[e]

(a) Holding time, after uniform through heating, varies from about 15 min, for small sections, to about 1 h, for large sections. Work is cooled from temperature in still air.

(b) Lower limit of range should be used for small sections, upper limit for large sections. Holding time varies from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(c) Maximum. Rate is not critical after cooling to below 540 °C (1000 °F).

(d) These steels are seldom preheated.

(e) Typical average values; subject to variations depending on austenitizing temperature and quenching medium

Normalizing should follow forging or any other operation in which the steel has been exposed to temperatures substantially above the transformation range. For the L steels, normalizing consists of through heating to 870 to 900 °C (1600 to 1650 °F) and cooling in still air. The use of a protective atmosphere is recommended.

Annealing must follow normalizing and precede any rehardening operation. Recommended annealing temperatures and cooling rates, as well as expected as-annealed hardness values, are given in Table 16.

Stress relieving prior to hardening may be advantageous for complex tools to minimize distortion during hardening. A common practice for complex tools is to rough machine, heat to 620 to 650 °C (1150 to 1200 °F) for 1 h per inch of cross section, cool in air, and then finish machine prior to hardening.

Austenitizing temperatures recommended for hardening the L steels are listed in Table 16; preheating is seldom employed for steels in this group.

Salt or lead baths and atmosphere furnaces are all satisfactory for austenitizing these steels. A neutral salt, such as No. 3 in Table 1 of the article entitled "Processes and Furnace Equipment for Heat Treating of Tool Steels," is recommended. This salt may be deoxidized, for control of decarburization, by the method indicated in the section on rectification of salt baths in the article "Processes and Furnace Equipment for Heat Treating of Tool Steels" in this Volume.

Quenching. Oil is the quenching medium most commonly used for the L steels. Water or brine may be used for simple shapes, or for large sections that do not attain full hardness by oil quenching. Rolling-mill rolls made of L7 are an example of parts for which water or brine quenching is used. These steels respond well to martempering.

Tempering. Tools made of the L steels should be quenched only to a temperature at which they can be handled with bare hands, about 50 °C (125 °F), and should be tempered immediately thereafter; otherwise, cracking is likely to occur.

The tempering characteristics of these steels are plotted in Fig. 21. For most applications, the S steels are used at near-maximum hardness. It is recommended that tools made of any of these low-alloy steels be tempered at a minimum of 120 °C (250 °F), even though maximum hardness is desired. Double tempering also is recommended.

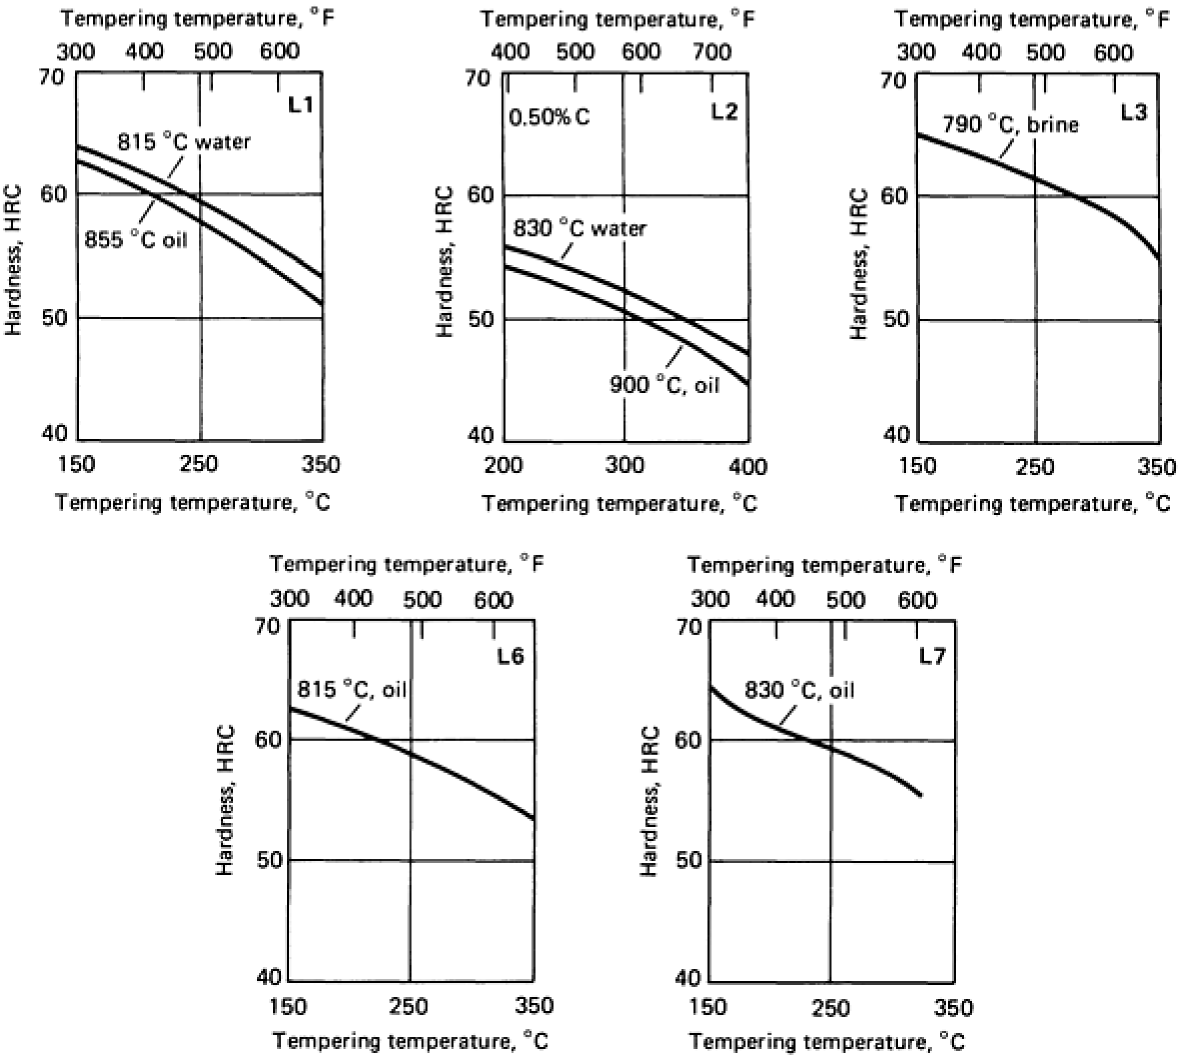

Fig. 21 Hardness of low-alloy special-purpose tool steels after tempering for 2 h

Carbon-Tungsten Special-Purpose Tool Steels

Nominal compositions of carbon-tungsten special-purpose tool steels are given in Table 1 of the article entitled "Introduction to Heat Treating of Tool Steels" in this Volume. Recommended heat-treating practices for these steels are summarized in Table 17.
